FOREWORD

Dear peers in the minerals industry,

On behalf of the Conference Committee and the IMPC Council, I am delighted to welcome you to the International Minerals Processing Council Asia-Pacific 2022 Conference (IMPCAP22). The conference is co-hosted by AusIMM, CSIRO and the IMPC Council. It brings together delegates from Australia, the Asia-Pacifica and around the world to share best practice and knowledge in minerals processing from our region. This is the second regional minerals processing conference organised by the International Minerals Processing Council.

In keeping with the high standards set by the IMPC, all papers have been fully refereed and feature the latest innovations and thinking in the field of minerals processing. Environmental, social and governance (ESG) and innovation are key drivers for the resources sector. We look to industry, suppliers and researchers to drive open and rapid innovation, helping our industry meet the challenges of today and the future. Any organisation that is wanting to reach a target of net zero is going to rely heavily on minerals and their processing to reach it.

The conference will showcase an impressive range of speakers and topics, with over 160 technical sessions and nine keynote speakers spread over three days, highlighting leading innovations and research in minerals processing. Presentations will also be recorded and made available to all delegates following the conference to ensure the insights are captured.

I would like to thank all our speakers and authors who have prepared presentations, compiled technical papers and are travelling far and wide to participate in the conference. I would also like to thank the Organising Committee, paper reviewers, sponsors and exhibitors for their time and energy to make the conference a success.

Without our dedicated community and ongoing support this event would not be possible.

Yours faithfully,

Professor Robin Batterham

ABSTRACT

The main techniques for removing phosphorus as an impurity element in iron ores are physical separation (eg magnetic separation, flotation) and chemical separation (acid leaching, alkaline leaching and bioleaching) processes. When phosphorus occurs in iron ores as phosphate minerals (eg apatite), physical separation techniques are available to remove the gangue minerals from iron ores. On the other hand, chemical separation techniques are suitable for reducing phosphorus levels when phosphorus is associated with iron oxides and hydroxide minerals (eg hematite and goethite) in iron ores.

In this study, the dephosphorisation behaviour of high-phosphorus iron ore was investigated using a combined alkaline roasting and water washing route. Roasting experiments were conducted in a laboratory electric muffle furnace using various concentrations of sodium hydroxide (0–50 g/kg-ore) at different temperatures (100–800°C), varying prolonged roasting times (0–2 h), and different particle size fractions (-45 – -250 μm) of iron ore. Subsequent water washing experiments were employed at various pulp densities (30–1000 g/L) and different times (30 s – 60 min) at ambient temperature. Hematite and goethite were the main minerals in the high-phosphorus iron ore identified using X-ray diffraction (XRD) analysis. The iron ore assaying 63.40 mass % Fe (total), 0.240 mass % P, 4.53 mass % SiO_2, and 4.87 mass % Al_2O_3 were determined using X-ray fluorescence (XRF) analysis.

The results showed that the dephosphorisation rate of the iron ore was reached 40 per cent under roasting with 50 g/kg-ore NaOH at 300°C for 2 hours followed by water washing for 30 s with a pulp density of 300 g/L, reducing phosphorus level from 0.240 mass % to 0.142 mass %. At the same time, the iron grade was reduced from 63.4 per cent to 59.5 per cent, caused by an iron loss. Results suggest that the phase transformation of goethite induces the dephosphorisation of high-phosphorus iron ore under alkaline roasting conditions.

INTRODUCTION

Iron ore is a raw material for the iron and steelmaking industries. Nowadays, higher-grade iron ore reserves are depleting because of enormous iron and steel production growth. Therefore, high-impurity iron ore deposits are expected to be used as iron ores in the future (Baawuah *et al,* 2020; Löf *et al,* 2019). Reduction in the quality of iron ore due to high levels of impurities is a severe issue in iron and steel manufacturing processes. Typical major components in iron ore are magnetite (Fe_3O_4), hematite (Fe_2O_3) and goethite (FeO(OH)) as iron minerals, and impurity minerals containing silica (Si), aluminium (Al), phosphorus (P), and sulfur (S). Additionally, quartz and alumina occur in iron ore as kaolinite (clay), gibbsite, illite, and lateritic materials, while phosphorus presents as phosphate minerals and inclusions in iron oxides and hydroxides. The high impurities in iron ore affect energy consumption, CO_2 emissions, slag amounts, and slag viscosity throughout the steel production processing (Clout and Manuel, 2015; Park *et al,* 2021; Pownceby *et al,* 2019). Among

them, a high level (>0.1 wt.% P) of phosphorus causes detrimental effects on the quality of steel and the process costs associated with removing phosphorus from iron ore through steelmaking. The removal of phosphorus from iron ore is a vital process; mainly, phosphorus is a predominant phase into impurity components in iron ore (Ofoegbu, 2019; Bao *et al,* 2021). The main techniques for removing phosphorus as an impurity element in iron ores are physical separation (eg magnetic separation, flotation), chemical separation (acid leaching, alkaline leaching and bioleaching), and various combined techniques with thermal and physical separation (Xiao and Zhou, 2019; Pereira and Papini, 2015; Delvasto *et al,* 2008; Roy *et al,* 2020). Physical separation processes are suitable for removing phosphorus-containing minerals such as apatite in iron ore. Besides, chemical separation techniques are employed to remove phosphorus that adsorbs onto iron oxides and iron hydroxide minerals' surfaces. However, acid leaching and alkaline leaching techniques can adequately remove phosphorus that exists as phosphate in iron ore but cannot sufficiently remove phosphorus adsorbed in iron oxides and hydroxides (Yu *et al,* 2013; Mochizuki and Tsubouchi, 2019a; Zhang *et al,* 2019). Some authors used a combined thermal treatment and leaching process to investigate phosphorus removal from different iron ores. They found that the phosphorus adsorbed in iron oxide minerals' surfaces could leach out with aqueous solutions after the structural disruption of the iron minerals by thermal processing (Gooden *et al,* 1974; Fisher-White *et al,* 2013; Sanchez-Segado *et al,* 2015; Zhu *et al,* 2016; Mochizuki and Tsubouchi, 2019b).

In this study, the dephosphorisation behaviour of high-phosphorus iron ore was investigated using an alkaline roasting and water washing route. Various processing parameters, including sodium hydroxide concentration, roasting temperature, roasting time, particle size distribution, pulp density, and washing duration through roasting and water washing, were investigated to reduce phosphorus levels in the high-phosphorus iron ore.

EXPERIMENTAL

Materials

The high-phosphorus iron ore sample received from an iron ore producing company was used in this study. The iron ore sample was pulverised by crushing and milling it into powder. Then individual iron ore particles ranging between -45 µm and -500 µm in various size distributions were produced using sieving and classification (JIS Z 8801 sieves, IIDA Manufacturing Co, Ltd).

Reagent grade sodium hydroxide (NaOH) and distilled water were used in the alkaline roasting and water washing processes.

Methods

The high-phosphorus iron ore sample was roasted in an electric muffle furnace (Advantec, KM-160) after drying with an appropriate NaOH solution at 60°C for 24 hours. A process flow chart regarding the dephosphorisation of the high-phosphorus iron ore is represented in Figure 1.

In the roasting process, NaOH concentration (5–50 g/kg-ore), roasting temperature (100–800°C), prolonged roasting time at the target temperature (0–2 h), and particle size distribution (-45 – -500 µm) were studied. The roasted sample was cooled in a desiccator to room temperature and ground in a pestle with a mortar. Then the ground sample was washed with distilled water in a beaker at a pulp density of 100 g/L, washing time of 30 seconds at ambient temperature (20°C).

The pulp density (30–1000 g/L) and washing time (30 s – 60 min) were examined at ambient temperature through the water washing. After washing the sample, vacuum filtration was conducted to separate solid and liquid phases. Each experiment was performed in duplicate to confirm reproducibility.

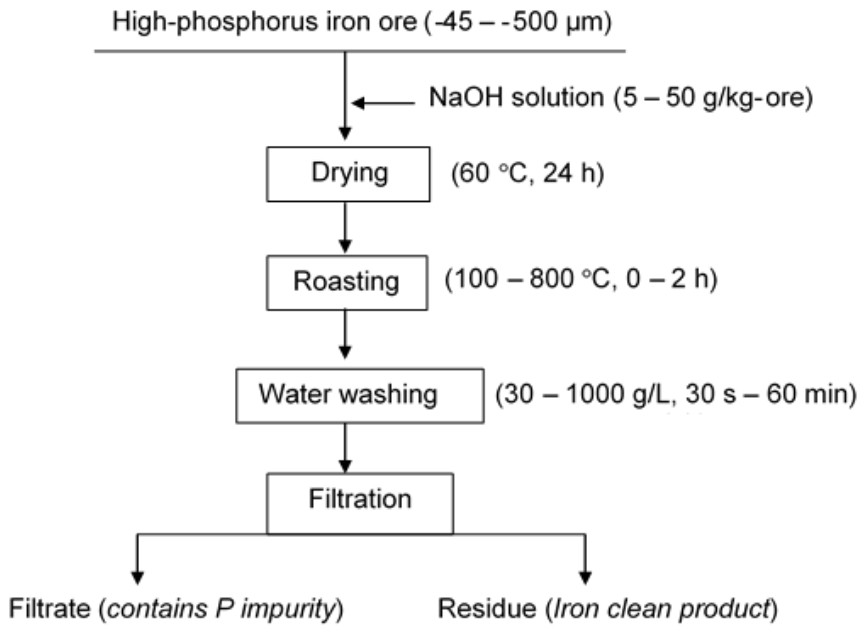

FIG 1 – A process flow for the dephosphorisation of the high-phosphorus iron ore.

Analytical

An electric muffle furnace (Advantec, KM-160) was used to roast iron ore samples. Temperature and agitation speed (revolutions per minute, rev/min) in water washing were controlled by an automatic multi-position magnetic stirring hot plate, HSH-6D (As One Corp).

The chemical constituents and mineral components in the initial iron ore samples, roasted samples, and washed residues were determined using an X-ray fluorescence spectrometer, XRF (Primus-II, Rigaku) and X-ray diffractometer, XRD (RINT–2200/PC, Rigaku), and scanning electron microscopy with energy dispersion spectroscopy, SEM-EDS (SU-70, Hitachi Hightech).

The dephosphorisation rate and iron loss through the processing of the high-phosphorus were calculated using the following equation (Equation 1).

$$R_{dephosphorisation/Fe\ loss}\,(\%) = 1 - \frac{T_{Fe/P}}{C_{Fe/P}} * 100 \quad (1)$$

Where:

- $C_{Fe/P}$ denotes the content of Fe and P in the initial iron ore sample used in this study.
- $T_{Fe/P}$ represents the content of Fe and P in the solid residue from the alkaline roasting and water washing.

RESULTS AND DISCUSSION

High-phosphorus iron ore sample characterisation

The chemical compositions of high-phosphorus iron ore samples with various particle size distributions are summarised in Table 1. The impurity components, namely phosphorus (P), silica (Si), alumina (Al), and sulfur (S) in the iron ore, range between 0.224–0.258 mass % for P, 9.18–10.9 mass % for SiO_2+Al_2O_3, and about 0.01 mass % for S, respectively (Table 1).

TABLE 1

Chemical constituents of the iron ore sample with various size distributions, mass %.

Particle size, (μm)	Fe, (total)	P	SiO_2	Al_2O_3	S
-500+250	63.24	0.230	4.48	4.84	0.009
-250+125 (head sample)	63.40	0.240	4.53	4.87	0.009
-125+90	62.55	0.224	4.34	4.84	0.007
-90+45	63.84	0.256	5.28	5.70	0.007
-45+38	63.62	0.258	5.11	5.55	0.008

The content of iron (Fe) in the iron ore is over 62.5 mass %, which is the iron content required from the ironmaking industries. The acceptable level of Fe, P, and the total amount of SiO_2 and Al_2O_3 (SiO_2+Al_2O_3) from iron- and steel-making industries should be higher than 60 per cent for Fe, and as low as 0.07 per cent for P, less than 5 per cent for SiO_2+Al_2O_3, and below 0.08 per cent for S, respectively (Clout and Manuel, 2015). It implies that the phosphorus level in the iron ore is several times higher than its acceptable level, while the SiO_2+Al_2O_3 level is about two times higher. It can be referred to as high-phosphorus iron ore because of its higher phosphorus content.

Hematite (Fe_2O_3) and goethite (FeO(OH)) are the main minerals in the high-phosphorus iron ore, as shown in Figure 2. Other minerals that contain phosphorus and aluminium were not identified by XRD analysis because of the low detection limits of these elements in the sample.

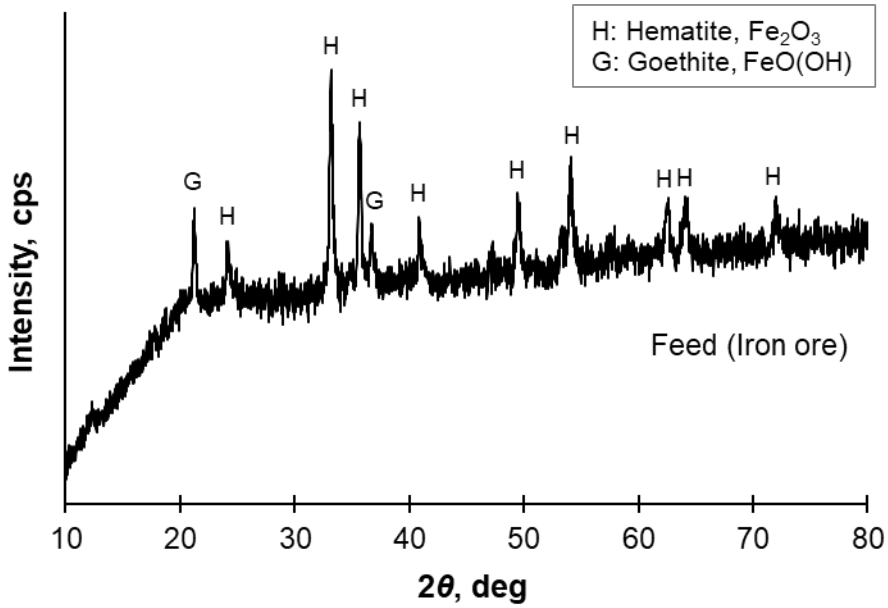

FIG 2 – XRD pattern of the high-phosphorus iron ore used in this study.

Alkaline roasting and water washing

The dephosphorisation of the high-phosphorus iron ore was investigated using alkaline roasting followed by a water washing route. The conditions determined for dephosphorisation of the iron ore through alkaline roasting and water washing were defined separately in the following sections.

Effect of NaOH concentration

Figure 3 shows a strong dependence of NaOH concentrations on the dephosphorisation of the high-phosphorus iron ore and iron loss through roasting at 300°C for 2 h.

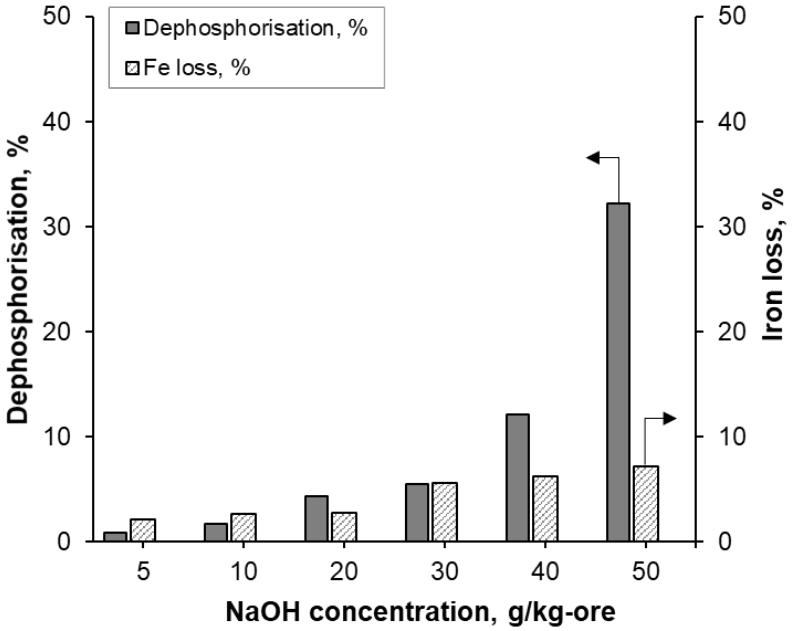

FIG 3 – Dependence of dephosphorisation and iron loss on NaOH concentration after heating at 300°C for 2 h.

Firstly, the dephosphorisation of the iron ore was increased from 1 per cent to 5.5 per cent with the increase in NaOH concentration from 5 g/kg-ore to 30 g/kg-ore and then increased drastically up to 32.2 per cent with further increases in NaOH concentration to 50 g/kg-ore. The iron loss increased in a straight line trend with the increase in the NaOH concentration. The minimum iron loss reached was 2.1 per cent with 5 g/kg-ore NaOH, while the maximum iron loss was 7.2 per cent with 50 g/kg-ore NaOH. It is unclear why the phosphorus removal rate and iron loss increase with an increase in NaOH concentration. It has been suggested that the appropriate amount of NaOH throughout the roasting process is crucial to removing phosphorus and controlling iron loss from the iron ore.

It is proposed that phosphorus-containing iron minerals (eg goethite) or phosphate minerals (eg apatite) in the iron ore may be converted to water-soluble compounds under high alkaline conditions. Some authors found that the phase transformation of goethite to hematite occurs at about 250°C (Liu H *et al,* 2013; Liu B *et al,* 2018).

Effect of roasting temperature

The dephosphorisation of the iron ore and iron loss associated with alkaline roasting temperature are presented in Figure 4. An increase in the roasting temperature from 100°C to 300°C in the presence of 50 g/kg-ore NaOH affects dephosphorisation which increases from 19.2 per cent to 32.2 per cent. Further increases in the roasting temperature to 500°C had no noticeable effect on the dephosphorisation of the iron ore. When the roasting temperature rises to 800°C, the highest dephosphorisation of 37.2 per cent was achieved. Moreover, the iron loss increases linearly from 4.2 to 7.2 per cent when the roasting temperature varies significantly from 100°C to 300°C under alkaline conditions, whereas there is no apparent change in the iron loss at 500°C. It can be seen that the iron loss decreased from 7.4 per cent to 4.3 per cent when the roasting temperature reached 800°C (Figure 4). Lowering the iron loss at the highest temperature (800°C) could correspond to a complete reduction of iron minerals.

It could be noted that the dephosphorisation of the iron ore is varied by temperature significantly of ≤ 100°C and ≥ 800°C, respectively, while no apparent variations at the temperatures between 300°C and 500°C. The roasting temperature of 300°C was selected for further studies due to economic reasons for high-temperature processing, which increases the energy consumption and other operating costs.

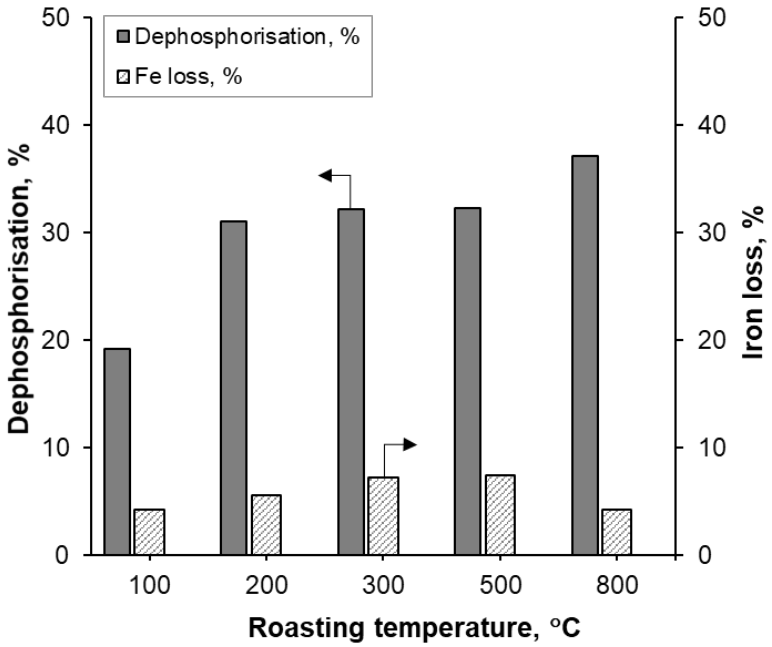

FIG 4 – Dependence of dephosphorisation and iron loss on roasting temperature (100–800°C) (NaOH concentration: 50 g/kg-ore, particle size: -250 µm, roasting time: 2 h).

Effect of roasting time

As shown in Figure 5, dephosphorisation and iron loss levels were varied depending on prolonged roasting times (0–2 h) under alkaline conditions (50 g/kg-NaOH) at 300°C. The prolonged roasting time was estimated after reaching the target temperature (300°C). The results show that when the roasting time extends from 0–2 hours, the dephosphorisation reduces from 39.2 per cent to 32.2 per cent.

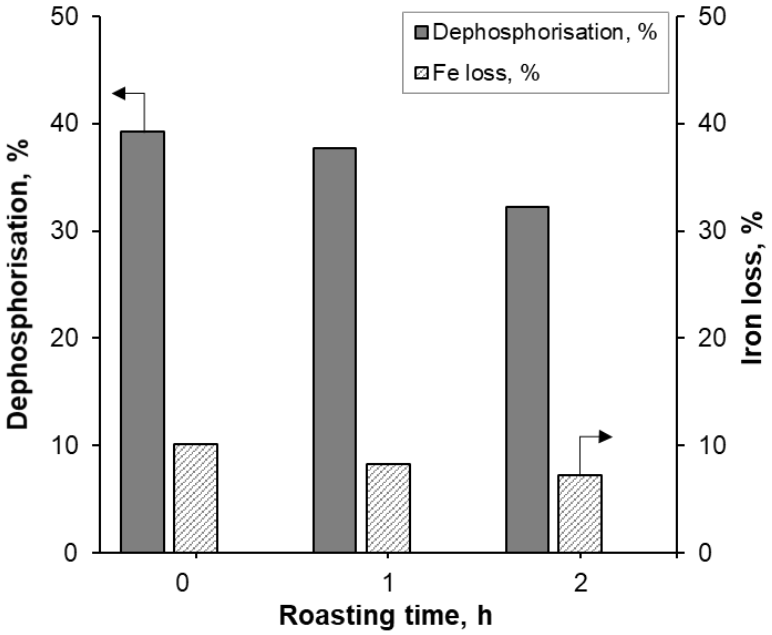

FIG 5 – Dependence of dephosphorisation and iron loss on roasting time (0–2 h), (NaOH concentration: 50 g/kg-ore, particle size: -250 µm, roasting temperature: 300°C).

Similarly, the iron loss at different roasting times decreases from 10.1 per cent to 7.2 per cent. It implies that the short roasting time has been beneficial for improving the dephosphorisation but detrimental to the iron loss compared to the extended roasting time (2 h). Except for the highest level of dephosphorisation, the lower iron loss is a crucial parameter for selecting applicable conditions for iron ore processing. At two hours of roasting, the dephosphorisation and the iron loss were

32.2 per cent and 7.2 per cent, respectively. Therefore, the prolonged roasting time of 2 h is selected as an optimal condition for further studies. These differences in the dephosphorisation and iron loss with roasting time could be related to the reaction behaviour of iron ore minerals with NaOH under the roasting temperature (300°C).

Effect of particle size distribution

The dephosphorisation and iron loss of the high-phosphorus iron ore with various particle size distributions throughout alkaline roasting followed by water washing are presented in Figure 6.

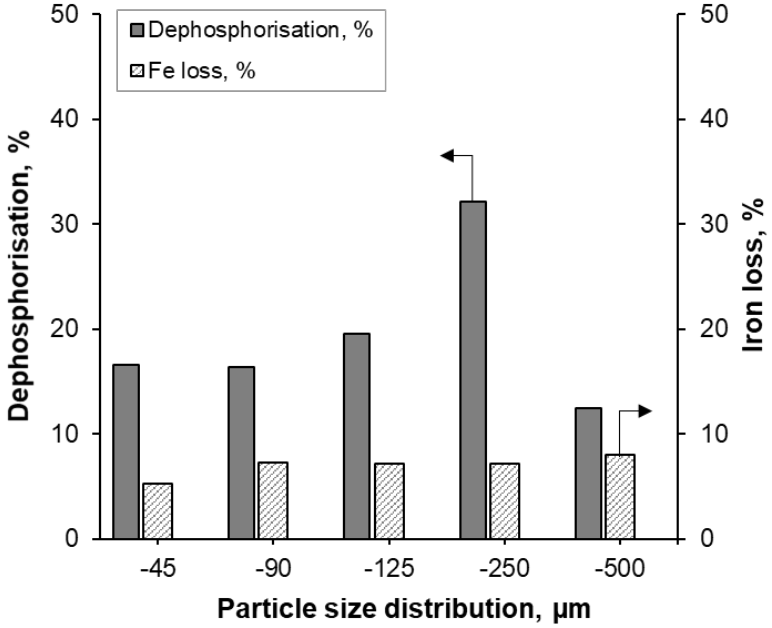

FIG 6 – Dependence of dephosphorisation and iron loss on the particle size distribution (-45 ~ -500 µm) (NaOH concentration: 50 g/kg-ore, roasting temperature: 300°C, roasting time: 2 h).

As can be seen in Figure 6, the level of dephosphorisation of the fine iron ore particles (-45 µm and -90 µm) was almost the same and increased from 16.4 per cent to 32.2 per cent with increasing the particle size from -90 µm to -250 µm. However, dephosphorisation is reduced in coarse iron ore particles and reaches 12.4 per cent as the particle size increases to -500 µm. Under the same conditions, the iron loss ranges between 5.3 per cent and 8 per cent. Notably, the iron loss is 5.3 per cent in the fine iron ore particles (-45 µm) throughout the alkaline roasting and water washing process. In comparison, about 7.2 per cent iron loss has occurred in a -90, -125 and -250 µm particle size interval, respectively. The iron loss is slightly higher as 8 per cent in the coarse iron ore particles (-500 µm).

It is observed that the phosphorus removal from the iron ore is size-dependent, while the iron loss is not much size-dependent. This observation may be related to the contact surface of the iron ore particles with various size distributions through the alkaline roasting followed by water washing.

Water washing

The ground iron ore sample from the alkaline roasting in a muffle furnace at the selected conditions (50 g/kg-ore NaOH, 300°C, 2 h) was washed with distilled water at different times (30 s – 60 min) and varying pulp densities (30–1000 g/L) at ambient temperature. The findings from the experiments mentioned above are discussed in the following session.

Effect of time

The levels of dephosphorisation and iron loss during the alkaline roasting followed by water washing at different times and an ambient temperature (20°C) are plotted in Figure 7. It can be seen that the levels of dephosphorisation are 32.2 per cent and 35.4 per cent during the water washing of the alkaline roasted samples for 30 s and 60 min, while the iron losses are 7.2 per cent and 7.0 per cent,

respectively. It indicates no significant differences in the dephosphorisation and iron losses between the short-term and long-term washing periods, such as 30 s and 60 min.

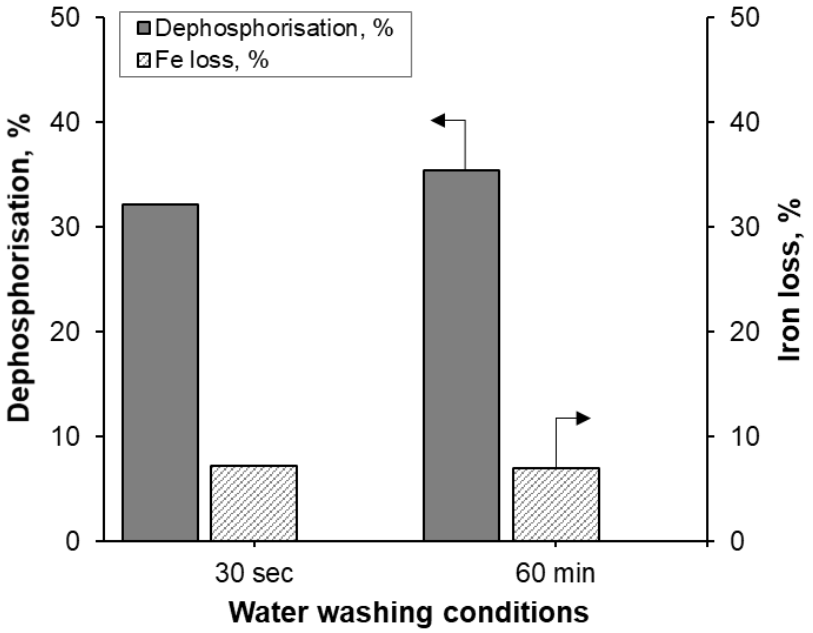

FIG 7 – Dependence of dephosphorisation and iron loss on washing time (30 s and 60 min), (Roasted conditions: 50 g/kg-ore NaOH, 300°C, 2 h; Washing conditions: H_2O, 100 g/L pulp density, 20°C).

This finding may be attributed to faster leaching kinetics of unstable phosphorus and iron species from the alkaline roasted iron ore. The shorter water washing time of 30 s is the best condition because of its economic efficiency.

Effect of pulp density

Figure 8 shows the influence of pulp density on the dephosphorisation and iron loss of the iron ore during the water washing after roasting. The pulp density effectively influences the phosphorus removal from the iron ore. Because the dephosphorisation is increased from 24.3 per cent to 40.6 per cent, increasing the pulp density from 30 to 400 g/L. However, a further increase in the pulp density to 1000 g/L reduces the phosphorus removal rate to 32.9 per cent. The maximum dephosphorisation of 40.6 per cent is achieved at a pulp density of 400 g/L, whereas the minimum dephosphorisation of 24.3 per cent at a 30 g/L pulp density. Results suggest that the dephosphorisation is efficient at slurry densities between 300 and 500 g/L (30–50 per cent solids). However, it is inefficient at lower (below 300 g/L) and higher pulp densities (above 500 g/L) depending on the mass transport phenomena in the water washing system. Generally, iron losses are slightly higher at low slurry density intervals between 30 g/L and 100 g/L than those at slurry densities above 100 g/L.

Whereas iron loss decreases with the pulp density increase, resulting in 5.9–7.3 per cent iron loss. The minimum iron loss was reached 5.9 per cent at a pulp density of 300 g/L, accompanied by 39.6 per cent phosphorus removal. It implies that the difference in the dephosphorisation rates and iron losses through the varying water washing conditions could be related to the specific gravity of solids and slurry viscosity caused by iron – and phosphorus-containing minerals.

Fisher-White *et al* (2013) reported that the phosphorus content of Australian goethite-hematite ores (Brockman ores) containing 0.146 per cent and 0.136 per cent P was reduced to 0.079 per cent and 0.095 per cent indicating phosphorus removal rates of 46.9 per cent and 35.2 per cent under the heating of 300°C followed by leaching with 20 per cent NaOH and a pulp density of 25 per cent at the balance point temperature (BPT) and 80°C, respectively.

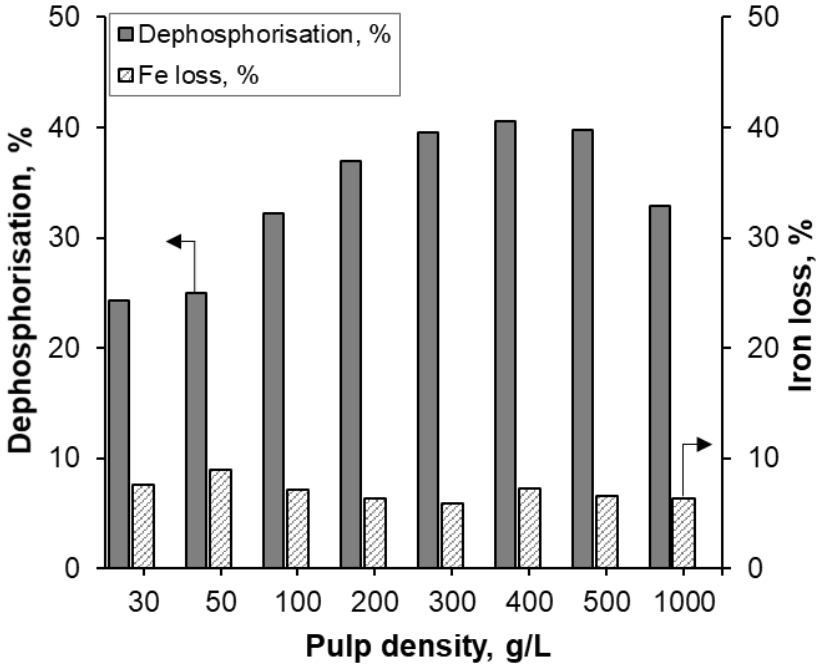

FIG 8 – Dependence of dephosphorisation and iron loss on the pulp density (30–1000 g/L), (Roasted conditions: 50 g/kg-ore NaOH, 300°C, 2 h; Washing conditions: H_2O, washing time: 30 s, 20°C).

As a result, the iron product that contains 59.5 mass % Fe and 0.145 mass % P could obtain from the high-phosphorus iron ore using a combined route consisting of alkaline roasting followed by water washing. The further challenging tasks in developing this proposed process are reducing iron loss and improving the phosphorus removal rate to produce a clean iron product containing over 60 per cent Fe and below 0.1 per cent P.

Mineral composition of the products

XRD patterns of iron ore samples before and after alkaline roasting and water washing are compared in Figure 9. The comparison of XRD patterns of the samples revealed the disappearance of diffraction peaks corresponding to the goethite from the iron ore sample after alkaline roasting at 300°C for 2 h. In contrast, the new diffraction peaks related to hydroxylsodalite as sodium aluminosilicate hydrate had appeared in samples after roasting and water washing (Figure 9). It can be seen that the mineral characterisation of the residue from water washing is almost similar to the roasted sample with NaOH in the roasting conditions. The result indicates that hematite is the major mineral phase in the final products from alkaline roasting and water washing processes.

The SEM-EDS analysis identified the variations in the morphology and compositional differences in impurity elements such as P in the initial iron ore sample, roasted sample, and residue, as shown in Figure 10.

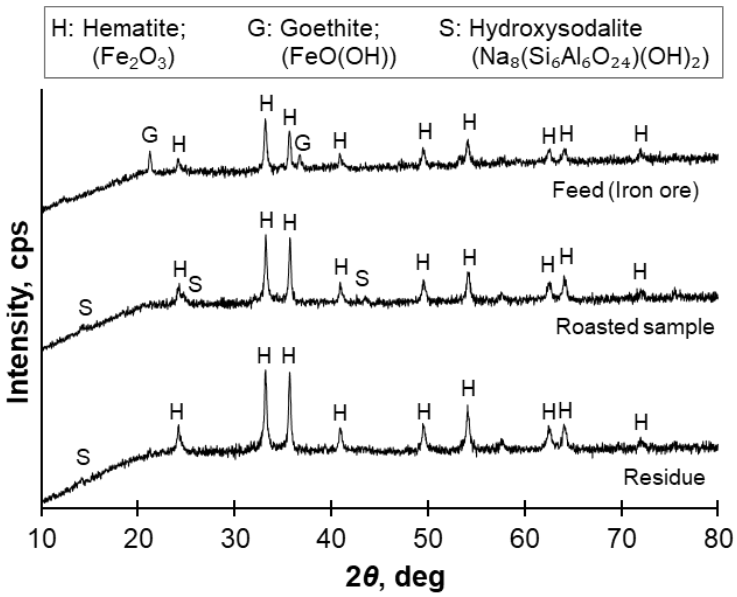

FIG 9 – XRD patterns of initial iron ore sample, roasted sample and residue from water washing, respectively (Roasting conditions: 50 g/kg-ore NaOH, 300°C, 2 h; Washing: H_2O, 100 g/L pulp density, 30 s, 20°C).

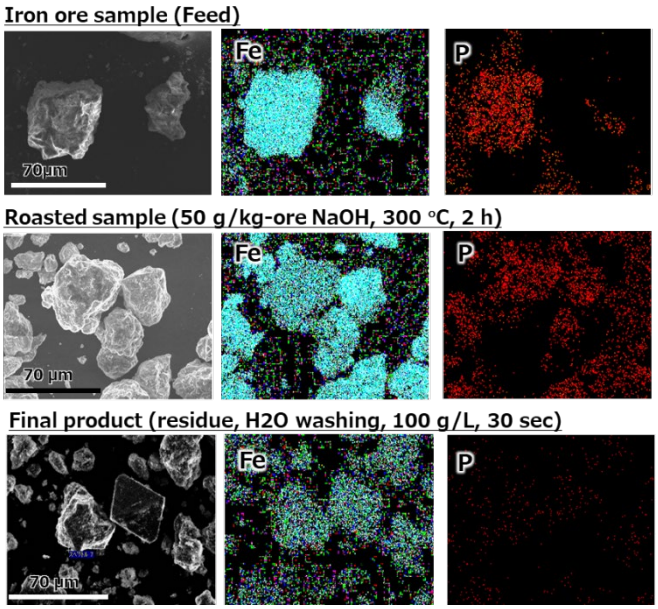

FIG 10 – SEM-EDS images of the iron ore samples: (A) initial iron ore sample; (B) roasted sample (50 g/kg-ore NaOH at 300°C for 2 h); (C) residue from water washing (pulp density of 100 g/L for 30 sec at 20°C).

CONCLUSIONS

The dephosphorisation of high-phosphorus iron ore was investigated using alkaline roasting followed by the water washing route throughout this study. Effects of various processing parameters in the roasting and water washing were examined to optimise the phosphorus removal from the iron ore.

Results showed that influential variables for achieving a higher dephosphorisation rate are NaOH concentration, temperature and duration through the roasting process, while pulp density in water washing. The phosphorus removal rate of the iron ore was increased with increased NaOH concentration and temperature through the roasting process and with pulp density in water washing. The maximum dephosphorisation of about 40 per cent was achieved from the high-phosphorus iron ore using the combined route of alkaline roasting and water washing under optimised conditions when the minimum iron loss was less than 6 per cent. The final iron product from the sequential processing contained 59.5 mass % Fe and 0.142 mass % P. It suggests that the dephosphorisation

of the iron ore could correspond to the phase transition of goethite to hematite or the decomposition of iron ore minerals containing phosphorus under alkaline roasting conditions.

ABSTRACT

For decades, organisations worldwide have been working to overcome challenges associated with new technology adoption while keeping up with rapid growth, development, and globalisation. In minerals processing, the challenges in developing and implementing solutions that contribute to the mining value chain are unique from other markets, as mining operations expect that world-class suppliers provide them solutions to gain a competitive advantage in their operation, production, performance as a financial asset, and as a long-term partner as we move into the future of mining. A simple shift in mindset is proven key to successful technology implementation. Change leaders must no longer think of their expertise in the area of application as their only responsibility; they must make a mental shift and see themselves in dual roles that strive to integrate the perspectives and needs of both developers and users. Successful change leaders must: (1) collaborate, seeking user involvement to ensure fit between product and operational needs, (2) demonstrate commitment to receive new technology, and (3) communicate to achieve an eventual shift of ownership from supplier to users that is seamless. Additionally, this strategy contributes to the mining value chain, as it allows developers and implementers to evaluate how change contributes to the asset's position both within the company and in the commodities market. This paper will explain the shift in perspective for new technology implementation in detail and provide recommendations that operations can emulate, using examples of real challenges and lessons learned during a commissioning of the CYCLONEtrac™ Particle Size Tracking (PST) system at Cerro Verde's C2 Concentrator. This concentrator has led technological change for plant optimisation, witnessed improved Net Metal Production (NMP), among other benefits with PST, the only technology in the market capable of providing real-time, online, and direct particle size measurement at the individual hydrocyclone level

INTRODUCTION

Hydrocyclone performance and particle size classification are crucial elements in the comminution process. The ability to measure particle size within individual cyclones is essential for grind circuit optimisation and for controlling product size sent downstream.

Current challenges

All cyclones within a cluster behave differently, yet until recently, operators were unable to measure the particle size from each individual cyclone. How can they ensure target size classification for optimal recovery? How is particle size variability controlled? In a macro economic environment where the demand for valuable mineral is outstripping the supply, how does a concentrator relax the grinding task, grind coarser, and increase throughput without violating the downstream process barrier? It is impossible to respond to industry challenges using conventional measurement technologies.

Innovative solutions

CiDRA's CYCLONEtrac™ Particle Size Measurement System (PST) with SMARTsensor™ technology is quickly becoming the industry standard for particle size measurement and is the only real time measurement system that directly measures and tracks particle size of individual cyclones every four seconds. The SMARTsensor is a waveguide that is inserted through the pipe wall on each overflow pipe. As the particles impact the waveguide, which is inserted in each hydrocyclone

overflow pipe, particles impinging on the wave guide create acoustic waves are generated, captured, and produce a frequency spectrum that is processed to determine particle size (Figure 1).

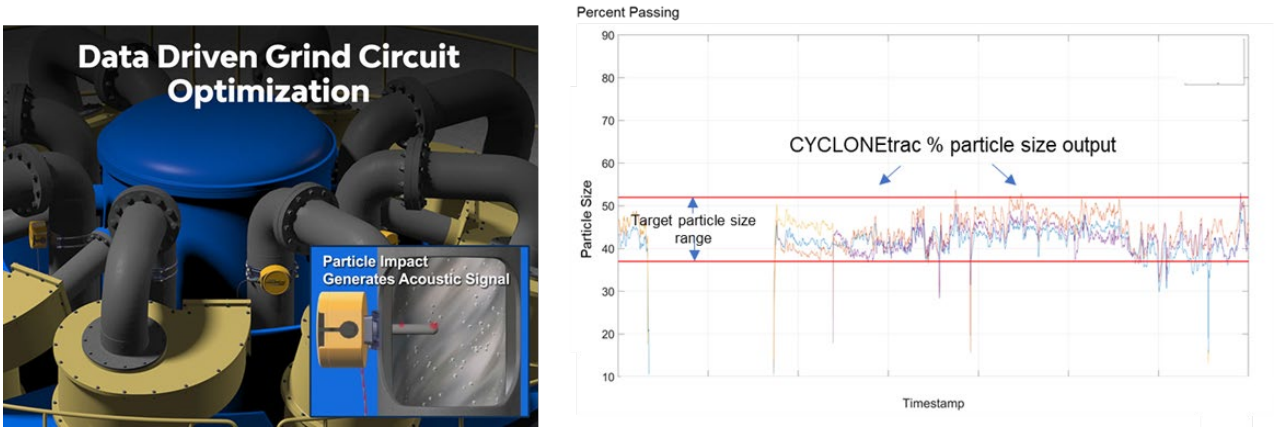

FIG 1 – Illustration of CYCLONEtrac Particle Size Measurement and Tracking System (PST) installed on a cluster of hydrocyclone overflow pipes together with a graph of five real time particle size measurements.

The paradigm shift

This unique technology allows minerals processing operations to make a step change from conventional particle size measurement analysers that take a periodic measurement from the *consolidated* overflow to a real-time measurement of *individua*l cyclones with the capability of providing up to five particle size measurements every four seconds. Operators can now make decisions that reduce particle size variability and achieve their target grind size (micro control strategy). CYCLONEtrac PST also enables a consolidated particle size measurement from all cyclones in the cluster to derive a P80 measurement for the control and optimisation of the grind circuit (macro control strategy).

The true shift in the paradigm is not achieved solely through implementing an innovative technology. The catalyst for the shift originates with internal 'change agents' with a shared vision and understanding how the new technology can bring increased and sustainable value to the enterprise. The change agents must also breakdown the barriers to adoption by working collaboratively with stakeholders. It's not just the challenge of having the organisation switch from one technology to another, the biggest challenges are changing the way we work (methods) and think about our jobs (culture).

CASE STUDY – CYCLONETRAC PST CHRONOLOGY AT CERRO VERDE MINING SOCIETY, PERU

2019

Cerro Verde identifies the CYCLONEtrac Particle Size Measurement and Tracking System (PST) as the technology for the optimisation at of its concentrators and the project begins.

2020

The PST technology was implemented on one cluster during the first quarter of the year and the CiDRA team together with Cerro Verde achieve all the quantifiable objectives established for the project. At the close of the project the Cerro Verde Project Management team and operations personnel shared their 'Lessons Learned' and in turn, the authors would like to share with our readers as it truly a handbook as to how to navigate and adapt to the application of a new technology. These thoughts are included at the end of this paper.

During the last quarter of 2020, using the data provided by the PST and the new knowledge provided, the next steps are analysed.

2021

During the first quarter, plant data was delivered to consultant Dr. Jaime Sepulveda for a Net Metal Production (NMP; Maron *et al*, 2019) study to evaluate the possibility of including his recommendations for an advanced, automated control strategy (see Table 1). The results follow:

- The data analysis confirms that by implementing the NMP strategy, the concentrator can expect results above concentrators of a similar size (benchmarking).
- The size of the flotation product (P80) significantly affects the yields of both the grinding stage and the flotation stage, so it is important to measure, and control said size around its ideal value that always maximises the NMP of the process, incorporating the real time PST real time particle size measurements to the corresponding Expert Control Strategy.
- The PST Technology, duly incorporated into the Expert Control System, also allows detecting and correcting the possible occurrence of total or partial blockages of the hydrocyclone discharges, thus avoiding harming the level of Recovery achievable in the subsequent Flotation stage.

TABLE 1

Net Metal Production benchmarking studies of concentrators in Peru and Chile performed by Dr. Jaime Sepulveda using actual plant data.

Benchmarking: Tonnage & Recovery vs. P80

2021

The results of the study and the expert's recommendations together with the performance of the CYCLONEtrac PST system are taken into account.

Cerro Verde lessons learned

Setting expectations for a new paradigm – challenges and opportunities

1. The site team should be encouraged to take inventory of current circuit physical constraints prior to implementing the PST System: flows, pressures, circulating loads, etc.

2. The entire execution team needs to challenge the operating paradigms and explore the entire range of operating conditions with ‘new eyes’ once the system is installed, with the mindset that new operating conditions may be found in previously ‘off limits’ territory.
    - Control system and operations understanding that they need to be there to back this up. The control room operator needs to be involved and know what to do if one cyclone is a bad actor during a stress test. (This is illustrated later in the appendix to this report).
3. Anticipate and reinforce at multiple stages that the PST shows you where opportunities are, but the site needs to take ownership to act on this information. Expect higher cyclone wear component replacement, call for cyclone changes, and that the follow up on process anomalies will be substantial. Ownership needs to come from all disciplines.
4. ‘The good news is that each individual cyclone’s performance can been seen. The bad news is that each individual cyclone´s performance can be seen.’ There is a wealth of new information that none of us have ever seen before regarding cyclone cluster operation. The challenge is to not allow this wealth of information to ‘vapor lock’ advancement on the project.
5. The key learning is the PST technology is powerful, but it is not ‘plug and play’. The stakeholder needs to roll up his sleeves to fully harness the benefits.
6. Expect much more than roping detection. If the client has been operating with minimal information on the ball mill product, prior supportive work should be done or revisited on optimal grind size (Bazin analysis, QEMSCAN lock/liberation profiles, tonnage/grind relationship analysis).

Concluding thought by Cerro Verde C2 Concentrator Metallurgy Supervisor ‘With the PST we are pushing more tonnage and producing more net valuable metal and that’s what counts.’

ACKNOWLEDGEMENTS

We would like to acknowledge and extend our sincere appreciation to the Cerro Verde Project and Management Teams together with the Operations, Instrumentation, Metallurgy and Process Engineers for their trust in CiDRA and its technology. We thank them their enduring commitment to the success of the program. A special thanks to Kyle Wiese who led the program with his talented team and for allowing us to share their ‘Lessons Learned’ thoughts and experiences in this paper.

Sensors and automation – a unique opportunity to leverage real-time gold recovery data through data analysis and automation in gold processing

S Gray[1]

1. Technical Director, Gekko Systems, Mitchell Park VIC 3350. Email: sandyg@gekkos.com

ABSTRACT

Based on the 2021 Volume 5 *State of Play*™ mining survey of key executives and board members in the mining sector, the key responses to 'Which of the following technologies will have the biggest impact on mining in the next 15 years?', were 'Sensing and Data' followed by 'AI and Analytics'.

From the early 1970s it would have been unlikely to predict the level of sensing and automation introduced to the broad industrial sector. No better example is the automobile industry where the combination of technological advances and external drivers (such as emissions control) have driven an incredible rate of change.

The introduction of sensing, data, AI, and automation in the mining industry is just ramping up. Until now our energy efficiency, environmental footprint, labour shortage, skills, and safety have not been challenged by stakeholders in the way we are seeing market forces develop today. In order to address these challenges, we need to look back to the automobile industry and learn their lessons to accelerate our application of digital capability, analysis, AI and automation This is critical, particularly as access to skilled human resources becomes more difficult.

An example of how this can be achieved in a gold processing plant utilising the latest real-time sensing technologies is the 'Carbon Scout' developed by Curtin University, and OLGA developed by CSIRO, which are both online technologies, coupled together with Gekko's 'Neon' digital platform to achieve a fully automated real-time gold processing system.

Investigating industrial feasibility of utilising magnetising roasting for goethite ore

ABSTRACT

Ore roasting has long been used for beneficiation and assay upgrading of different ores. In this process, which is mainly used for sulfide ores, the ore is heated to a high temperature. More specifically, it is a metallurgical process involving gas-solid reactions at elevated temperatures. Some types of Iron ore are weak in magnetic properties. Hematite, goethite and limonite are classified in this group. Unlike magnetite, which shows strong magnetic susceptibility, these ores are hard to beneficiate through magnetic separation route. Many researches have focused on gravity separation and flotation routes for upgrading these ores and these methods have also been utilised in the industry. One of the methods to whose industrial application less attention has been paid is magnetising roasting in which the non-magnetic iron ore is transformed to magnetite which is further beneficiated through magnetic separation. In this study, magnetising roasting tests have been performed on one goethite sample in order to check the feasibility of using this method for this specific ore in industrial scale. It is worth mentioning that high intensity magnetic separation have been performed on this sample before but the achieved results were not promising. Results have revealed that through magnetising roasting magnetite content of the ore could be increased from 1.7 per cent up to about 25 per cent. FeO content of the feed sample was increased from 1.03 per cent up to around 9.25 per cent. Also optimum size distribution for achieving the best results in magnetising roasting for this sample has been determined through this study. The best results were achieved when the ore size was 0–10 mm. The effect of coal ratio, time and temperature on the process have also be studied. A coal ratio of 5 per cent, time of 30 min and a temperature of 850°C were determined to be the optimum conditions. Finally, the technical feasibility of utilising magnetising roasting for this specific ore has been confirmed.

INTRODUCTION

In recent years, the rapid development of Iron and steel industry has led to a rapid decrease in high-grade magnetite iron ore deposits. Exhaustion and depletion of iron ore resources with strong magnetic properties has highlighted the importance of exploring methods for beneficiation and upgrading Fe content of iron ores with weak magnetic properties. As a result researchers have been looking into alternative resources of iron ore. Non-magnetic iron ores including hematite, goethite, limonite and siderite are usually hard to beneficiate as they lack strong magnetic properties. Therefore, alternative methods other than magnetic separation have to be used for upgrading the Fe content in these ores. Also, these ores often contain impurities and require some form of beneficiation in order to achieve the typical grades required for sale to downstream steel producers Nunna *et al* (2021). Magnetising roasting or reduction roasting followed by magnetic separation is an important method for the beneficiation of low-grade iron ores which are also weak in magnetic properties (Tang *et al*, 2019). Magnetising roasting is a process of converting a particle or substance from non/weak magnetic properties to high magnetic content at a critical temperature range of 500–900°C using a reducing agent considering the time duration. Below the critical temperature, conversion and reduction will be incomplete, but in the temperature above that, the formation of wustite which is paramagnetic will take place by fusion Ravisankar *et al* (2017).

Upgrading low-grade iron ores and tailings, often containing appreciable amounts of goethite, with magnetising roasting have been reported by many researchers. Yu *et al* (2017) demonstrated that through magnetising roasting followed by magnetic separation a high-grade concentrate containing 65.4 per cent iron can be achieved from an iron ore feed with Fe grade of 34.6 per cent. Nunna *et al* (2020) utilised magnetising roasting for recovering iron from an ore containing 57.0 wt per cent goethite and 31.1 wt per cent hematite.

As magnetising roasting has also been utilised for recovering iron bearing minerals from iron tailings as reported by Mitov *et al* (2021) and Yuan *et al* (2020b). Mitov *et al* (2021) showed that applying magnetising roasting followed by magnetic flocculation and magnetic separation on iron tailings results in an iron recovery of 88.00 wt per cent. They showed that the Fe per cent of the feed sample will increase from 45.72 per cent to 59.98 per cent. Yuan *et al* (2021) applied magnetising roasting to iron tailings with iron grade of 24.27 per cent containing hematite and magnetite. They demonstrated that iron concentrate with total iron content of 65.01 per cent and recovery of 89.07 per cent could be obtained.

Li *et al* (2018) reported successful application of magnetising roasting technology to recover iron oxides from red mud (bauxite residue). They showed that a magnetic concentrate with a total iron grade of 57.65 per cent and recovery of 90.04 per cent could be obtained from a red mud containing 44.32 per cent Fe. The same application was also reported by Yuan *et al* (2020a) who showed that the hematite and goethite phases in the red mud could easily be reduced to magnetite. They demonstrated that an iron concentrate with a total iron grade of 55.54 per cent and iron recovery of 95.22 per cent could be achieved from a red mud containing 47.67 per cent Fe. Samouhos *et al* (2013) also reported that a magnetic concentrate with an iron grade of 35.15 and 69.3 wt per cent metallisation could be recovered from a Greek red mud with 43.19 per cent Fe_2O_3.

In the present study, magnetising roasting was used for testing the feasibility of applying this method to samples received from a non-magnetic iron mine in Iran. This was done because processing this ore using conventional beneficiation methods comprising of gravity separation in combination with high gradient magnetic separation resulted in weight recovery, Fe and FeO grades of 41.86 per cent, 60.7 per cent and 2.43 per cent, respectively which were not suitable and acceptable. The effect of feed size distribution, coal ratio, time and temperature have also been studied in this article.

MATERIALS AND METHODS

Feed specifications

Iron ore received from mine in Iran named Badiz was used for this study. Iron and iron oxide grades of the feed sample were analysed through titration method. Iron and iron oxide grades of the feed were 39.56 per cent and 1.47 per cent, respectively. Fe/FeO ratio of the feed was 26.92 which shows the non-magnetic nature of the feed. X-ray Fluorescence analysis, results of which are shown in Table 1, was done on the feed sample to check the compounds and impurities associated with the feed.

TABLE 1

Results of XRF analysis for the feed.

SiO_2 (%)	Al_2O_3 (%)	BaO (%)	CaO (%)	Fe_t (%)	K_2O (%)	MgO (%)	MnO (%)	Na_2O (%)	P_2O_5 (%)	SO_3 (%)	TiO_2 (%)	LOI (%)
20.23	1.19	<	5.90	39.74	1.07	5.10	0.18	0.06	0.07	0.05	<	9.39

The specific gravity of the feed sample was also measured using a water pycnometer. The results show that the specific gravity of the feed was 3680 kg/m^3. The apparent density of the feed sample was measured to be 1890 kg/m^3.

Magnetising roasting tests

Magnetising roasting tests were performed on the feed sample. Coal was used as the reducing agent in the roasting tests. A muffle furnace was used for performing the roasting tests.

The effect of feed particle size distribution, coal addition ratio, roasting time and roasting temperature on magnetising roasting process were studied. Conditions in which the tests were performed are as mentioned in the following section.

Studying the effect of particle size distribution

For studying the effect of particle size distribution, the feed sample was divided into four fractions of 0–1 m, 1–4 mm, 4–10 mm and 0–10 mm. Chemical analysis of these different size fractions is as shown in Table 2. Roasting tests were done in the muffle furnace with a coal ratio of 5 per cent. In all of these test the temperature was set to 850°C. The duration of the tests was also set as 30 min.

TABLE 2

Chemical analysis of feed different size fractions.

Size distribution (mm)	Fe (%)	FeO (%)	Fe_3O_4 (%)
0–1	36.19	1.18	1.6
1–4	42.65	1.01	1.9
4–10	39.41	0.92	1.7
0–10	39.83	1.03	1.8

Studying the effect of coal addition ratio

For studying the effect of coal addition ratio to the feed, the result of determining the best particle size distribution were studied and these tests were done in the optimum feed size distribution which was confirmed to be 0–10 mm in the previous stage of tests. Roasting tests were done at coal ratios of 1, 3, 5, 7 and 9 per cent. In all the tests the feed size distribution was set as 0–10 mm, roasting temperature was set as 850°C and the roasting time was set as 30 min.

Studying the effect of roasting temperature

For studying the effect of roasting temperature, roasting tests were done at roasting temperatures of 550, 650 and 750°C. According to the results achieved from the previous stage, in these tests coal ratio was set to be 5 per cent. Similarly the feed size distribution was 0–10 mm. In these tests roasting time was 30 min.

Studying the effect of roasting time

Effect of roasting time on roasting process was also studied. The roasting time was set to be 15, 20, 25 and 30 minutes. The temperature in this stage was set according to the results achieved from the previous tests and was set to be 850°C. According to the results achieved from the previous stage, in these tests coal ratio was set at 5 per cent. Similarly the feed size distribution was 0–10 mm.

Satmagan tests

For determining the magnetite content of the feed and product in each of the roasting tests, Satmagan device was utilised.

X-ray diffraction tests

X-ray diffraction (XRD) tests were done on the feed sample and the sample roasted in optimised conditions. These tests were done to determine and compare the mineral phases present in the feed sample and the roasted sample and to compare them to better understand the effect of roasting process on the mineral phases change.

Davis tube tests

Davis tube tests at a magnetic field of 3800 Gauss was used to check the magnetic performance of ore roasted in the optimum conditions determined in each set of roasting tests. These tests were performed in two particle size distributions of K_{80} ~ 106 μm and K_{80} ~ 63 μm.

RESULTS AND DISCUSSIONS

Roasting tests results

Effect of feed particle size distribution on roasting test results

Results of the magnetising roasting tests performed on different particle size fractions are as shown in Figure 1. It can be seen in the graph that dividing the feed sample to different size fractions doesn't result in any significant difference in the roasting results. Therefore, the original feed size fraction of 0–10 mm was chosen as the optimum feed size fraction.

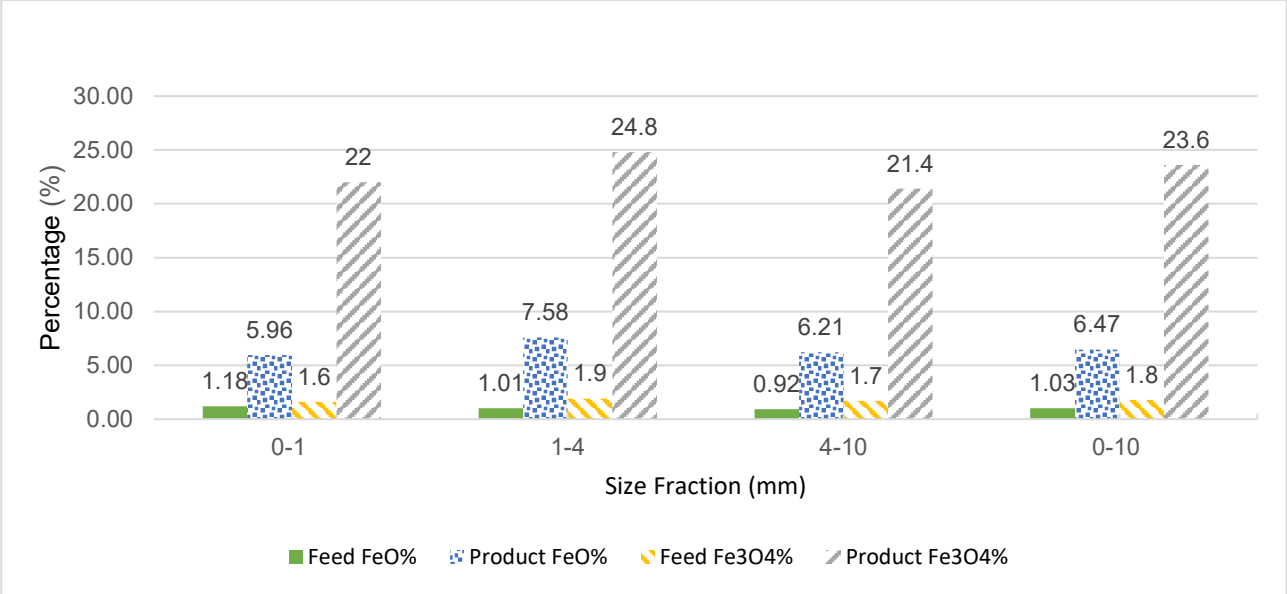

FIG 1 – Effect of feed particle size distribution on roasting product properties.

Effect of different coal ratios on roasting tests results

Results of varying the coal ratio are shown in Figure 2. These tests were performed on the optimum particle size fraction which is 0–10 mm and was determined in the previous stage of tests. As the graph in Figure 2 shows, as the coal ratio increases up to 5 per cent, FeO content and Fe_3O_4 content increase. This reveals that increasing the coal ratio up to 5 per cent results in an increase in magnetic susceptibility of the feed sample. The graph shows that further increasing the coal ratio to 7 per cent and 9 per cent doesn't result in any noticeable increase in the FeO and Fe_3O_4 contents. Hence, coal ratio of 5 per cent was chosen as the optimum coal ratio for performing further tests.

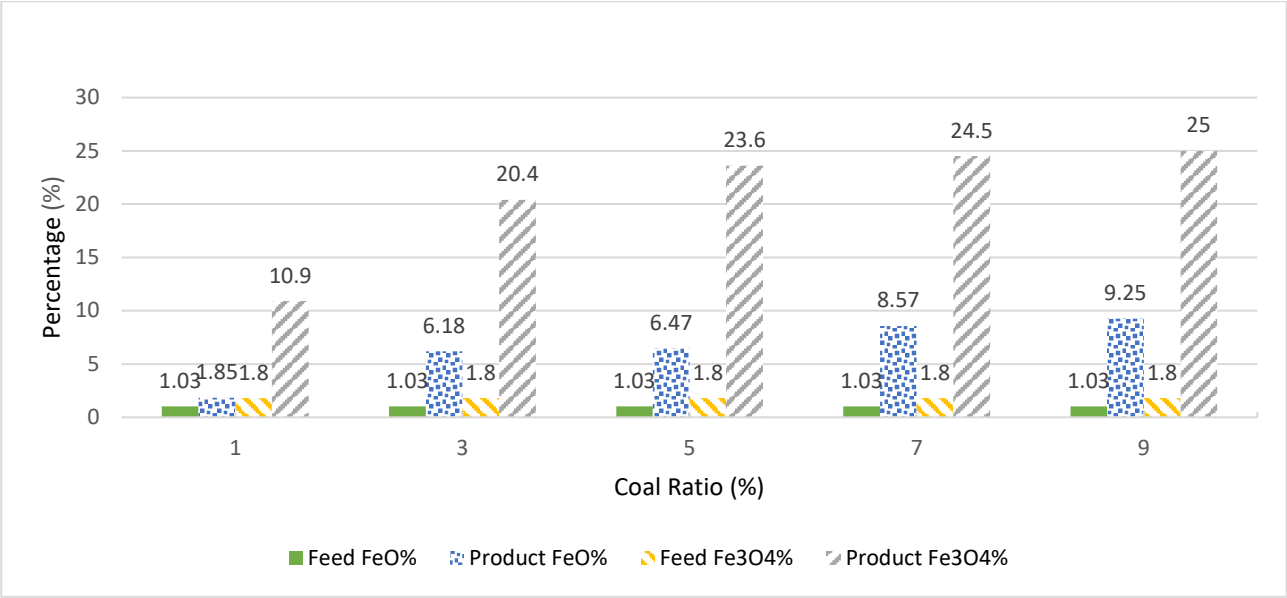

FIG 2 – Effect of coal ratio on roasting product properties.

Effect of roasting temperature on roasting tests results

Effect of roasting temperature on roasting product magnetic properties is as shown in Figure 3. As can be seen when the temperature is low and is 550°C, the roasting reactions do not take place. FeO content only increases ~0.8 per cent which is negligible. Fe_3O_4 content of the product is so low that is not detectable using Satmagan equipment. As the roasting temperature increases, the FeO and Fe_3O_4 contents of the product increase. It shows that at higher temperatures roasting reactions take place more easily and more quickly. Further increasing the temperature results in roasting reactions to proceed reversely. So the temperature of 850°C was chosen as the optimum roasting temperature.

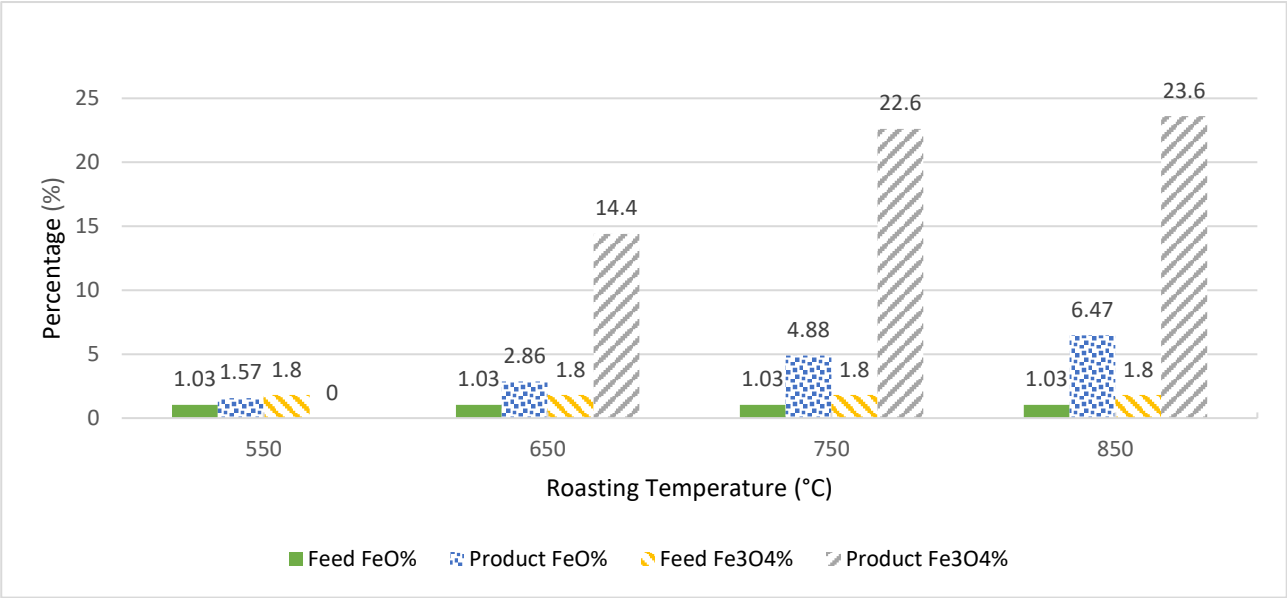

FIG 3 – Effect of roasting temperature on roasting product properties.

Effect of roasting temperature on roasting tests results

Effect of roasting time on roasting product magnetic properties is as shown in Figure 4. From the results we can see that increasing the roasting temperature from 15 min to 30 min has no significant effect on the FeO and Fe_3O_4 contents of the product.

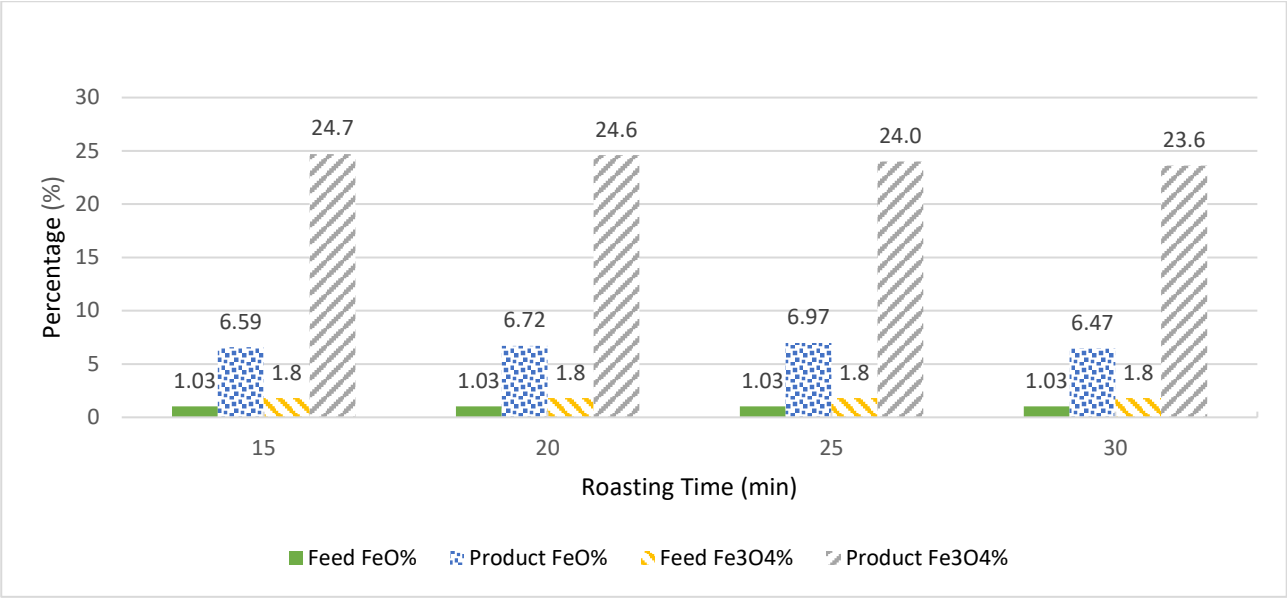

FIG 4 – Effect of roasting time on roasting product properties.

For further studying the effect of time on roasting reactions and the reactions accompanied with it, Fe content of the feed and product of the roasting tests were also measured. Table 3 illustrates the results of analysing the Fe contents of roasting feed and products.

TABLE 3

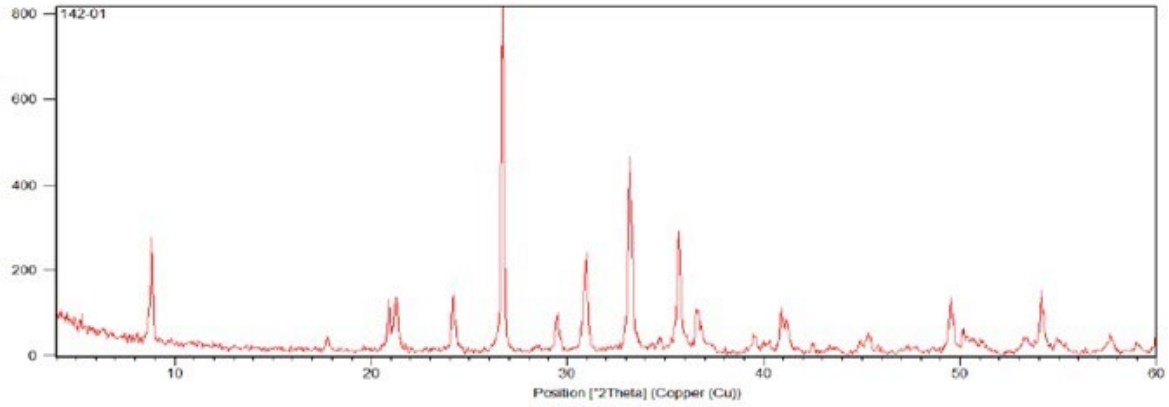
Fe content of roasting feed and product in different roasting times.

Roasting Time	Feed Fe (%)	Product Fe (%)
15	39.83	40.95
20	39.83	40.91
25	39.83	40.93
30	39.83	41.51

From the figures tabulated in Table 3 it can be seen that in all roasting times, iron content of the product increases compared with the iron content in the feed sample. We can also see that as the roasting time increases, iron in the product of the roasting process also increases. One of the reactions that take place when the temperature is elevated is evaporation of volatile materials called LOI (loss on ignition). This increase in Fe content is related to this LOI burn out. It can be seen from Table 3 that when the roasting time is short, this increase is almost negligible. As the roasting time increases, increase in Fe content also goes up. Therefore, it can be concluded that when the roasting time is short, time duration is not enough for complete LOI burnout. So, the roasting time of 30 min in which the maximum LOI burnout has taken place was chosen as the optimised roasting time.

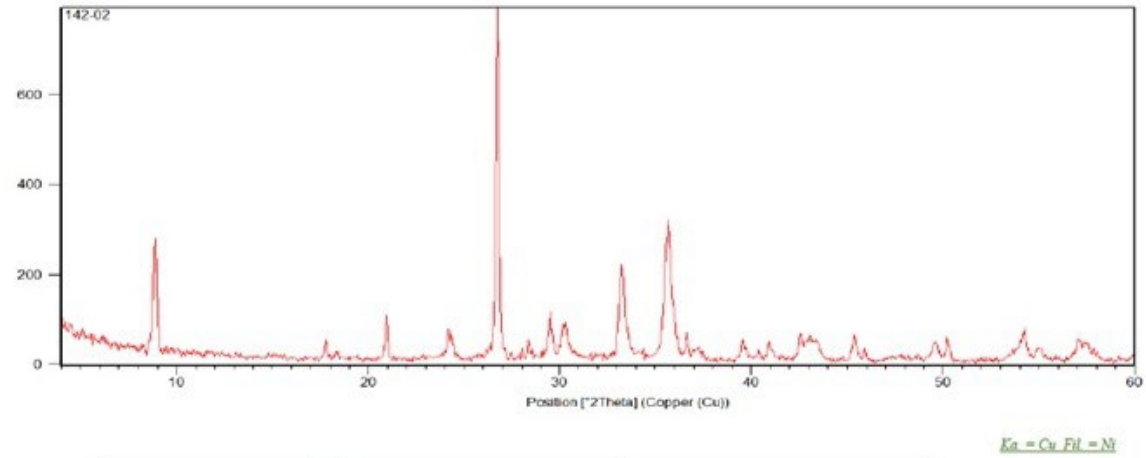
X-ray diffraction test results

Results of XRD test performed on feed sample and the sample roasted in optimised conditions are as shown in Figure 5.



Sample	Phase(s)	Phase(s)
00-142-01	Quartz (33-1161) = 17%	Hematite (33-0664) = 41%
LAB: 142-01	SiO2	Fe2O3
Date :	Calcite (05-0586) = 5%	Goethite (29-0713) = 16%
4.2.2022	CaCO3	FeO(OH)
kV = 40	Dolomite (36-0426) = 12%	*Note: FeO Check*
mA = 30	CaMg(CO3)2	
Ka. = Cu	Mica - illite (26-0911) = 7%	
Fil. = Ni	K(Mg,Fe)3(Al,Fe)Si3O10(OH)2	

a. Feed sample



Sample	Phase(s)	Phase(s)
00-142-02	Quartz (33-1161) = 18%	Magnetite (19-0629) = 24%
LAB: 142-02	SiO2	FeFe2O4
Date :	Calcite (05-0586) = 9%	*Note: FeO Check*
4.2.2022	CaCO3	
kV = 40	Hematite (33-0664) = 37%	
mA = 30	Fe2O3	
Ka. = Cu	Mica - illite (26-0911) = 10%	
Fil. = Ni	K(Mg,Fe)3(Al,Fe)Si3O10(OH)2	

b. Product sample

FIG 5 – XRD analysis of (a) feed sample, (b) product sample roasted in optimised conditions.

Results of the XRD analysis show that Fe present in the feed sample is in the form of hematite (41 per cent) and goethite (16 per cent). It can be seen that there is no Fe in the form of magnetite present in the unroasted sample. Studying the XRD analysis of the roasted sample it can be seen that that the percentage of hematite has decreased slightly but goethite has been eliminated completely. Magnetite has been formed though the roasting process and its percentage in the roasting sample equals to 24 per cent. This shows that all the goethite and some part of the hematite present in the feed sample have been converted to magnetite.

Davis tube test results

Davis tube tests were performed on the product of the roasting test performed in optimum conditions which are particle size distribution of 0–10 mm, coal ratio of 5 per cent, roasting temperature of 850°C and roasting time of 30 min. Results of the Davis tube tests are as shown below.

Davis tube test results at K_{80} ~ 106 μm

- Concentrate: Fe= 60.12%, FeO= 9.28%, M-Wt= 60.33%, $Fe_{rec.}$= 88.04%
- Tailing: Fe= 12.42%, FeO= 3.19%, M-Wt= 39.67%, $Fe_{rec.}$= 11.96%

Davis tube test results at K_{80} ~ 63 μm

- Concentrate: Fe= 61.17%, FeO= 9.88%, M-Wt= 57.43%, $Fe_{rec.}$= 85.86%
- Tailing: Fe= 13.59%, FeO= 2.54%, M-Wt= 42.57%, $Fe_{rec.}$= 14.14%

From the results we can see that in both particle size distributions, Fe content of the magnetic product is more than 60 per cent and it can be predicted that in case the field intensity and particle size distribution be reduced, higher Fe grades in the product can be achieved.

CONCLUSIONS

Performance of magnetising roasting process in a laboratory muffle furnace with coal as the reducing agent was studied for a non-magnetic sample received from a mine in Iran. Effects of roasting conditions on different properties of the roasting product have been detailed. Optimum conditions for reduction roasting in laboratory scale were determined which can be used as the basis for pilot scale tests.

The feed sample contained 39.56 per cent and 1.47 per cent of iron and iron oxide, respectively. The results of studying the effect of different particle size distributions on roasted product properties showed that particle size distribution has no notable effect on the quality of the roasted product. As a result particle size distribution of 0–10 mm was chosen as the optimum size distribution for the roasting tests.

Studying the effect of different coal ratios on roasting product properties showed that increasing the coal ratio up to 5 per cent results in an increases the FeO content in the product sample. This shows that coal addition up to 5 per cent helps to promote the magnetic nature of the product sample. It was also seen that increasing the coal ratio to 7 per cent and 9 per cent doesn't result in any noticeable increase in the FeO and Fe_3O_4 contents. Therefore, coal ratio of 5 per cent was chosen as the optimised coal addition ratio.

The results of investigating the effect of roasting temperatures indicated that increasing the roasting temperature leads to improved magnetic properties of the roasting products. Roasting temperature of 850°C was the highest temperature tested and was chosen as the optimised roasting temperature.

FeO and Fe_3O_4 content of the product roasted at different time durations demonstrated that these two contents are not that much dependable on the roasting time duration. But it was seen that when the roasting time is short, the volatile materials in the sample don't have sufficient time for evaporation. Therefore, when the roasting time duration was short, the Fe content of the roasting product was confirmed to be lower. That being the case, roasting time of 30 min was determined to be the optimum time duration for magnetising roasting of this specific sample.

XRD analysis was performed on the feed sample and the roasting product roasted in optimised conditions. It was observed that Fe present in the feed sample is mainly in the form of hematite and goethite with percentages of 41 per cent and 16 per cent, respectively. No Fe is in the form of magnetite in the unroasted sample. XRD analysis results of the roasted sample revealed that the percentage of Fe in the form of goethite has been eliminated completely. Magnetite has been formed through the roasting process and its percentage in the roasting sample equals to 24 per cent. This shows that all the goethite and some part of the hematite present in the feed sample have been converted to magnetite.

Davis tube magnetic tests were performed on the sample roasted in optimised conditions which are particle size distribution of 0–10 mm, coal ratio of 5 per cent, roasting temperature of 850°C and roasting time of 30 min. It was concluded that in both particle size distribution of the sample used as the feed for Davis tube tests, which were K_{80}s of 106 μm and 63 μm, Fe content of the magnetic product is higher than 60 per cent. It can be foreseen that if the field intensity and particle size distribution be reduced, higher Fe grades in the product can be achieved.

Thereby, it's concluded that magnetising roasting is a feasible and suitable process for this sample and the results achieved in this study can be used as the basis for semi-industrial tests needed for conceptual design of a roasting plant for this specific iron ore mine.

ABSTRACT

Yuanjing processing plant is a scheelite and wolframite plant in southern China. Water shortages and recent environmental regulations mean that the plant must reuse the wastewater that comes from the mining operation. This paper describes the efforts to reuse the mining and ore washing wastewater (MOW) in the processing plant.

Initial attempts to reuse the MOW in the strong magnetic separation were unsuccessful because the magnetic media pack was seriously fouled by the micro-fine precipitate generated. The focus changed to reuse the MOW in the scheelite flotation circuit, which includes one roughing, one cleaning and three scavenging steps. Laboratory batch tests showed this would likely be successful because using MOW reliably improved the flotation performance in the laboratory tests.

Then a 20 day industrial trial was run in the plant. The trial was very successful with the enrichment ratio of WO_3 increasing from 17.4 to 23.6, while the recovery remained around 79.2 per cent. The industrial trial was so successful the company immediately adopted the new scheme, which has remained in use ever since.

This technical solution not only alleviated serious water shortages, and satisfied environmental regulations but also improved the plant performance.

THE YUANJING DEPOSIT

The Yuanjing processing plant is located in a remote mountainous part of Hengyang, in Hunan Province, China and is owned by China Tungsten and Hightech Materials Co., Ltd. (CMT). The mining area in Hengyang has a complex geological structure with complete exposed strata of an important metallogenic belt for non-ferrous metals (Huang, 2011). Tungsten is main non-ferrous metal in the Henyang mining area but there are also significant deposits of tantalum-niobium ores, lead-zinc ores and iron ores.

THE YUANJING PROCESSING PLANT

The Yuanjing processing plant has daily processing capacity of around 3000 T. The rock obtained from the underground mine is mainly sandstone quartz vein type and slabstone quartz vein type. The most important mineral is scheelite, followed by wolframite. The deposit is described in more detail by Zheng (2008).

Figure 1 shows the summarised flow sheet of the Yuanjing plant. First, the run-of-mine ore is pre-treated by ore washing and screening to remove the slimes. The -22 mm size fraction is then classified using spiral classification and the oversize is transported to an ore bin. The fine portion flows into a thickening tank where the ore washing wastewater is produced. The +50 mm screen product from the ore washing is crushed and sent to an ore bin. And the -50 + 22 mm size fraction is processed by photoelectric separation, before also being sent to the ore bin. The ore from the ore bin is ground and classified to obtain a flotation feed with 65 per cent passing 74 μm.

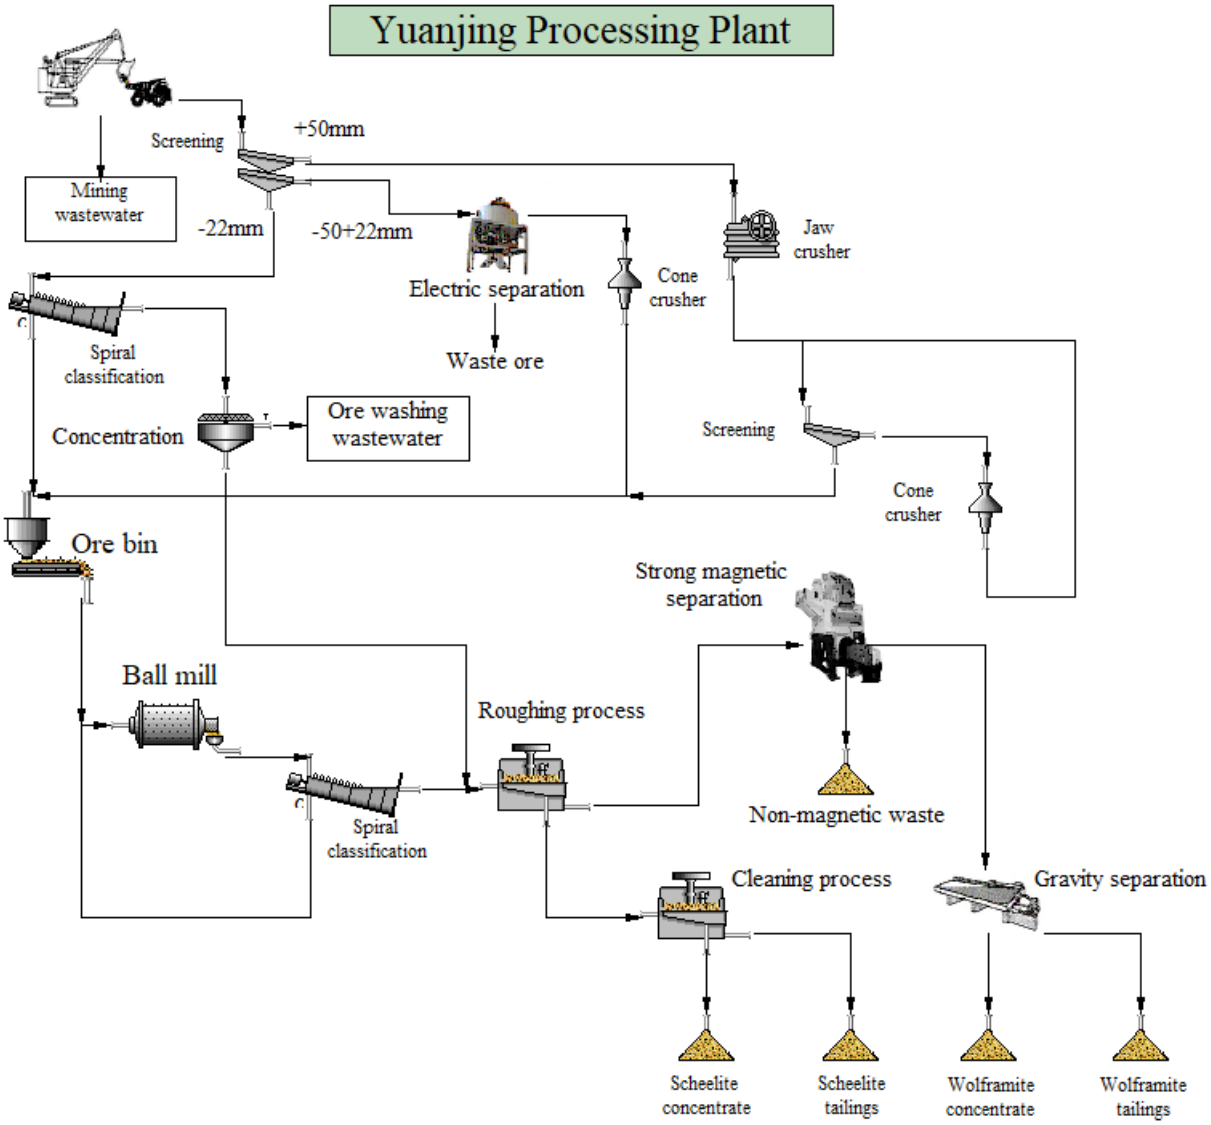

FIG 1 – Summarised flow sheet of the Yuanjing plant.

The scheelite concentrate is produced by using a roughing process followed by a cleaning process. The roughing process uses sodium carbonate to adjust pH, water glass (360 g/t) to depress floating gangue minerals and fatty acids to collect scheelite at ambient temperature. The cleaning process uses Petrov's process – water glass (50 kg/t) as a depressant at high temperature (around 90°C) to produce scheelite concentrate. The tailings of the roughing process are processed by magnetic separation and gravity separation to produce a wolframite concentrate.

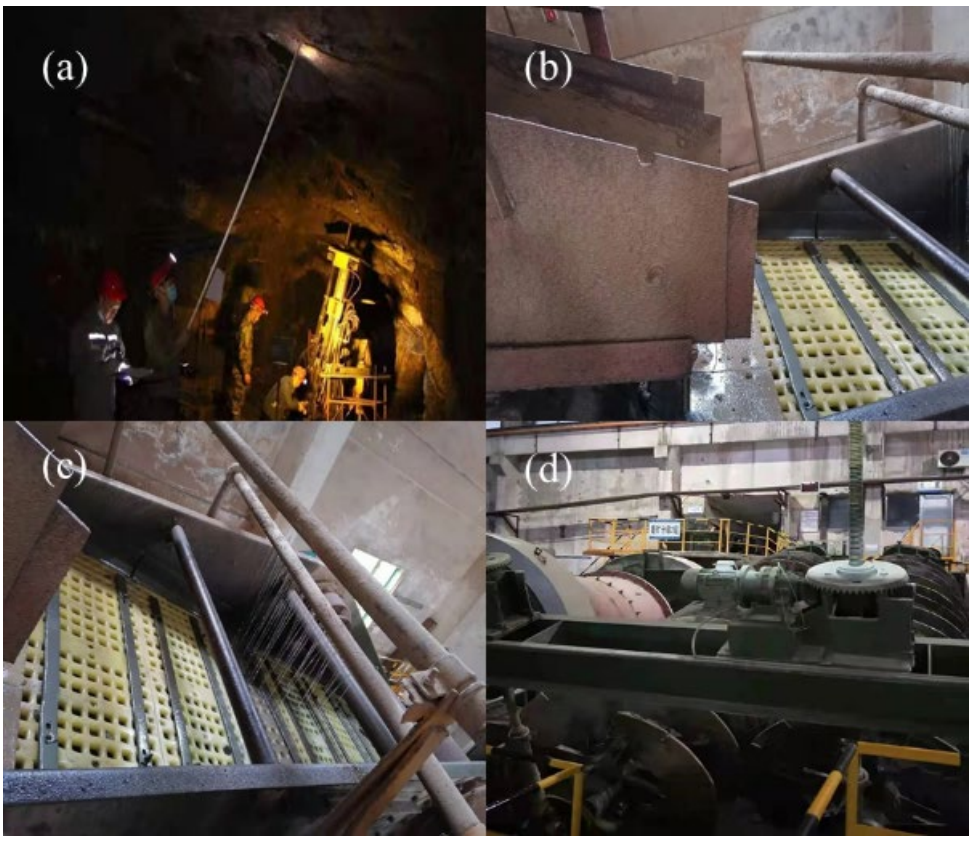

FIG 2 – The underground mine (a) ore-washing screen (b and c) and Grinding and Classification of the Scheelite Ore (d) at the Yuanjing Plant.

THE DRIVERS FOR WASTEWATER REUSE – WATER SUPPLY ISSUES AND REGULATORY CHANGES

The fresh process water used in the Yuanjing plant is mostly sourced from the Longxiqiao reservoir which is located 3 km south-west of the plant. However, the water level of the Longxiqiao reservoir changes seasonally. And when the water levels in the reservoir are low, the water supply to the plant is restricted. Relying so heavily on the water supply from this reservoir has been identified as a key production risk for the Yuanjing plant especially during the dry seasons. Because the Yuanjing plant is located in a remote mountainous region, obtaining freshwater from other sources is expensive. So it has become an urgent priority for the plant to ensure continuity of production by exploring new means of water supply or supplementation.

Considering that the wastewater from the mining operation and the ore washing wastewater produced by the plant were traditionally discharged to the surrounding environment, finding a way to reuse this wastewater in the plant became a key priority. Although of course, the wastewater reuse should not adversely affect mineral processing performance.

In addition to these economic drivers, there are also regulatory drivers impacting the use of the wastewater. The mining and ore washing wastewater (MOW) contains pollutants such as suspended solids (SS) and inorganic matter. Direct discharge of the MOW may pose a threat to the surrounding environment. And in recent years, the Chinese government has established rigorous standards for wastewater discharge to foster ecological conservation and sustainable development (Yang and Li, 2017). As a result, many Chinese mining companies are turning to recent advances in process chemistry to realise a zero discharge of wastewater, improve the water-use efficiency, and reduce net water consumption (Azevedo *et al*, 2018).

Based on these considerations, successful implementation of MOW reuse is not only beneficial to reduce operational costs, but also minimise environmental impact.

THE FIRST ATTEMPT TO REUSE MOW

Engineers at the Yuanjing mineral processing plant first attempted to reuse the MOW in the magnetic separation process. Magnetic separation is used to recover wolframite from the tailings of the scheelite roughing process, as shown in Figure 1. Magnetic separation is a physical separation process which is relatively simple compared to flotation (Meng *et al*, 2017). Because a significant amount of wash-water is required in magnetic separation, reusing the MOW in this process seemed to be a reasonable option. Before the MOW was reused, it was first treated to reduce the high suspended solids (SS: 674.5 mg/L) content. Carbide slag was used to treat the wastewater and followed by an inclined pipe settlement process. Carbide slag is an industrial waste residue which is readily available at a low price (Li and Zhang, 2010). So, using carbide slag to treat MOW is an environmentally-friendly treatment method that uses one waste to treat another. After the addition of carbide slag, the wastewater drains into the inclined tube settler to remove the suspended matter. The overflow from the inclined tube settler had an SS content of 42.5 mg/L in the treated MOW.

Unexpectedly, the yield of the wolframite concentrate gradually decreased over time after the introduction of the treated wastewater into the magnetic separation process. However, the gradual reduction of the yield meant that the cause remained hidden for some time. Ultimately, inspections of the magnetic media pack of the separator revealed that it was seriously blocked by a white precipitate. It was then postulated that this was due to a high Ca^{2+} concentration in the treated wastewater. Later detailed analysis at Central South University showed this precipitate to be $CaCO_3$. And detailed analysis of the treated wastewater revealed that during carbide slag treatment the Ca^{2+} concentration of the wastewater increased to 253.44 mg/L from 97.84 mg/L. This meant that the $CaCO_3$ fouling the media pack was likely caused by the interaction of Ca^{2+} in the reused wastewater and CO_3^{2-} in the roughing tailings pulp. The precipitate adhered and caused fouling in the spaces in the magnetic media pack and proved difficult to clear. The magnetic separator and some blocked magnetic media packs are shown in Figure 3. These results indicated that it was not feasible to use the treated water in the magnetic separation process.

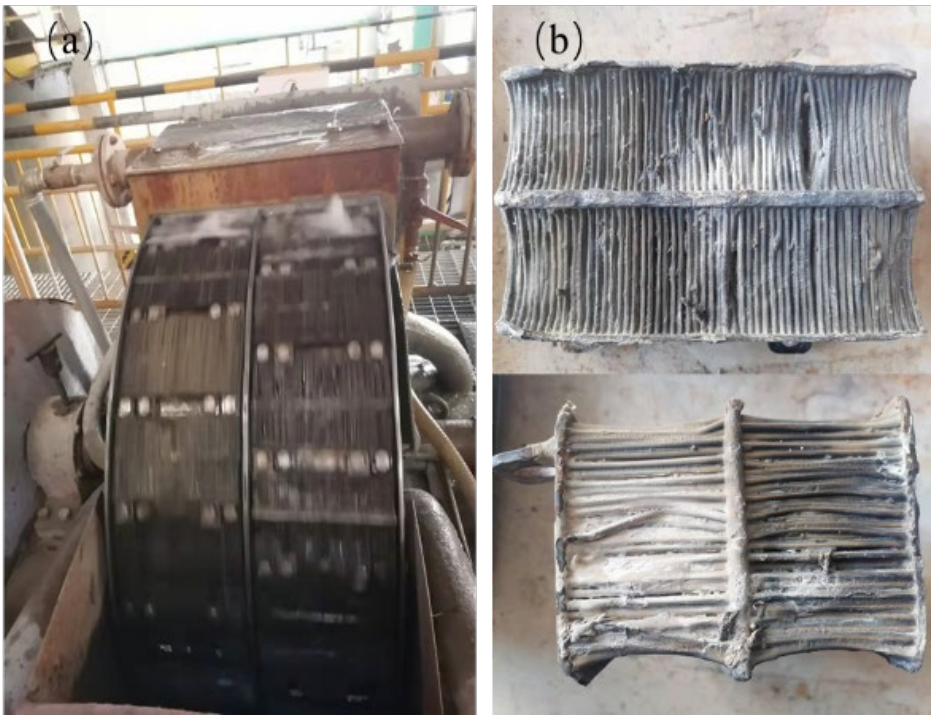

FIG 3 – The magnetic separator (a) and a fouled magnetic media pack (b).

REUSE OF MOW IN THE SCHEELITE ROUGHING PROCESS

Given that the reuse of the MOW in the magnetic separation process had proven infeasible, other approaches to reusing the wastewater were investigated. So the feasibility of reusing the MOW in the scheelite roughing process was explored. The performance of the scheelite flotation circuit is the main determinant of the economic benefits of the Yuanjing plant. So the effects of reusing MOW on

the WO_3 grade and recovery were carefully studied in the laboratory prior to conducting a plant trial. It was noted that the amount of water consumed by the roughing process was greater than the amount of wastewater being captured for reuse. This meant that to be used in the scheelite roughing process the MOW would need to be used as a supplement to the water from the Longxiqiao reservoir. So the effect of the MOW proportion (reused water/total process water) on the scheelite recovery was explored though a rigorous program of laboratory-scale flotation experiments using the existing reagent regime. The laboratory program and its surface chemistry have been discussed in detail elsewhere (Jing *et al,* 2022) but the key flotation results are presented here in Figure 4.

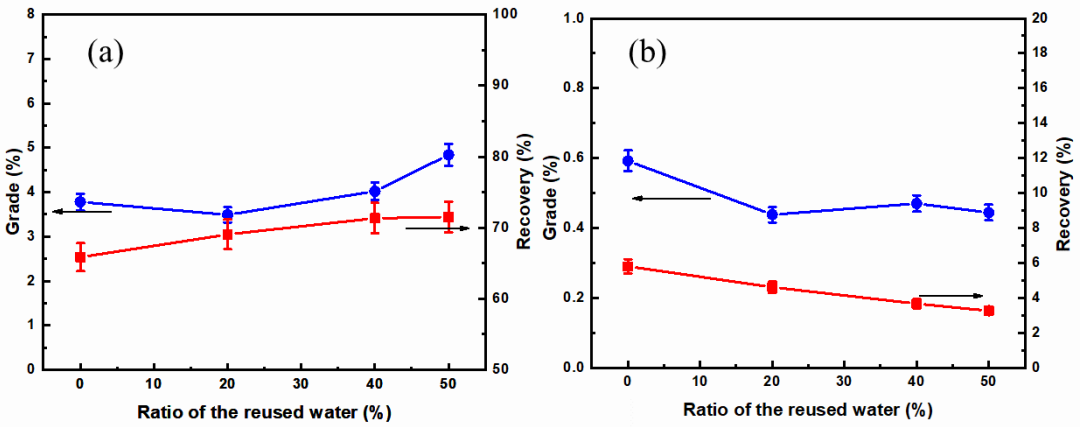

FIG 4 – Results of laboratory experiments using treated MOW in the rougher (a) and scavenger (b) processes (Rougher: Na_2CO_3 1500 g/t, water glass 1.0 kg/t, fatty acid 360 g/t; scavenger: fatty acid 120 g/t) (adapted from Jing *et al* (2022)).

It can be seen that the WO_3 grade and recovery are 3.78 per cent and 65.84 per cent respectively, in basic agreement with the recent production performance of the plant. The WO_3 recovery increased with increasing ratio of reused water/total process water. The WO_3 grade at the ratio of 20 per cent reused water is slightly lower than that using fresh process water but further increases in the percentage of reused water resulted in a significantly higher WO_3 grade. These results indicated that satisfactory results would be likely if the MOW were to be reused in the scheelite roughing process. The laboratory experiments showed no adverse effects on the recovery of scheelite and even better results could be obtained than using fresh process water. In the case of the scavenger flotation, the WO_3 grade and recovery of the obtained concentrate were 0.59 per cent and 5.80 per cent, which meant that most of the scheelite had been recovered by the roughing process. The WO_3 grade and recovery fluctuated slightly with increasing ratio of reused water/total process water.

As previously mentioned, the treated water is characterised by a high Ca^{2+} concentration. Previous studies have reported that the presence of Ca^{2+} will affect the flotation performance of several minerals such as fluorite and spodumene when sodium oleate is used as the collector (Fa *et al*, 2006; Wang *et al*, 2019). Classic activation theory explains that pre-adsorbed Ca^{2+} will increase the number of active sites on the mineral's surface, resulting in an increase of fatty acid adsorption (Gao *et al*, 2021). Another view is that the fatty acid and Ca^{2+} form metal-collector complexes first and are then strongly adsorbed on the mineral's surface. In scheelite flotation, the presence of Ca^{2+} is generally known to have a negative impact on scheelite recovery (Zhang *et al*, 2019). However, in this situation, the reuse of high Ca^{2+} containing wastewater had a significant positive impact on scheelite flotation, indicating that Ca^{2+} may exhibit different effects in different flotation systems. Presumably this is directly due to the high concentration of Ca^{2+}, but due to the complexity of the MOW, further research is needed to reveal the exact surface chemistry mechanism causing this improvement.

INDUSTRIAL TRIAL OF THE MOW REUSE IN THE SCHEELITE ROUGHING PROCESS

The laboratory-scale experiments were repeated several times to validate the results. Then an industrial trial was arranged at the plant. During the industrial trial, the ratio of the reused water fluctuated with the variability in the mining and ore washing processes but remained below

50 per cent. The scheelite roughing process consists of one rougher step, one scavenger step and three cleaner steps. The reused wastewater was used in the roughing process and the trail lasted 20 days. The performance of the roughing process for the 20 days immediately prior to the industrial trial was used as a baseline comparison. And in particular, the WO_3 grade, recovery and enrichment ratio were monitored. The concentrate obtained using fresh feed water before the industrial trial had an average WO_3 enrichment ratio of 17.41 and an average recovery of 79.17 per cent, while during the MOW reuse trial, an improved average WO_3 enrichment ratio of 23.61 at a similar recovery of 79.23 per cent was achieved. These results further confirmed the value of reusing the MOW in the roughing process and the plant immediately adopted this reuse strategy. And it has remained in place since. Reusing the MOW has also prevented subsequent water shortages at the Longxiqiao reservoir from limiting production at the Yuanjing plant. Effectively mitigating a key production risk. And it also has minimised any environmental impacts caused by the discharge of wastewater. More importantly, the authors believe that, based on these results and the subsequent scientific investigation into the surface chemistry (Jing *et al*, 2022), this method may be also feasible for other similar mineral processing plants.

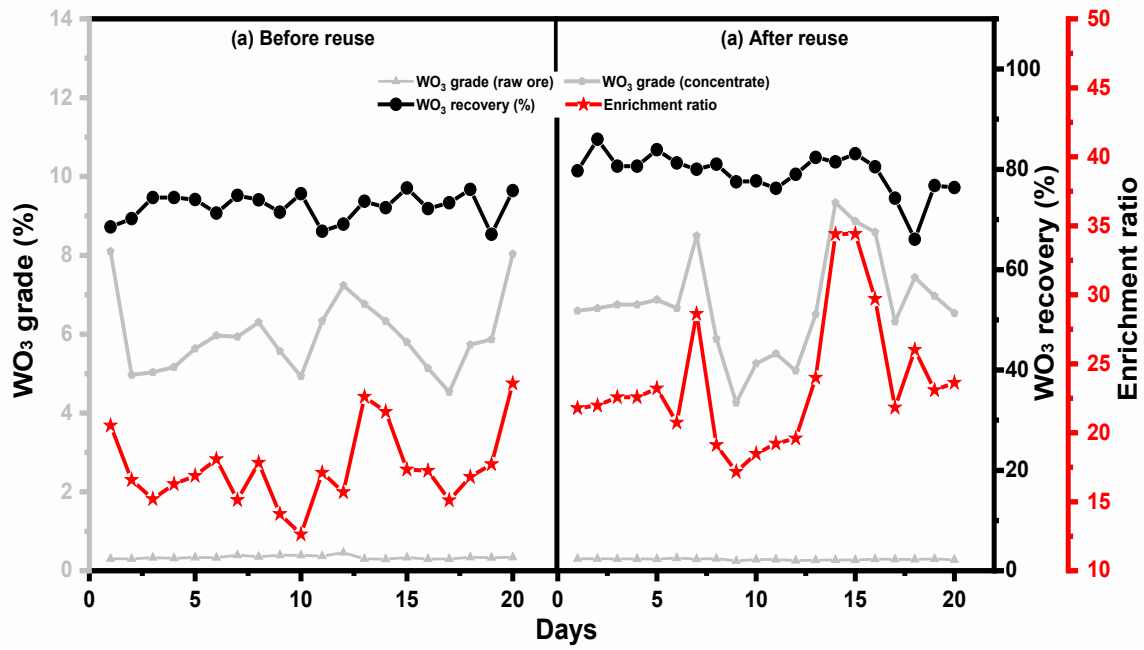

FIG 5 – Key results of the Industrial Trial of the MOW reuse – the WO_3 grade, recovery and enrichment ratio during the pre-trial comparison period (a) and during the industrial trial (b) (from Jing *et al* (2022)).

DISCUSSION AND FUTURE DIRECTIONS

As has been previously documented, wastewater reuse in mineral processing plants can be categorised into external reuse and internal reuse (Farrokhpay and Zanin, 2012; Shengo *et al*, 2016). To date, the authors are unaware of any other reuse of mining and ore washing wastewater in the processing plant. Our research indicates that carbide slag combined with an inclined pipe settlement process is an efficient method to remove suspended solids (SS) in the wastewater. However, the high concentration of Ca^{2+} introduced by carbide slag may influence the mineral separation processes and needs to be carefully investigated on a case-by-case basis. Using wastewater treated in such a way in a strong magnetic separation process will likely block the magnetic media pack, resulting in the decline production performance. This work has demonstrated that using the treated wastewater in a scheelite roughing process is feasible, and may even improve the recovery of scheelite. Not only has this process significantly alleviated the problems caused by water shortages at the Yuanjing plant, but it is also in accordance with the tenants of environmental protection and sustainable development. The authors presume that the improvement in the scheelite flotation is related to the high concentration of Ca^{2+}. However, due to the complex composition of the MOW, the further detailed studies are needed to conclusively reveal the relevant mechanisms.

ACKNOWLEDGEMENTS

The authors would like to thank Central South University Master's student Zichen Tang for using his JKSimMet skills to produce the flow sheet diagram of the Yuanjing processing plant.

ABSTRACT

Process plants are characterised by variability of performance over a wide range of time-scales; reflected in fluctuations in metal recovery, concentrate grade, plant throughput and reagent costs. In turn, these fluctuations impact financial metrics such as operating costs and revenue.

The primary cause of plant variability is variation in the physical, lithological and mineralogical characteristics of the ore fed to the plant. The variability of the ore is driven by the intrinsic heterogeneity of the geology and mineralogy of the orebody, the mining method and mine production plan, the capacity to stockpile and blend, as well as the plant flow sheet and the level of plant automation.

Whilst the impact of ore variability on process plants is universally recognised, it is rarely quantified in financial terms. Consequently, opportunities to reduce its impact are often overlooked due to the lack of a basis for a quantifiable cost-benefit analysis to justify improvement initiatives.

This paper will present case studies using production data from the Renison tin concentrator and a zinc concentrator. These case studies demonstrate that as the standard deviation of plant head grade increases (as a proxy for ore variability), plant metal recovery subsequently reduces. The metal recovery is then converted into plant revenue losses, to quantify the economic impact of ore variability.

The Renison case study demonstrated that whilst a very rare occurrence, revenue losses were as high as 34 per cent (relative to the baseline) when standard deviation was at its highest.

The zinc concentrator case study demonstrated that revenue losses were as high as 6 per cent (relative to the baseline) when standard deviation was at its highest.

Options are available for reducing and managing ore variability in the process plant. These options include changing mining practices so that the ore is fed to the plant with less variability, more advanced process plant control systems and the use of predictive geometallurgical models.

INTRODUCTION

Mineral processing plants are characterised by variability of performance over a wide range of time-scales. This variability is reflected in fluctuations in metal recovery, concentrate grade, plant throughput and reagent consumption. In turn, these fluctuations impact financial metrics such as operating costs and revenue.

The primary cause of performance variability is the variation in the physical, chemical and mineralogical characteristics of the ore fed to the plant. These characteristics that vary include head grade, ore hardness (which drives plant throughput), the mineralogy of the target commodity and gangue mineralogy. Variability is also a function of the mining method mining rate; the operations ability to stockpile and blend ore prior to being fed to the plant and the level of plant automation.

Whilst the impact of ore variability on process plants is universally recognised, it is rarely quantified in financial terms. Consequently, opportunities to reduce its impact are often overlooked due to the lack of a basis for a quantifiable cost-benefit analysis to justify improvement initiatives.

This paper will present case studies using production data from the Renison Bell tin concentrator and a zinc concentrator. These case studies demonstrate that as the standard deviation of plant feed grade increases (as a proxy for ore variability), plant metal recovery subsequently reduces. The metal recovery is then shown as plant revenue losses, to quantify the economic impact of ore variability.

THE CAUSES OF ORE VARIABILITY IN PROCESS PLANTS

The heterogeneity of orebodies

Orebodies are intrinsically heterogeneous in terms of their geology and mineralogy. David (2010) summarised orebodies as:

> *…naturally occurring phenomena with little consistency from location to location. Orebodies situated within a few hundred metres of each other can be as geologically different as orebodies on opposite sides of the earth. Within a single orebody it is possible have primary igneous rock sources, igneous intrusions, faulted zones, oxidised zones, alluvial accumulations and much more.*

Hoban and Brassnett (1978) described how the heterogeneity of the Mt Isa orebodies impacted the grinding and flotation circuits in the lead/zinc concentrator. This was due to the varying mineral textures from the Black Rock and Black Star orebodies that fed the lead/zinc concentrator.

Mining method and mine production rate

Ore variability in the process plant is also caused by the mining method, the mine production plan and the mining production rate.

The mining method will impact the head grades of the mined material. McCarthy (2015) observed that some underground mining methods, such as sublevel and block caving, allow no short-term control of product quality. Provided the ore is above the mining cut-off grade, in the short-term the ore is delivered to the surface as it presents from the drawpoints.

McCarthy (2015) also observed that there are physical limits to the rate that any orebody can be mined. High rates of mining are associated with greater day-to-day or month to month production volatility, with a tendency for dilution of the ore to become excessive at high rates as the pressure of production reduces the ability to mine more carefully and selectively. This volatility is demonstrated in Table 1.

TABLE 1

Monthly volatility of benchmarked mining operations of a 12 month period (McCarthy, 2015).

	Underground mines			Surface mines		
	Min (%)	Max (%)	Ave (%)	Min (%)	Max (%)	Ave (%)
Ore Mined (t)	6	34	14	11	62	25
Head Grade	5	28	11	3	22	9
Ore Processed (t)	3	32	13	4	22	10
Processed Grade	5	23	12	3	16	8

Impact of stockpiling and blending practices

Stockpiling and blending methods can also have a major impact on plant variability.

Where the mine is bottleneck of the operation, or where there is limited stockpiling footprint; the mine may have to supply ore directly to the plant so there is no ability to blend to reduce ore variability. Hoban and Brassnett (1978) described that as there was limited stockpile footprint, the ratio of the Black Star and Black Rock ores that fed the Mt Isa lead/zinc concentrator varied significantly which causes impacts on plant performance.

THE IMPACT OF ORE VARIABILITY ON PROCESS PLANT PERFORMANCE

Historically, the inability to sufficiently blend different ores would impact base metals concentrators which had limited automation and process control. Initially, the flotation circuit would be fed by a period of high-grade ore. The operators would increase air flow and reagent addition to the flotation banks to recover the ore. A period of low-grade ore would soon follow. Operating at plant settings

suited for high-grade ore would mean that the flotation circuit would operate with high mass pull, and in turn recover gangue minerals which would reduce concentrate grade. To compensate for this, the operators would reduce air flow and reagent addition to reduce the recovery of gangue minerals. The low-grade ore would soon be met with another period of high-grade ore. The plant settings, now set for low-grade ore, meant that some of the valuable minerals would not be recovered as there is insufficient air and reagent. The drop in recovery of valuable minerals would cause a reduction in revenue.

In gold cyanide leach plants, it is common for the plant to be fed from a different ore such as oxide, transitional and sulfide ores. If these ore sources are not sufficiently blended, the variable feed to the plant can cause plant problems. Flow sheets for gold plants where sulfide ore is treated typically includes a flotation circuit where the flotation concentrate reports to a regrind mill in closed circuit with hydrocyclones, ahead of a cyanide leach circuit. The plant may experience a period of sulfide ore feed where a flotation concentrate is produced. A period of oxide ore would follow, where only a minor flotation concentrate is produced. This variability in the production of flotation concentrate would cause poor classification in the regrind mill hydrocyclone circuit so that coarser material would report to the leach circuit. The coarse material may be insufficiently liberated and thus reduce gold recovery in the leach circuit.

CASE STUDIES

Introduction

The performance of the Renison tin concentrator and a zinc concentrator were examined to assess the impacts of ore variability on plant revenue.

The authors tested a theory that as standard deviation of plant head grade increases (as a proxy to ore variability) then plant recoveries, and subsequently revenue decreases.

Standard deviation of head grade was chosen as the selected variable for analysis, as plant feed grade is a variable that is commonly measured on an instantaneous level. Whereas other variables, such as mineralogy or lithology, are not instantly or consistently measured.

Case study 1 – Renison tin concentrator

The Renison tin mine is an underground tin mine located near Zeehan in Tasmania. Figure 1 shows that the Renison tin concentrator flow sheet is complex and consists of crushing, grinding, sulfide flotation, gravity separation, desliming, oxide flotation and concentrate leaching circuits.

The plant generates five separate tailings streams. Nominal throughputs are 0.9 to 1 Mt/a, with a typical overall tin recovery of 80 per cent at a tin concentrate grade of 57 per cent.

Each unit operation within the flow sheet serves a specific purpose and the performance in one section of the plant can significantly impact performance in another, both downstream and upstream. Many factors influence plant performance, but the focus of this case study is tin feed grade.

Variability in run-of-mine (ROM) ore treated, specifically the proportion of minerals presented, influences how the plant is operated. In order to operate the plant within the design criteria, efforts are made to minimise the variability through Mine to Mill scheduling and stockpile management. The tin metal units processed is further trimmed via manipulating the mill throughput rate. Process control systems and operator intervention further reduces process variability in order to achieve the key performance indicators of throughput, tin recovery and concentrate grade.

Unchecked variability in feed can lead to poor performance in both tin recovery and/or concentrate grade. The concentrator is equipped with a 24 stream on-stream analyser (OSA) to provide the operations team with regular assay updates on elements present. The stream data, combined with targets and accepted operating windows, provide guidance to the operations team.

The raw plant assay data, which was measured approximately every 9 to 18 minutes, was collated. The plant streams chosen for this analysis were Mill Feed (SFD), Tin Flotation Feed (CFF), Tin Flotation Concentrate (CFC) and Tin Flotation Tail. To minimise the impact of abnormal operation, various data points were removed from the data set. Utilising the two-product formula, a stage

recovery for the tin flotation circuit was generated. A 24-hour standard deviation of the mill feed data was normalised by dividing by the average tin grade for that time period.

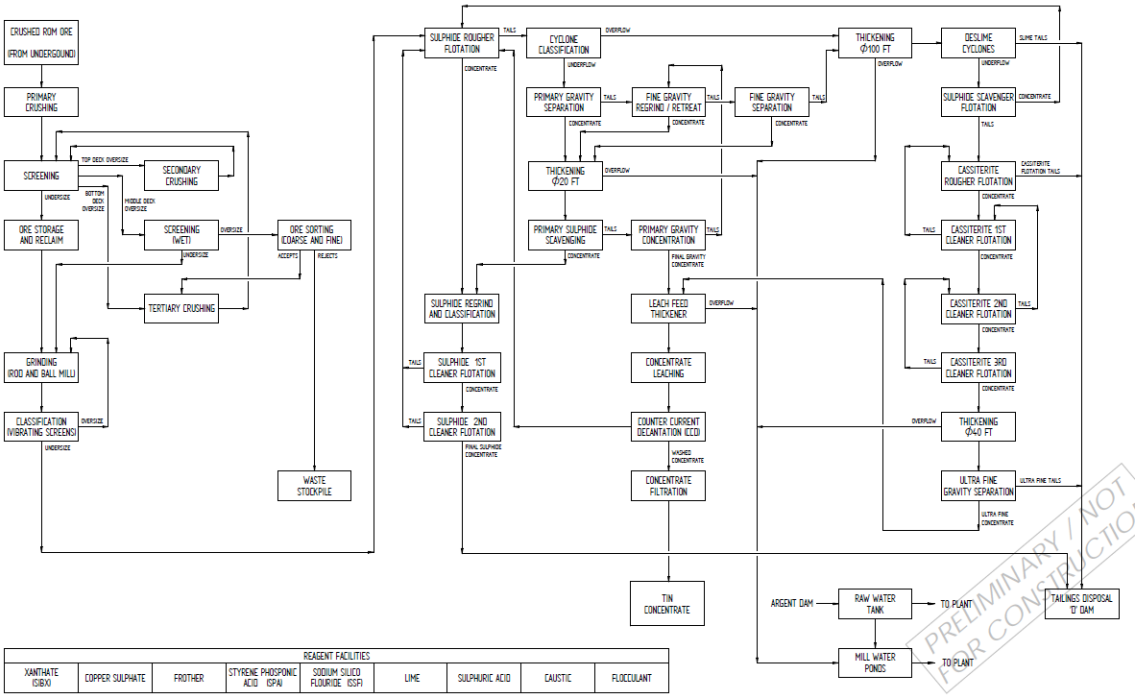

FIG 1 – Renison plant flow sheet.

Figure 2 depicts the tin stage recovery versus the normalised standard deviation in tin plant feed grade (Mill Feed). Of note is the decline in quantity of data points as the feed variability increases. The authors note that this thinning of the data set is due to the operational strategy of the plant, whereby high variability is minimised wherever possible to simplify the operation of the plant and sustain higher recovery.

FIG 2 – Tin flotation circuit tin stage recovery versus normalised StDev of plant tin feed grade.

The analysis highlights two main points. Firstly, the tin flotation circuit, in its current design and under current operating strategies, can withstand moderate variability in mill feed and upstream plant performance. Secondly, as the variability increases, a tipping point is reached and performance starts to fall away. In put a revenue value on the impact of the ore variability, Figure 3 depicts a filtered data set where data points of normalised plant tin feed standard deviation less than 25 per cent are omitted.

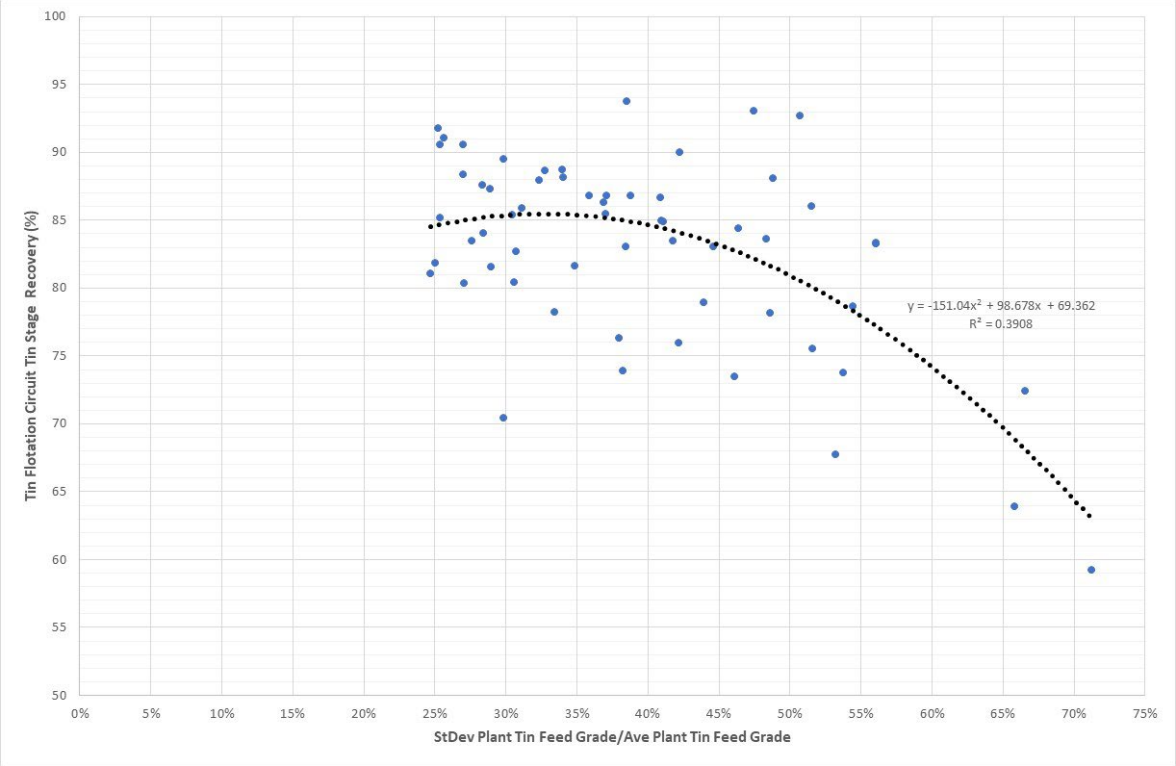

FIG 3 – Trimmed data of tin flotation circuit tin stage recovery versus normalised StDev of plant tin feed grade.

Figure 3 shows that there is a parabolic relationship, where after a normalised StDev of about 40 per cent, stage recovery tends to drop considerably.

A high-level economic analysis was performed utilising the nominal annual throughput, downstream tin recovery factors, typical tin feed grade and typical tin price. Figure 4 depicts the relative reduction in tin revenue versus the normalised standard deviation of plant tin feed grade (with a minimum of 25 per cent).

Figure 4 demonstrates that at the highest normalised standard deviation of 75 per cent, the relative reduction in revenue is 34 per cent.

Figure 4 highlights that if the controls used to mitigate feed grade variability were completely removed and the ore is treated in an un-optimised fashion, significant losses in revenue can occur.

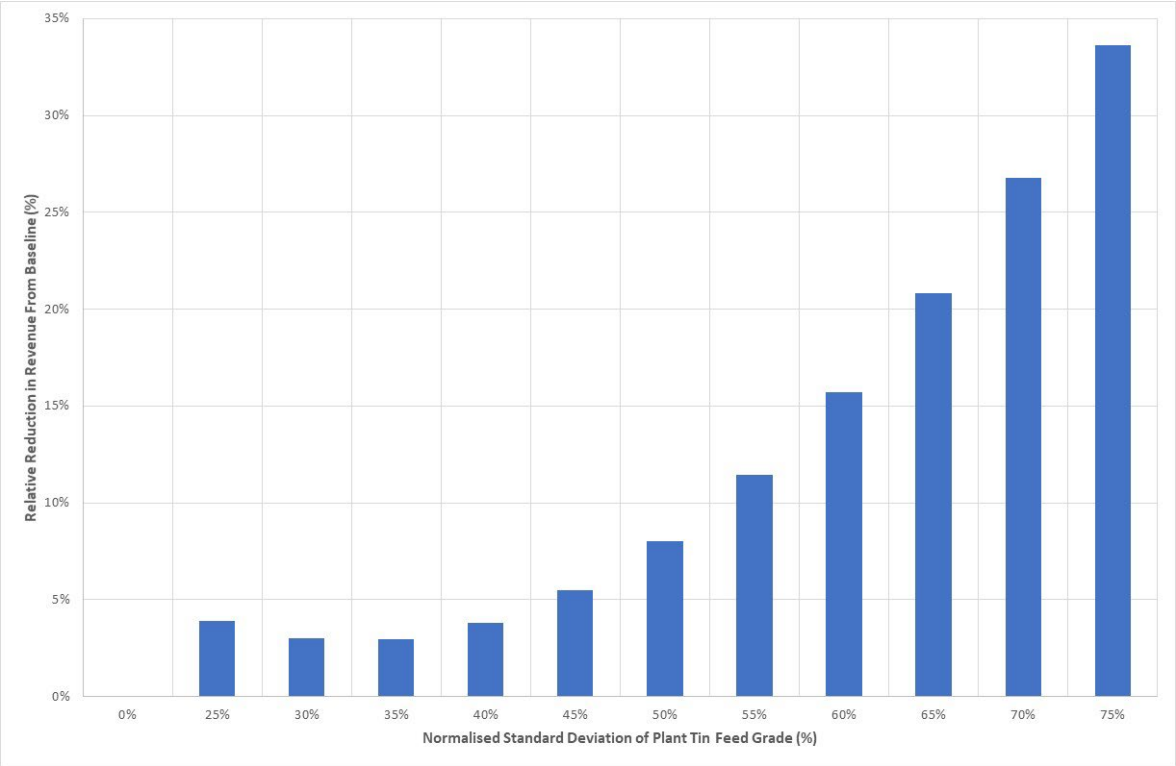

FIG 4 – Relative reduction in tin revenue versus normalised standard deviation of plant tin feed grade.

Case study 2 – Zinc concentrator

The zinc concentrator flow sheet, shown in Figure 5, had:

- a crushing circuit where the ROM stockpile feeds three stages of crushing before reporting to a coarse ore stockpile.
- a grinding circuit consisting of a ball mill operating in closed circuit.
- a zinc rougher/scavenger flotation circuit.
- a regrind mill circuit where the zinc rougher/scavenger concentrate is reground.
- three stages of zinc cleaner flotation to produce a final zinc concentrate.
- concentrate thickening and filtering of the zinc concentrate.
- flotation tailings thickening and disposal.

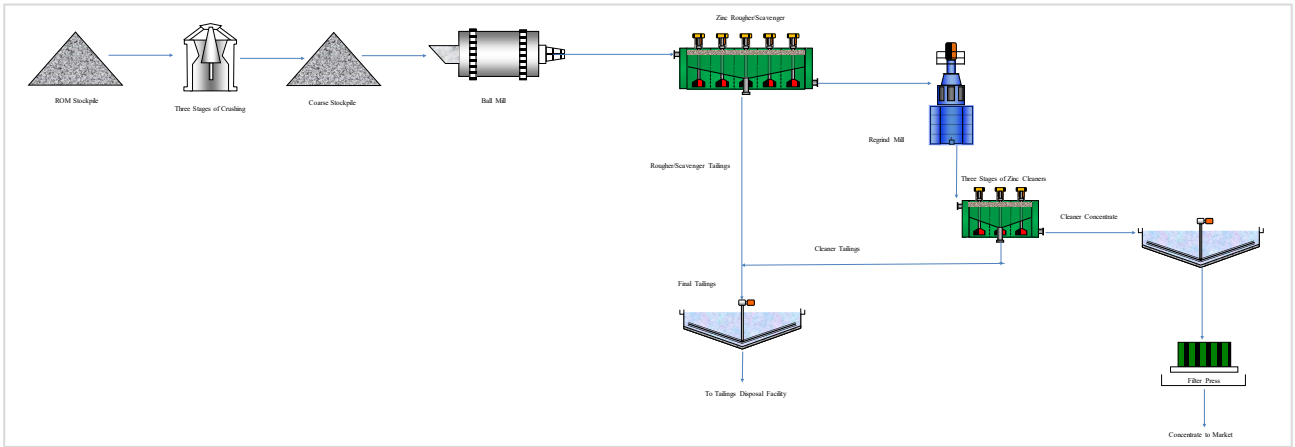

FIG 5 – Zinc concentrator flow sheet.

The zinc concentrator has a design throughput of 2 Mt/a and the target zinc concentrate grade was 50 per cent.

The concentrator has limited process control capabilities and relied on operators to change concentrator settings. There was also only minor stockpiling footprint, so the ability to blend ores was minimal.

A campaign was conducted on the concentrator to ascertain the impact of ore variability on plant recovery and revenue.

Two-hour sample composites were taken including plant feed, zinc concentrate and final tails. Daily zinc recoveries were calculated from the from the weighted average assays using the two-product formula. The standard deviation of plant zinc feed grade over the 24-hour period was then calculated from the 2-hour composite assays.

As was the case with the Renison production data, the standard deviation was divided by the average daily zinc feed grade to normalise the data.

The following data points were removed from the data set:

- To reduce the impact of high head grade on zinc recovery, the data was limited to zinc head grades of less than 5 per cent.
- Data points where the zinc concentrate grades were below 40 per cent, as these are well below the required marketing specifications.
- Data points where zinc recovery was less than 85 per cent were considered outliers and removed from the data set.

Figure 6 shows the daily zinc recovery versus the normalised standard deviation of daily concentrator zinc feed grade.

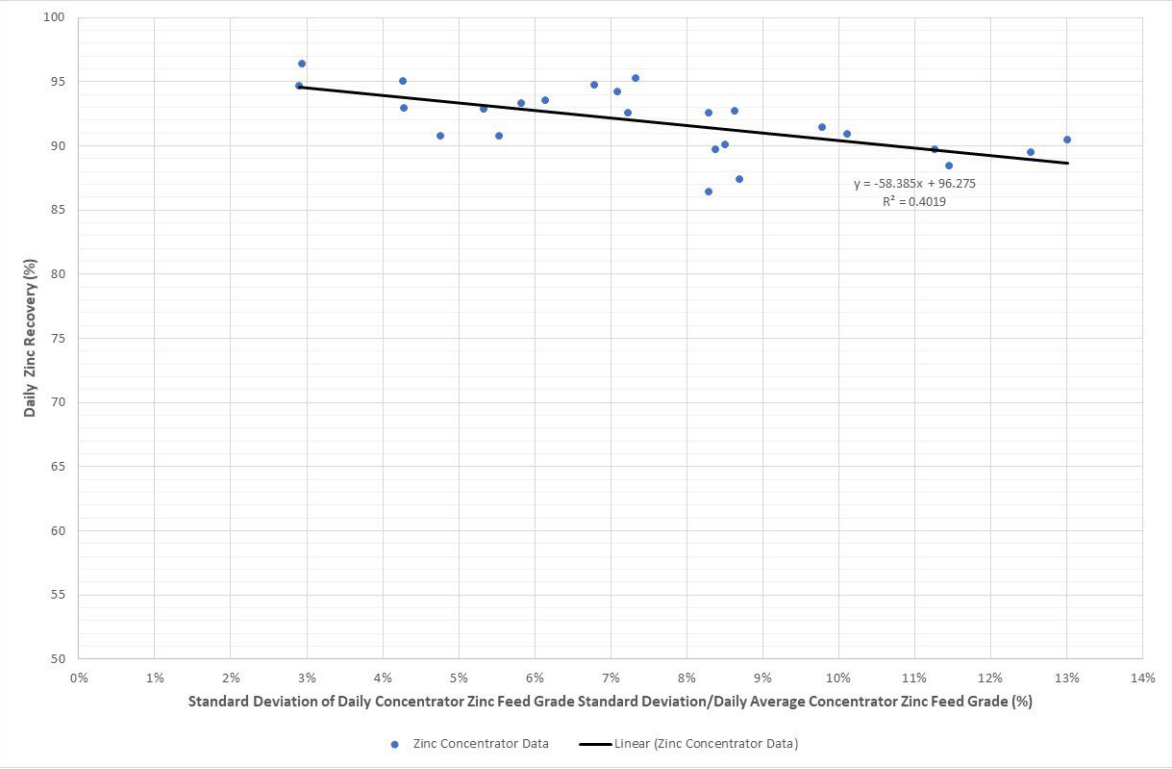

FIG 6 – Daily zinc recovery versus normalised standard deviation of daily concentrator zinc head grade.

The trend line in Figure 6 shows that there is a reasonable linear relationship that demonstrates as normalised StDev increases that zinc recovery tends to reduce. This produced a linear relationship where:

$$\text{Zinc recovery (\%)} = (-58.385 * \text{Normalised StDev}) + 96.275 \quad (1)$$

The correlation coefficient (R^2) of 0.4 is moderate, but the authors considered this to be reasonable given there are other parameters that may impact recovery other than just the standard deviation of head grade. These other parameters include the grain size of zinc sulfide minerals, macro textures of zinc minerals and quartz minerals (and subsequent liberation), amount of iron sulfides in the concentrator feed and the concentrator throughput (as this will impact flotation residence time).

Of intertest is that the range of normalised standard deviation (from 3 per cent to 14 per cent) was much lower than the Renison data range (up to 75 per cent) and this may be due to not having the number of data points that the Renison data set had.

A high-level economic analysis was performed. Equation 1 was used for calculating zinc recovery from the same range of normalised standard deviations as the data set. Zinc recovery was then converted into revenue.

The following inputs were used:

- A zinc price of US$3600/t.
- The zinc concentrator feed grade was kept constant at 4.2 per cent (which was the average zinc grade of the data set).

A normalised StDev of 3 per cent is considered the baseline as it was the lowest normalised StDev from the data set. The impact of normalised standard deviation on revenue is demonstrated in Figure 7.

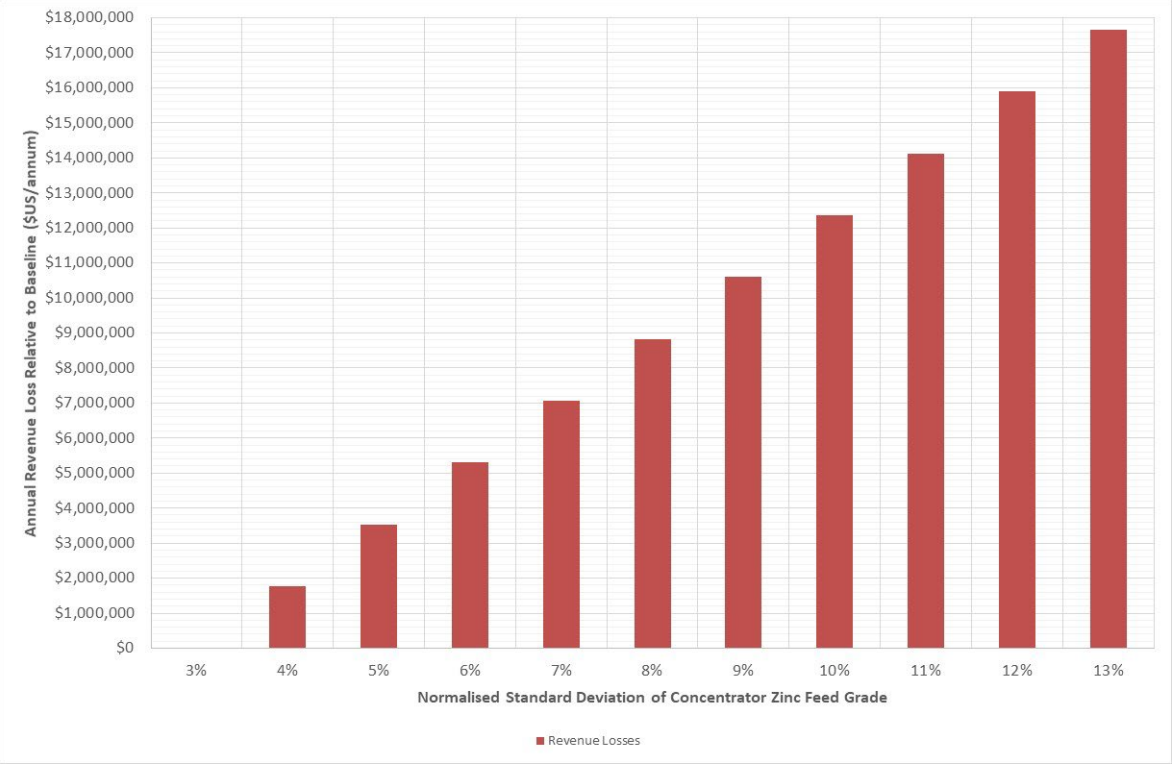

FIG 7 – Annual revenue loss (relative to the baseline) versus normalised StDev of concentrator zinc feed grade.

The revenue losses vary from US$1.8 million/a (at a normalised StDev of 4 per cent) to US$17.7 million/a (at a normalised StDev of 13 per cent). A StDev of 13 per cent is a 6 per cent reduction in revenue relative to the baseline.

OPTIONS FOR REDUCING THE IMPACT OF ORE VARIABILITY

Options are available for reducing and managing ore variability in the process plant. These options include changing mining practices so that the ore is fed to the plant with less variability, more advanced process plant control systems and the use of predictive geometallurgical models.

Mine planning and design

Changes to the mining practice can smooth out the variability of the ore delivered to the process plant. These changes can include mining method, mine production rate and the mine production plan. McCarthy (2015) observed that there is evidence that more selective mining is possible if it is designed into the process from the outset and the planned mining rate is adjusted downward to allow it to take place. A good example is the selective mining of acid-generating and benign waste from a pit, with the benign waste was used for capping.

Stockpiling and blending

Further focus should be put on stockpiling and blending to smooth out ore variances.

McCarthy (2015) recommended that the mine operation should be designed so that all stockpiles, including orepasses in an underground mine, have adequate capacity to smooth the short-term surges to a level acceptable for the system as a whole.

Process plant control

Flotation circuits can use process control systems for managing ore variability.

Rantala *et al* (2014) described an advanced control system at the Kevitsa nickel, copper and platinum group metal (PGM) concentrator in Finland. In the concentrator, an on-stream analyser (OSA) continually measures feed grades into the flotation circuit. As feed grades changes, the control system uses advanced algorithms to automatically change flotation circuit parameters such as froth speed, air flow rates and reagent additions to each flotation cell so that recovery and concentrate grade are optimised.

Plant flow sheet changes

Some process plants use an agitated storage tank after the grinding circuit and ahead of the downstream circuits to smooth out grade fluctuations (Wills, 2016, p 317). In flotation circuits, these tanks often have a pump with a fixed flow rate so that the flow to the flotation circuit is kept constant (and subsequently fluctuations to residence time are reduced).

An example of this was the Lone Tree gold plant in Nevada where agitated surge tanks (with 11 hours of capacity) were installed after the grinding circuit and ahead of the autoclave circuit to reduce variability to the autoclave circuit (Simmons, 1993).

Predictive geometallurgical models

Predictive geometallurgical models have become more common at mining operations. These models take the existing resource block models and populate each block with characteristics of the ore. These characteristics can include elemental data (both target commodity and gangue/deleterious elements), ore hardness data (such as A*b values taken from SMC tests) or mineralogical data.

When the mine is supplying ore directly to the plant, the information from the geometallurgical model allows the plant staff to be more proactive about changing plant settings prior to the ore reaching the plant to assist in plant optimisation. Compan *et al* (2015) expressed that the predictive geometallurgical model used at the Chuquicamata copper concentrator in Chile was able to predict plant copper recovery with acceptable accuracy.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Dr Paul Greenhill for providing plant data to complete the analysis. The authors also thank Bluestone Mines for allowing them to use the Renison data.

INTRODUCTION

Fluorine is a penalty element due to its reactive nature. In acidic environments many fluorine minerals dissolve to form hydrofluoric acid (HF), changing processing conditions. When smelted HF can be released, causing negative effects to nearby people and the environment, as well as potentially damaging the smelter. Sale of ore with high fluorine levels elicit a financial penalty or are banned outright.

Real-time sensors create the opportunity for instantaneous decisions on ore processing due to changing conditions. A fluorine sensor would allow rises in fluorine concentration in a processing stream to be flagged, and decisions on processing conditions or diversion to stockpile before processing could be undertaken. As fluorine is a light element, it is difficult to detect with in-field XRF devices and does not work well with PGNAA. There are currently no existing sensors to quantify the presence of fluorine in real-time, and thus decisions based on fluorine grade cannot be made at minute- or even hour-scales.

Sensors designed to measure the presence of minerals that contain fluorine are a possible avenue to enable the real-time detection of this element. Mineral-based sensing may also give an added advantage of additional information about how the fluorine will react under different processing steps.

The authors were given a grant under CRC ORE II (project number P1–005) to search for mineral-specific signatures suitable for real-time analysis. The work focused on novel regimes and applications of fluorescence as a means to detect specific minerals. The aim was to exploit fluorescence responses unique to minerals of interest in mining systems in order to produce sensors that address gaps in existing capability. After the successful discovery of signatures specific to two major fluorine minerals an additional grant (P1–014) was funded to develop the research into a prototype on-belt sensor, in partnership with Scantech International Pty Ltd.

This paper details the development of a sensor package through multiple Technology Readiness Levels (TRLs) through collaboration with government/industry grant schemes, academics from university, and a sensor-focused Mining Equipment and Technology Services (METS) company. We give a brief description of the new sensor technique and provide a case study of multi-disciplinary collaboration.

PROJECT BACKGROUND

The CRC ORE II project P1–005 was funded to explore novel fluorescence signatures for real-time detection and identifications of minerals of economic significance. Fluorescence is a technique whereby a specific wavelength of light interacts with the sample of interest, which subsequently

produces a different target wavelength for detection. Conventional fluorescence utilises UV excitation; the induced fluorescence emission is observed in either longer-wavelength UV or in the visible waveband. ‘Novel Fluorescence’ mineral sensing is an emerging platform technology based on regimes of fluorescence that lie outside this limited conventional range of single-photon excitation/emission, and consequently have been understudied and generally overlooked. The utilisation of these ‘novel fluorescence’ modalities opens up the technique to more than the ‘classic’ fluorescence minerals, and can provide further advantages for sensing such as safer excitation wavelengths, lower noise backgrounds, and better separation between excitation and emission wavelengths.

An early win for the project was the observation of multiple signatures from two fluorine-bearing minerals. Many fluorine-containing crystals are known for their high propensity for fluorescence – both fluorine and fluorescence are named after the same fluoride mineral, fluorite/fluorspar. For a fluorescent signature to be useful for sensing, however, it needs to be present within all members of the mineral subset (this can be all of the naturally-grown mineral species, or all of the mineral present at a particular mine site, depending on the use-case.) Signal characterisation must therefore be conducted on a relevant subset of mineral samples as the origins of fluorescence may be due to variable mineral properties.

Many fluorescence signatures come from ion impurities within the mineral which may or may not be present in all samples across a mine site. Multiple mineral samples obtained as offcuts from museum specimens were tested to assess the ubiquity of the signatures. Three complex ore types were also tested to check for background signals from other common minerals. The two target minerals had fluorescence signals in a similar wavelength band that appeared to be common for all samples, and these were chosen as target signatures for the next stage of the project (Spooner, 2020). These signatures were excited in the visible part of the electromagnetic spectrum and emit in the infrared, which differs from the UV-to-visible regime that mineral fluorescence is commonly assumed to operate within. This allows safe excitation even at high powers, and minimises the overall background from sunlight and artificial lighting.

Collaboration with Scantech International enabled development of a prototype on-belt sensor for testing these target signatures in a more ‘lifelike’ scenario, funded by CRC ORE II project P1–014. A new targeted fluorescence platform was designed, and components were tested at the University of Adelaide before a full-scale prototype to measure belt widths up to 600 mm was assembled at Scantech International. The test planning followed methods standardised by Scantech and utilised for other similar on-belt analysis equipment. The prototype behaviour was characterised with initial tests conducted using museum-quality samples. Testing is ongoing and currently involves ore samples with known fluorine content in order to assess prototype behaviour under ‘realistic’ conditions and move the TRL of the system to 5.

An advantage of novel fluorescence as a mineral detection system is its adaptability. Once the initial prototype has been developed for a particular use-case (ie on-belt, handheld), only small changes need to be made to the system in order to make use of fluorescence signatures of other minerals. While the initial prototype focuses on signatures from fluorine minerals, continuation of the P1–005 project has found novel fluorescence signals of interest for other potential targets, including lithium minerals and heavy mineral sands.

SENSOR DESIGN CONSIDERATIONS

Fluorescence sensing requires an excitation source and a detector, and both must be considered when translating from a laboratory set-up to a field-deployable system. Detection and characterisation of mineral signatures in P1–005 were conducted using highly sensitive laboratory equipment that provide the high degree of flexibility required for a research environment but do not translate well into the field. A field-deployable device must take into account changes in temperature, dust and vibration, as well as the potential impact of ambient light conditions. Laboratory-style laser systems and sensitive detectors would have a very short operational life in a mining environment.

Light Emitting Diodes (LEDs) were chosen as the excitation source for the sensor prototype as these were readily available, commercial off-the-shelf (COTS) components with a high degree of reliability. Advantages over off-the-shelf lasers systems included an increased safety in a complex working

environment and the ability to excite a broad sample area instead of a small point. This allows greater sampling statistics and is more suitable for an on-belt application.

Detection devices on the initial prototype included a spectrometer for wavelength-dependent detection and a photodetector with specialised filters for intensity-dependent detection. This two-detector method was used to test each method and validate positive measurements. It was assumed that the process of using two detectors would remain for the set-up phase and for calibration for on-site conditions in the field, but that during steady-state operation only one detector system would be needed.

Design and construction of the prototype focused on scalability and modularity of components, in part to ensure laboratory tests could be conducted before construction of a full-scale prototype and also to allow for reconstruction to test different scenarios and scales of the on-belt sensor. Parts were limited to COTS equipment to ensure speed of construction and affordability of potential future beta-prototype and commercial products.

Lab-based sensor prototype

An initial small laboratory-based prototype was constructed to test both the detectors and the change of excitation source from high-powered pulsed laser source to continuous-wave LED. While in general Stoke's fluorescence has an easily extrapolated, linear excitation-to-emission dependence, nonlinear effects can occur, especially at high powers. Changes in heat deposition, and potential saturation of quenching effects at high powers had to be considered and tested before LEDs were confirmed as a suitable excitation source. Small, easily obtainable LEDs were used initially to test the target mineral's response to LEDs before higher powered LEDs suitable for the full-scale prototype were sourced.

The more rugged, COTS detectors were less sensitive than those in the P1–005 laboratory system, and the processing requirements needed to optimise their sensitivity to the target signatures were found and tested during this phase.

Scaling up from the lab to full-size

Once LEDs were confirmed to be suitable excitation sources, higher-powered LEDs used for industrial lighting were ordered and tested. Full optical systems were designed before construction of the prototype; these could not be tested beforehand as their optimum conditions were dependent on the sensor dimensions which was too large to test in a laboratory environment.

The full sampling area of the prototype was 600 mm × 1200 mm, with a maximum clearance of 1125 mm (see Figure 1). Clearance is likely to be smaller on a final product, with a corresponding distance-squared increase in signal detection (ie half the clearance distance results in a four-fold increase in signal intensity).

FIG 1 – The full-scale fluorine-mineral sensor prototype, showing the scale of the system, the LED arrays, and the detection optics (centre).

Validation tests at scale were conducted using a museum-grade sample of approximately 10 mm diameter. Emission detection over the full 'belt' width was confirmed. Optimal placement of excitation LEDs and detection optics depends on the final size and clearance of the final sensor product, so optimisation of these conditions was not finalised at this stage.

To aid in data collection and processing, specialist software was commissioned to synchronously run the detectors and excitation LEDs, as well as collect data from the detectors and from passive temperature and excitation level monitors. Through a Graphical User Interface (GUI) the operator of the sensor prototype was able to modify many parameters of the operation. The software also conducted real-time data analysis and output. The GUI was originally designed in the testing phase to output the data analysis in the form of a graph of detected intensity; in a field-deployable device that was correctly calibrated this output could instead be a live reading of fluorine grade or provide a 'traffic light' warning at threshold grades.

FLUORINE SENSOR TECHNOLOGY READINESS PROGRESS

Technology Readiness Levels (TRLs) provide an internationally agreed-upon standard to describe system development (see Table 1). Commercial Readiness Levels occur at the TRL stages 7–9 and beyond; before then sensor development must occur without a commercial product to produce cash flow or induce investment.

TABLE 1

Technology Readiness Levels and their definitions as per Australian Government guidelines.

TRL level	Definition
1	Basic Principles observed and reported
2	Technology concept and/or application formulated
3	Analytical and experimental critical function and/or characteristic proof of concept
4	Component/subsystem validation in laboratory environment
5	System/subsystem/component validation in relevant environment
6	System/subsystem model or prototyping demonstration in a relevant end-to-end environment
7	System prototyping demonstration in an operational environment
8	Actual system completed and qualified through test and demonstration in an operational environment
9	Actual system proven through successful operations

The CRC ORE II grant P1–005 started when the fluorine sensor was at TRL 2: fluorescence is a well-known and well-studied concept in other materials, and broad but limited fluorescence studies had been undertaken in the past on natural as well as synthetic minerals. Identifying and characterising the target signatures from fluorine minerals brought the TRL level to 3. CRC ORE II grant P1–014 progressed the TRL level through level 4.

Current work is aimed towards completion of TRL 5. To validate the system in a relevant environment, the system must be able to distinguish between ore with fluorine grades that differ by 100 ppm F, as discussions with end users suggest that this is the relevant benchmark for fluorine in Australian mining companies. The full-scale prototype was validated and characterised with museum-grade samples but has not yet been validated with natural crushed ore with fluorine minerals dispersed throughout the material, rather than concentrated in a discrete sample.

ISSUES ENCOUNTERED DURING THE TECHNOLOGY DEVELOPMENT

The lab-scale prototype was demonstrated to be effective on museum-grade samples and was able to detect to low fluorine levels in crushed museum samples blended to create a concentration series. A concern at this point in the project was that museum samples are selected for their ‘interest’, rather than their ‘typical-ness’, and this may bias observations of typical fluorescence efficiency, and therefore excitation power and detection time requirements. Construction of the full-scale prototype was delayed while typical industry samples were investigated in the lab-scale prototype. We recommend future sensor development by universities engage fully with industry partners as soon as possible, and quickly build full-scale prototypes of sensors for testing, for the following reasons:

- Target grades, especially for penalty elements, are generally quite low in ore samples. A full-scale prototype is therefore necessary to acquire relevant sampling statistics. Acquisition of enough data to allow for statistically relevant analysis of low-grade ore quickly becomes infeasible with laboratory-scale tests.
- It is difficult to acquire samples from mining partners in order to validate system response in target conditions. Industry partners are more likely to have contacts and mechanisms in place to acquire mine samples, in quantities relevant for sensor testing.

FURTHER IMPROVEMENTS AND LEARNINGS

Further improvements to the prototype are considered desirable in order to achieve TRL 5 for the target fluorine grade of 100 ppm. Natural background must be accounted for in intensity measurements – characterisation of typical background variability suggests background levels should be recalibrated every 1–5 seconds, and can in the current prototype only be sensed when

the excitation LEDs are off. LEDs capable of high pulse rates, or a continuous background monitoring system, would be a necessary addition to a new model of prototype.

Emission intensity is proportional to excitation power as well as target presence. The LEDs in the current prototype are typical in that their intensity is proportional to temperature – both ambient and self-generated. Temperature control or accurate excitation illumination monitoring are desirable to lower uncertainties in sensor output.

Signal-to-noise can be improved with greater excitation intensity at the sample; this can be achieved by lowering the clearance height, or by focusing the LED light to a narrow line across the belt width – as the sample will be moving along the belt, excitation coverage across the width of the belt matters for sampling statistics, but not length over the belt. This would also allow detection optics to be redesigned to focus on a narrower band of the belt, lowering background interference from other light sources.

Alternative applications of the technology

Alternative forms of fluorine-mineral sensors were discussed during the prototype design and development. Fluorescence has an advantage in that the technology is readily scalable and can be applied in many forms from hand-held to cross-belt. Hand-held mineral sensors utilising fluorescence are an alternative product development pathway being investigated.

Collaboration learnings

There is a well-known technology 'Valley of Death' in TRLs 3–5, where both universities and industry generally lack the funding and experience to take a proven idea to a prototype capable of demonstrating the idea to investors. CRC ORE's policy was not only to provide funding for projects at this level, but to facilitate collaboration between university and industry. Having a grant body with extensive experience at communicating to both academics and industry is rare, however, and learnings from our experience could prove valuable for future collaborations.

From the grant funding body

As a Co-operative Research Centre, CRC ORE's role was not only to fund research and development for improving the Australian mining industry, it also had a mandate to link Industry, METS and Research organisations to perform research in a co-operative framework. This builds deep connections between industry and researchers that can improve the success rate of low to mid TRL projects progressing through the 'Valley of Death'. This project has been an exemplar in the way that Co-operative Research can be performed in Australia and is a testament to the Co-operative Research Centre principles that is supported by the Australian Government.

A key learning from projects funded in this way is that the Co-operative Research Centre approach not only provided the funds but also the legal and communication framework to allow multiple parties to work together as each partner in the project had signed on to the common legal, commercial and Intellectual Property terms and conditions of CRC ORE. This greatly simplified the project proposal process as all parties were aligned to the same guiding principles. Execution of the project was also simplified as the interests of the Researchers, METS company and Industry representatives were aligned and communicated throughout the project delivery stage.

From the university

University research funding in Australia is funded in the main by grants, and thus the focus of research is to meet the deliverables of these grants. While CRC ORE was very good at communicating the requirements of these deliverables, especially of audience, length, and detail required for reports, it is good practice for a university to 'check in' with the detail of deliverable requirements between reports, in order to ensure research is moving along the right track.

The University and Scantech International had a previous relationship, which allowed good lines of communication between the two partners. This was vital for planning mitigation strategies to allow experimental work to continue through changing COVID-19 restrictions. While a global pandemic is a rare event, setbacks in a project are not, and developing a strong and honest relationship between collaborators as soon as possible is an important part of technology development in this space.

Research publications in peer-reviewed journals are major objectives for Universities and many grant funding bodies. This may be difficult when partnering to create new prototype systems. This project benefited from the support of the CRC ORE and Scantech International who were both keen to share the learnings, but publication may be a risk for other development partnerships.

From industry

A key benefit for industry partners is to gain access to cutting edge technological developments while being able to have initial R&D (prior to TRL4) completed at low cost. By partnering early, there is the possibility of influencing the approach and learning from any shortcomings in the early prototyping stages. With a demonstrated underlying technological base, commercialisation follows a straightforward path, involving additional prototyping, refinement for quality of results, quantification of limits on result accuracy, and ruggedisation of the equipment. It is also possible to obtain valuable market feedback on what the technical requirements are, such as performance accuracy and market interest, while the project is taking place. For a dynamic technology-focused company like Scantech, it is possible to move quickly and establish a market foothold, particularly through publication, which aligns well to university objectives.

CONCLUSION

This paper has discussed the development of a novel mineral-specific sensor technology in the innovation 'Valley of Death' at TRL3–5.

Design, construction and testing of a full-scale prototype encountered several issues, from unexpected power instability to the inability to obtain appropriate samples.

The fluorine-mineral sensor prototype is currently at TRL4–5, with planned improvements to enable very low detection limits and improved sampling of the belt surface. This sensor technology is the first real-time fluorine-mineral sensor, and the application of this sensor is not restricted to cross-belt scales. Further development of the cross-belt prototype will be undertaken parallel to alternative sensor scales.

ACKNOWLEDGEMENTS

The authors wish to acknowledge CRC ORE II, which funded this research and Scantech International who provided testing facilities and assistance. Resonate Systems designed and produced the software to run the full-scale prototype. The TATE Museum, School of Physical Sciences, The University of Adelaide; and the South Australian Museum provided samples for initial and further testing.

ABSTRACT

Aitik is a large copper porphyry type deposit located in northern Sweden, currently exploited at an annual rate of approximately 45 Mt. The ore's exceptionally low head grade of 0.25 per cent Cu and varying degrees of hardness across the entire deposit pose challenges to the two fully autogenous grinding lines, each of which comprises a primary autogenous mill in series with a pebble mill.

The variability in ore grindability frequently leads to fluctuations in mill throughput. Within the framework of a geometallurgical approach, the present study investigated the relationships between ore grindability and modal mineralogy. For this purpose, drill core samples from different lithologies were subjected to Boliden AB's in-house grindability tests. This fully autogenous laboratory-scale test generates a grindability index mainly related to abrasion breakage, which is a significant breakage mechanism within autogenous mills. The test results suggested divergent degrees of grindability within and across the selected rock types.

A combination of scanning electron microscopy, X-ray powder diffraction, and X-ray fluorescence analyses was performed for the grinding products and bulk mineral samples. The resulting mineralogical and elemental properties were subsequently correlated to the parameters from the grindability tests. It was shown that the main mineral phases, such as plagioclase, quartz, and micas, correlate well with the grindability indices. Similar correlations were found regarding the sample's chemical composition, attributable to the main mineral phases.

A further inverse correlation was established between the sample's calculated average Mohs hardness and the grindability indices. Moreover, mineral liberation information provided by scanning electron microscopy was associated with the parameters mentioned earlier. The identified relationships between grindability, modal mineralogy, and element grades may help Boliden develop a predictive throughput model for Aitik based on the mine's block model.

INTRODUCTION

As global resource demand rises, increasingly complex mineral deposits have to be exploited, implicating challenges such as declining head grades, orebody variability and ores that are more difficult to process (Dominy *et al*, 2018). A continuous decline in ore grades over time is indeed being observed in the copper mining sector (Guiomar *et al*, 2016). Karlsson (2020) reports a similar development for the Aitik copper open pit mine. These challenges lead to additional production risks and uncertainties for mining operations. Geometallurgy provides the ability to forecast mine production and economic variables (Rincon, Gaydardzhiev and Stamenov, 2019). This discipline can be understood as a cross-disciplinary approach integrating information from mineral processing, metallurgy, geology, and mining engineering, aiming to improve production forecasting, reduce production risks, and maximise a mining project's economic value (Dominy *et al*, 2018; Lishchuk *et al*, 2020).

Orebody variability can reduce plant throughput through fluctuations regarding ore hardness (Dominy *et al*, 2018). In the last decade, the Aitik mine underwent two major expansions to increase

its plant throughput to 45 Mt per annum from 2019 onwards, currently operating two fully autogenous grinding circuits. Variations in ore grindability have since long led to fluctuations in plant throughput and daily plant production (Westerlund, 2017). These circumstances impede meeting production targets and the scheduling of mining activities accordingly. The necessity arose to predict the grindability of Aitik's ore and consequently the mill throughput.

A well-known parameter influencing the performance of a comminution circuit, mainly throughput, is grindability (Shi *et al*, 2009), which is defined as an ore's resistance to breakage (Verret, Chiasson, and McKen, 2011). In the context of the present investigation, grindability is understood as the mass of fines generated due to abrasive grinding (Parian and Palsson, 2020). Since grindability is a variable parameter, it adds uncertainties and hinders the sound evaluation of a mining project's feasibility (Tungpalan *et al*, 2015). Laboratory-scale grindability tests are a standard tool to assess ore grindability and, depending on their suitability, may be used to map the variability of grindability throughout a mineral deposit (Mwanga, Rosenkranz and Pertti, 2017; Verret, Chiasson and McKen, 2011). Geometallurgical programs incorporate this type of mapping to predict metallurgical performance (Parian *et al*, 2015).

Traditionally, the design of AG mills is based on parameters derived from pilot-scale comminution tests performed on relatively large ore bulk samples (Verret, Chiasson and McKen, 2011). However, the collection and preparation of such bulk samples are expensive and time-consuming, and uncertainty remains regarding their ability to accurately represent the orebody (Morrell, 2004). Therefore, small-scale grindability tests have been developed over the past decades, some of which are suitable for geometallurgical mapping, characterised by their comparatively low cost, smaller required sample sizes, and ease of execution (Mwanga, 2016).

The principal objective of the presented study was to establish a link between grindability indices and rock type mineralogy. The methodology of the present study comprised a laboratory test method to assess the decomposition of large mineral particles by autogenous comminution developed by Boliden Mineral (grindability test, wear test). Different analysis techniques for chemical and mineralogical characterisation were implemented. Automated mineralogy provided additional information regarding mineral liberation. The geometallurgical approach of the project encompassed relating grindability indices to sample mineralogy, seeking to predict grinding performance through mineral grades as a proxy. The present paper reports on the results from the grindability tests and chemical and mineral characterisation.

Project site

The Aitik mine is one of two of Boliden Group's open pit mines (Boliden, 2020). The Cu-Au-Ag deposit is situated in Sweden's northernmost county, Norrbotten, approximately 10 km south-east of the town of Gällivare and 60 km north of the arctic circle (Karlsson, 2020). It is considered one of Europe's largest producers of Cu, Au, and Ag (Wanhainen *et al*, 2012). Since commencing production at Aitik with 2 Mt processed in 1968, the amount of processed ore has constantly risen and peaked at 41.6 Mt in 2020, while the average head grades of milled ore have constantly decreased (Karlsson, 2020). As compared to other copper producing open pit and underground mines whose ore grades average at around 1 per cent Cu (Guiomar *et al*, 2016), Aitik's average Cu-grade of 0.22 per cent is notably lower (Karlsson, 2020). Through a combination of strategic planning, automatisation, electrification, and digitalisation, Aitik has become one of the world's most productive open pit copper mines (Mackenzie, 2017; Beyglou, Schunnesson and Johansson, 2015; Boliden, 2020).

The deposit sits along a fault zone, with the hanging wall and footwall respectively constituting banded feldspar-biotite gneiss and feldspar-biotite-amphibole schist. The main ore zone is dominated by quartz-muscovite schist as well as biotite gneiss and biotite schist (Wanhainen *et al*, 2014). Furthermore, pegmatite dykes can be found within the deposit's ore zone and hanging wall. These dykes are generally mineralised within the ore zone and barren in the hanging wall (Wanhainen *et al*, 2014). Wanhainen *et al* (2012) suggests classifying Aitik as a hybrid deposit between both porphyry type and IOCG type deposit.

After blasting and crushing, the ore is conveyed to two parallel grinding lines, each of which comprises an Ø 11.6 m × 13.7 m primary autogenous mill in series with a Ø 8.1 m × 11.3 m

secondary pebble mill (Markström, 2012; McElroy *et al*, 2019). Each primary AG mill operates in a closed circuit with a cone crusher to crush salient pebbles aiming at increasing the AG mill's throughput (Hilden, Yahyaei and Powell, 2019). This set-up of the grinding lines indicates that the pebble fraction within the mill feed is a limiting factor for plant throughput.

Grindability

In general terms, grindability is defined as an ore's resistance to breakage. A well-known index to express an ore's grindability is the Bond Ball Mill Work Index (BWi) expressed in kWh/t, which indicates the specific energy requirement (kWh) to grind 1 t of ore to the desired target size (GMG, 2015). At Boliden, grindability is generally expressed as the mass of particles below 45 µm generated per kWh (Westerlund, 2017) and calculated according to Equation (1), where Out is the % <45 µm in the mill discharge, In the % <45 µm in the mill feed, and F and P respectively the feed rate (t/h) and mill power (kW).

$$Grindability = \frac{Out-In}{1000} * \frac{100*F}{P} = \frac{10(Out-In)}{Spec.Energy} \quad (1)$$

Boliden AB developed its laboratory grindability test in the 1970s to assess ore decomposition due to abrasive grinding and to be able to evaluate an ore's suitability for autogenous grinding by employing a grindability index k_s (Markström, 2018). The general idea was to compare and corroborate the results derived from the grindability tests with data from pilot plant tests and industrial mineral processing plants. Hence, this would allow appraising the grinding behaviour of a specific ore in an industrial grinding circuit on a laboratory scale (Borell and Lager, 1983). Other grindability tests developed to assess autogenous grinding are the SAG Mill Comminution test (Morrell, 2004), the MacPherson Autogenous Grindability Test (Macpherson, 1976) and the Advanced Media Competency Test (Morell, 2019).

Investigating the relationship between grindability and mineralogy

Recently, Rincon, Gaydardzhiev and Stamenov (2019) subjected nine ore samples from the Dundee Precious Metals' Chelopech mine in Bulgaria to grindability tests within a laboratory ball mill. The results suggested that grindability correlates positively with the sample's kaolinite content. To predict grinding performance at Aitik, Markström (2020) conducted a study aiming at indicating the relationship between ore mineral/element composition and plant performance. Belt-cut samples from the AG mill were subjected to SAG Mill Comminution Tests as well as Boliden's in-house grindability test method. No correlations were found between mineral, element grade, and AG mill grinding energy. In connection with the development of a predictive geometallurgical model at Hot Chili's Productora copper project in Chile, drill core samples were subjected to metallurgical tests for the determination of BWi and geochemical analysis for the determination of chemical composition (King and MacDonald, 2016). Subsequent regression analysis of the acquired data was aimed at using element concentrations as geometallurgical proxies. The BWi was best predicted by Al and K concentrations; hence, an equation for the calculation of BWi was developed based on this relationship.

MATERIALS AND METHODS

Samples

Sweden is a significant European mining region, with active iron oxide, sulfide, and precious metal mines situated in the mining districts of Norrbotten, Skelleftefältet, and Bergslagen. Regarding the amount of Cu in produced concentrates, Sweden accounts for approximately 11 per cent of the European Union's output (Norlin *et al*, 2020). Aitik is Sweden's largest sulfide mine (Wanhainen *et al*, 2012) and was responsible for 91 per cent of the country's production of Cu concentrates in 2020 (Norlin *et al*, 2020), underlining the mine's importance for the Swedish raw materials industry.

For this study, 11 ore samples in the form of drill cores were collected from four locations of the open pit mine (Figure 1) and according to the following classified rock types: Diorite (4), Mica Gneiss (3), and Sericite Schist (4). Mica Gneiss and Sericite Schist samples were retrieved from the deposit's main ore zone, whereas the Diorite samples originated from the footwall. Table 1 shows the collected samples with their respective logged textures and grain sizes of the mineral matrix.

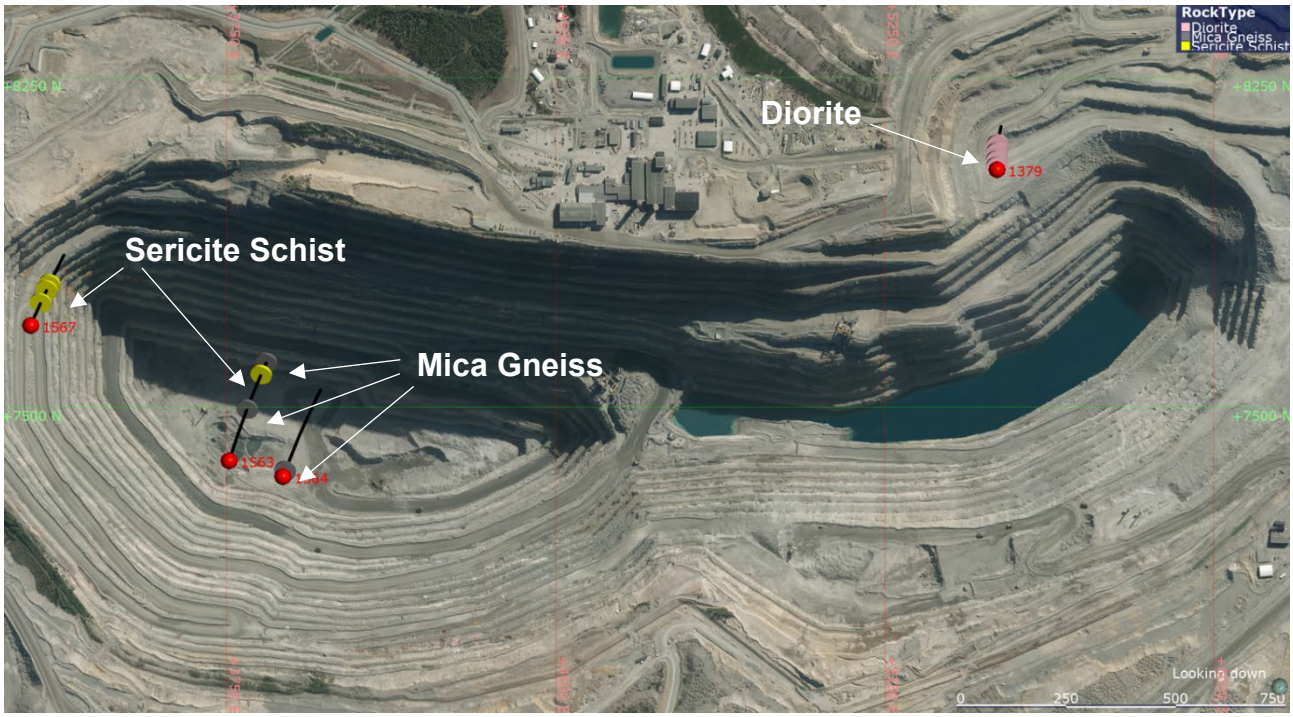

FIG 1 – Plan view of the Aitik open pit mine with the locations of the drill holes from which samples were retrieved. The disks are coloured according to the different rock types (red = Diorite, grey = Mica Gneiss, yellow = Sericite Schist) and illustrate the approximate depths of the samples.

TABLE 1

Ore samples with their corresponding rock type, depth at which the sample was taken, and information regarding texture and grain size of the mineral matrix.

Sample	Rock type	Texture	Matrix grain size	Type of sample	Depth (m)
1	Diorite	Phaneritic	Medium	Half drill core	84.0
2	Diorite	Phaneritic	Medium	Half drill core	10.0
3	Diorite	Phaneritic	Medium	Half drill core	44.0
4	Diorite	Phaneritic	Medium	Half drill core	122.0
5	Mica Gneiss	Porphyritic	Fine	Half drill core	206.0
6	Mica Gneiss	Porphyritic	Fine	Half drill core	24.7
7	Mica Gneiss	Porphyritic	Fine	Half drill core	388.7
8	Sericite Schist	Porphyroblastic	Fine	Half drill core	94.5
9	Sericite Schist	Porphyroblastic	Fine	Half drill core	173.9
10	Sericite Schist	Porphyroblastic	Fine	Half drill core	340.6
11	Sericite Schist	Porphyroblastic	Fine	Half drill core	150.0

Since the purpose of the present study was to investigate the relationship between grindability and rock type mineralogy, other parameters influencing grindability had to be isolated. The literature shows that an ore's grain size and texture influence grinding performance (Kekec, Ünal and Sensogut, 2006; Djordjevic, 2013; Mwanga, Rosenkranz and Pertti, 2017; Ghanei, 2020). Hence, these two variables were maintained uniform when collecting the ore samples of each rock type. Furthermore, it is important to mention that the number of selected samples was not sufficient to accurately represent the deposit's distribution of rock types or to map geometallurgical parameters such as grindability across the deposit. However, a larger number of samples would have exceeded

the study's scope. Geometallurgical studies typically require between 100 and 300 grindability tests and over 1000 mineralogical tests (Williams and Richardson, 2004).

After crushing and performing the grindability tests, the ore samples passed through different preparation steps according to the subsequent analyses. Representative portions of the grinding products were subjected to particle size distribution analyses. Consecutively, fine-grained parts of the grinding product in the ranges of 0–45, 45–90, and 90–180 µm were taken for the preparation of resin-mounted samples for automated mineralogy (quantitative evaluation of minerals by scanning electron microscopy, QEMSCAN). Furthermore, mineral bulk samples were prepared by pulverising crushed material in a ring mill and splitting it into representative portions for X-ray powder diffraction (XRD) and X-ray fluorescence (XRF) analyses.

Methods

X-ray powder diffraction in combination with Rietveld analysis

For mineral characterisation by XRD, a PANalytical Empyrean X-ray diffraction diffractometer equipped with a Cu LFF HR X-ray tube and a PIXcel3D detector at Luleå University of Technology's (LTU) department of chemistry was used.

As previously mentioned, 11 ore samples were pulverised by a ring mill at LTU's mineral processing laboratory to reduce the powder particle size and to provide for a random orientation of the mineral crystals (Alderton, 2021). The fine powder was then filled into Ø 26 mm back-loading holders. The diffractometer's scan axis was set to gonio-mode. The 2θ start and end positions were respectively set to 5° and 75° with a step size of 0.026° and a scan step time of 337 seconds, resulting in a scan time of approximately 60 minutes per sample.

Mineral phase quantification was accomplished by using Malvern PANalytical's XRD analysis software HighScore Plus in combination with the Inorganic Crystal Structure Database (ICSD), which at the time of the study contained 177 337 reference patterns for different inorganic crystal structures. During Rietveld refinement for improved phase-quantification in HighScore Plus, background corrections, specimen displacements, peak widths, and crystal lattice and peak shape parameters were considered.

Automated mineralogy – QEMSCAN

Automated mineralogy provides numerous methods for investigating mineral characteristics, amongst others the quantification of a sample's modal mineralogy and the measurement of grain size and shape, and the determination of the degree of mineral liberation (Parian *et al*, 2015).

For this study, modal mineralogy and mineral liberation information were decisive, since it was expected that this information would correlate well with the results of the grindability tests. Epoxy resin-mounted samples were prepared from ground ore samples of narrow size fractions (0–45, 45–90, and 90–180 µm) and bulk mineral samples. The latter allowed for a comparison between the measurement results from automated mineralogy and XRD.

The device implemented within this study was Boliden AB's FEI QEMSCAN® 650, equipped with a W-filament electron-gun, Energy Dispersive X-Ray Spectroscopy, and an electron backscatter detector. All analyses were processed using FEI company's iMeasure and iDiscover software suite (version 5.4), where the former was used for data collection and the latter for mineral identification. Particle Mineral Analysis (PMA) was the selected method of analysis, which enabled the determination of mineral abundance and mineral liberation. Boliden AB provided a custom-made species identification protocol (SIP) which was based on past mineralogical studies of the Aitik deposit. This database contained mineral phase definitions for mineral identification. The SIP was used as the starting point of the mineral characterisation procedure and modified by the author as required. Proportions of unknown mineral phases were minimised by applying two types of preprocessors: the touching particles and the boundary phase processor. The former allowed to split or filter touching particles, and the latter helped to mitigate falsely identified pixels (Warlo *et al,* 2019).

Chemical analyses

Chemical analyses of loose powder samples were performed at Boliden AB's mineral processing laboratory in Boliden according to the company's standardised techniques. XRF (SPECTRO XEPOS energy dispersive X-ray fluorescence) is routinely employed at the company's laboratory to determine the chemical composition of samples originating from its processing plants or pilot and laboratory-scale tests.

Representative portions of the samples prepared for XRD analyses were subjected to XRF analyses. These samples were previously pulverised in a ring mill to obtain a P_{80} <50 µm. Boliden's standard measurement setting for ore powder samples 'TQ Boliden Ore' was applied, which was configured to a measurement time of four minutes per sample. Results were reported as per cent by mass per detected element and imported into digital spreadsheets. Hence, no further data evaluation was required.

Grindability tests

Only half-core samples from Aitik mine were available for the grindability tests. The minimum sample mass for a single grindability test is approximately 15 kg (Markström, 2018). However, the required sample mass depends on how rapidly the ore decomposes in the grinding environment. The outcomes of the grindability tests performed throughout this study were used to generate a grindability index k_s based on the weight loss of a pebble charge over time due to wear. Hence, the grindability tests are also referred to as 'wear tests'.

Each grindability test requires a preparative step; broken and crushed drill cores are subjected to an autogenous grinding process in a Ø 284 mm laboratory mill (Sala Mill) over several hours at a low rotational speed of approximately 38 rev/min and under the addition of water and grinding sand. The autogenous grinding action at low rotational speed enforced the breakage mechanisms of attrition and chipping, which led to the removal of edges, asperities, and rough surfaces, producing well-rounded 'pebbles'. Subsequently, the mill discharge was cleaned and sized into fine, medium, and coarse size classes, which were used to assemble a pebble test batch of a specific weight.

For each wear test, a Ø 200 mm bench-top laboratory grinding mill was filled with a pebble test batch and combined with <1 kg of finely crushed material (<3.15 mm) of the same sample and water to reach a pulp density of approximately 10 per cent. Thus, the pebbles act as the grinding media and the finely crushed material as the mill charge. Sequentially, the mill charge was ground at 46 rev/min for 60, 90, and 150 minutes. Following each grinding process, the mill was emptied, and the weight loss of each of the test batch's size classes was measured and recorded. Before the next round of grinding, each size class was refilled with the amount of fresh material equal to the mass loss due to the grinding action. The k_s index was then determined by plotting the total percent weight loss of the test batch against the three grinding times. The slope of a straight line of best fit through these three points and the origin calculated using the least squared method is the wear index, expressed as % weight loss/(min*10^{-2}).

RESULTS

Grindability test results

The evaluation of the data from the grindability tests revealed disparities across k_s-values acquired from samples of different rock types (Figure 2). Likewise, the wear indices from samples of the same rock types show little congruency, except for Diorite 1 and 4 and Mica Gneiss 1 and 3. A high k_s-value implies a high mass loss of pebbles during grinding and thus a low resistance due to abrasive grinding. Sericite Schist samples experienced the highest mass loss during the grindability tests, whereas Diorite samples were less affected by the prevailing breakage mechanisms. K_s-values from Mica Gneiss samples lie intermediate between both other rock types.

The grindability indices derived from Sericite Schist samples diverge more strongly and appear to be between two to four times higher than those for Diorite and Mica Gneiss samples. In terms of grindability/resistance against abrasion, the test results suggest the following order: Diorite > Mica Gneiss > Sericite Schist. Hence, it becomes evident that different rock types from the Aitik mine vary in their comminution behaviour.

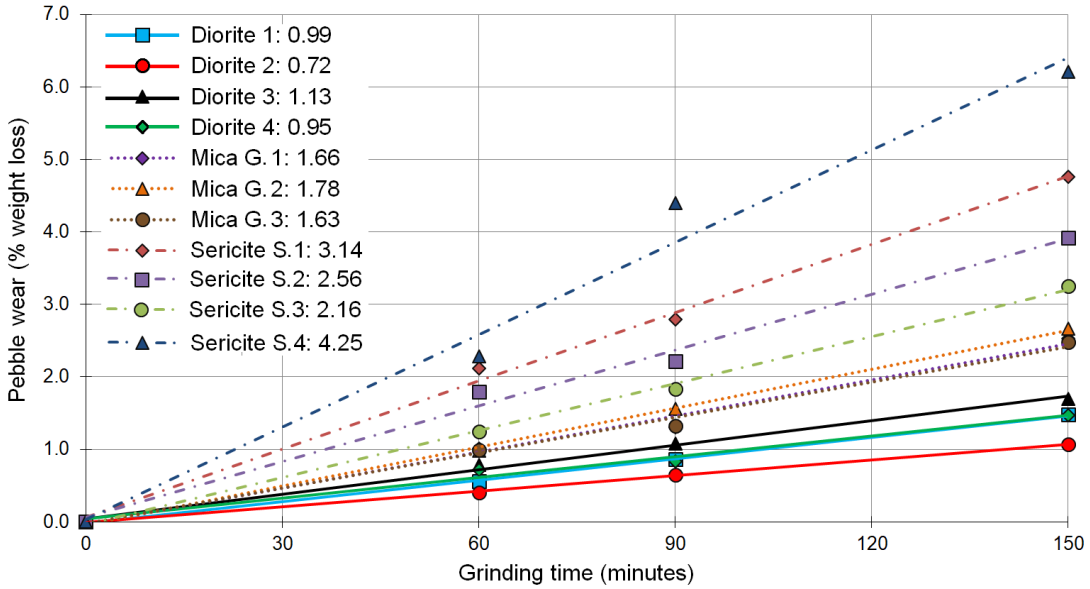

FIG 2 – Pebble wear as a function of grinding time for the different rock type samples. The legend shows the samples and their respective k_s-values.

The presented data allows for the following hypotheses: Texture and grain size of samples from the same rock type are equal (Table 1); Thus, differences in the mineral assemblage of the samples must be responsible for the varying grindability indices. Due to the low mass loss of Diorite samples observed during laboratory grindability tests, this rock type bears the potential of forming a critical size fraction during autogenous grinding. On the other hand, the Sericite Schist rock type may not provide suitable grinding media due to its relatively rapid decomposition.

Particle size distributions

Although the principal outcome of the grindability tests comprises the loss of mass of the pebble test batch, the particle size distribution (PSD) curves of the finely crushed <3.15 mm mill charge over time were investigated. The curves depicted in Figure 3 allow for the qualitative assessment of the PSD starting from the mill feed towards the final grinding product for the different samples of each rock type.

As for the mill feed (Figure 3a), different levels of coarseness are evident, which indicates a difference in crushability between the samples. The spread of the curves increases until 150 minutes of grinding time (Figure 3d). Analysing the order of the curves, it becomes apparent that the PSDs, from coarse to fine and grouped according to rock type, have obtained the following order: sericite schist > mica gneiss > diorite. This arrangement indicates that diorite samples generally generated higher proportions of fines, followed by mica gneiss and sericite schist samples. Hence, samples with high k_s-values, such as sericite schist, lead to a high % mass loss and a relatively coarse grinding product. Conversely, samples with low k_s-values lead to a low % mass loss and a finer grinding product.

To better comprehend the development of the fineness of the grinding product, the proportions of the -45 µm size fraction of the mill discharge were plotted against the grinding time (Figure 4). For long grinding times and as previously identified, samples with high k_s-values tend to generate proportionally less fines than samples with lower k_s-values. Thus, diorite samples presented the highest proportions of fines and sericite schist the least, whereas mica gneiss samples were positioned intermediate between the two. The inset plot of Figure 4 shows a correlation plot between the k_s-values and the proportions of the fine grinding product after 150 minutes of grinding time. Correspondingly, a correlation coefficient of -0.78 was found for a plot between the k_s-values and the proportion of fine grinding product after a grinding time of 90 minutes. The strong negative correlation coefficients indicate that the higher the k_s-values, the lower the proportions of generated fines and vice versa. However, such a relationship did not hold in the case of a grinding time of 60 minutes.

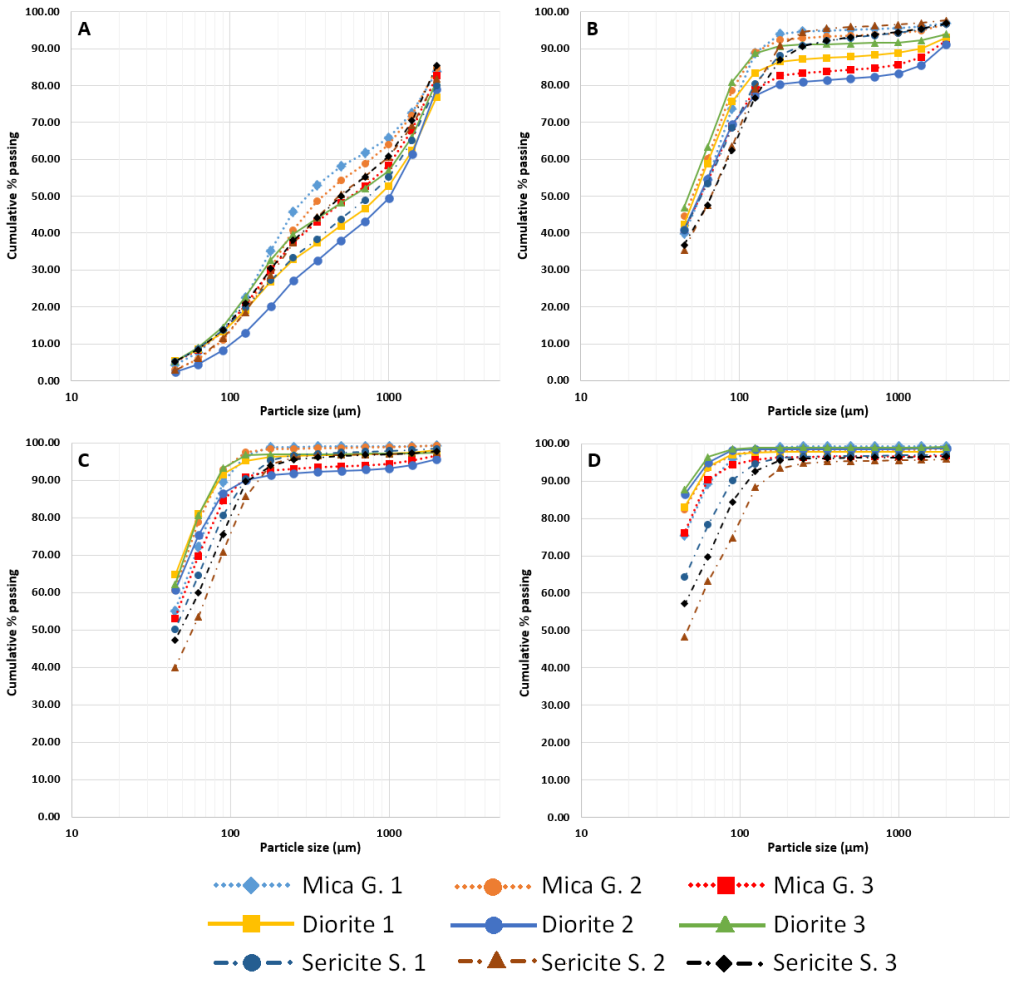

FIG 3 – Development of the particle size distribution of the mill feed (A), and after 60 (B), 90 (C), and 150 minutes (D) of grinding time.

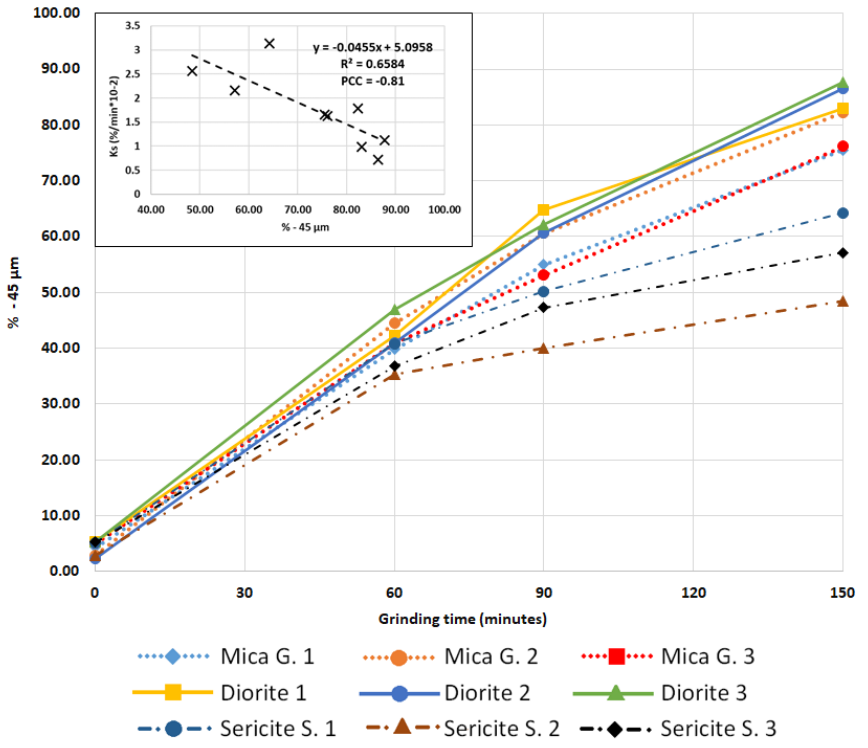

FIG 4 – Plot of grinding time versus fine grinding product (% -45 µm). The inset plot shows a correlation plot between the % -45 µm fraction and the k_s-values of the respective samples.

Mineral characterisation by XRD and QEMSCAN

Aiming at facilitating the comparison of the data acquired by mineralogical analyses and the subsequent correlation analyses between the identified mineral phases and the grindability indices, it was determined to bin the identified minerals into mineral groups (Table 2).

TABLE 2

Identified mineral phases and their corresponding mineral groups.

Mineral group	Identified mineral phases	
	X-ray diffraction	Automated mineralogy
Quartz	Quartz	Quartz
Plagioclase	Oligoclase	Albite, Anorthite, Oligoclase
Garnet	Spessartine	Spessartine, Almandine
K-Feldspar	Orthoclase	Orthoclase
Mica	Biotite, Muscovite	Biotite, Muscovite, Phlogopite
Amphibole	Actinolite	Actinolite
Clinopyroxene	Diopside	-
Chlorite group	Clinochlore	Clinochlore
Sulfides	Chalcopyrite, Pyrite, Pyrrhotite	Chalcopyrite, Pyrite/Pyrrhotite
Fe Oxides	Magnetite	Iron oxide
Others	-	Titanite, Barite, Apatite, <1 per cent by weight

Due to the different mineral characterisation techniques that were applied, not all identified mineral phases agreed. For example, the main plagioclase group mineral identified by XRD was oligoclase, whereas QEMSCAN analyses reported albite and anorthite as the main minerals of this group. However, Wanhainen, Broman and Martinsson (2003) and Frietsch (1980) confirmed the occurrence of both oligoclase and albite at Aitik. The mixed diffraction spectra of the natural samples subjected to XRD and the similar chemical composition of oligoclase and albite exacerbate the distinction of both minerals. The same applies to pyrite and pyrrhotite, which QEMSCAN can hardly distinguish.

Comparing the mineral assemblages obtained by XRD of the eleven bulk samples reveals the variations in mineral composition across the different samples and rock types (Figure 3). The mineral phases which occurred in the highest proportions are quartz, plagioclase, k-feldspars, and micas. Plagioclase is the main mineral phase in both diorite and mica gneiss samples. Its content is highest in diorite samples and decreases towards mica gneiss and sericite schist samples. The opposite is true for quartz: It is the main mineral phase in sericite schist samples and decreases towards mica gneiss and diorite.

Micas are most abundant in sericite schist samples, and their contents decline from mica gneiss towards diorite. K-feldspar is most abundant in mica gneiss samples and varies between approximately 10 to 25 per cent in diorite and sericite schist samples. Sulfides, chlorites, garnets, clinopyroxenes, and oxides were identified as the minor mineral phases (<3 per cent). Amphibole grades vary between 5 and 7 per cent in diorite samples.

When correlating the different mineral phases with each other, it was found that there are negative correlations between plagioclase and quartz, micas, and sulfides amongst others (Figure 5). Hence, as plagioclase content increases within the samples, quartz, mica, and sulfide contents tend to decrease. The unidentified mineral fractions reported by QEMSCAN are approximately 4–7 per cent. Compared to XRD, QEMSCAN analyses consistently yielded lower proportions of plagioclase and higher proportions of micas, meaning that the former is underestimated by QEMSCAN or

overestimated by XRD, whereas the opposite applies to the content of mica minerals. The sample preparation procedure and the plate-like shape of clay minerals, such as micas, may lead to the preferred orientation of the mineral crystals within the sample, hence intensifying XRD X-ray counts and introducing a measurement error (Lippmann, 1970; Hillier, 1999; Środoń *et al*, 2001). Similar issues were reported for minerals belonging to the plagioclase group, such as albite (Kleeberg, Monecke and Hillier, 2008).

FIG 5 – Modal mineralogy of the different rock type samples and Pearson correlation matrix of the identified mineral species. The results are according to XRD analyses from the bulk mineral samples.

Correlating grindability indices with mineralogy and chemical composition

Pearson correlation matrices were established to identify the strength of the linear relationship between modal mineralogy and grindability indices. The most relevant correlations were found for the bulk mineral samples.

Figure 6 shows the correlation plots of the most significant correlations between mineral phases identified by XRD and the respective k_s-values. Contrary to diorite and mica gneiss, the data points of sericite schist samples are spread around the regression lines. This disparity is a consequence of the greater spread in k_s-values reported for this rock type. The strongest Pearson correlation coefficient of -0.89 was found in the case of plagioclase (Figure 6b). Thus, with an increasing plagioclase content, the mass loss due to abrasion decreases. The opposite applies to quartz, mica, and the content of sulfides, which show positive correlations with their respective k_s-values. Hence an increase in the proportions of these minerals results in an increased mass loss due to wear. It is also worthwhile to mention that Pearson correlation matrices between the different mineral phases indicated negative correlations between plagioclase, quartz, mica, and the content of sulfides.

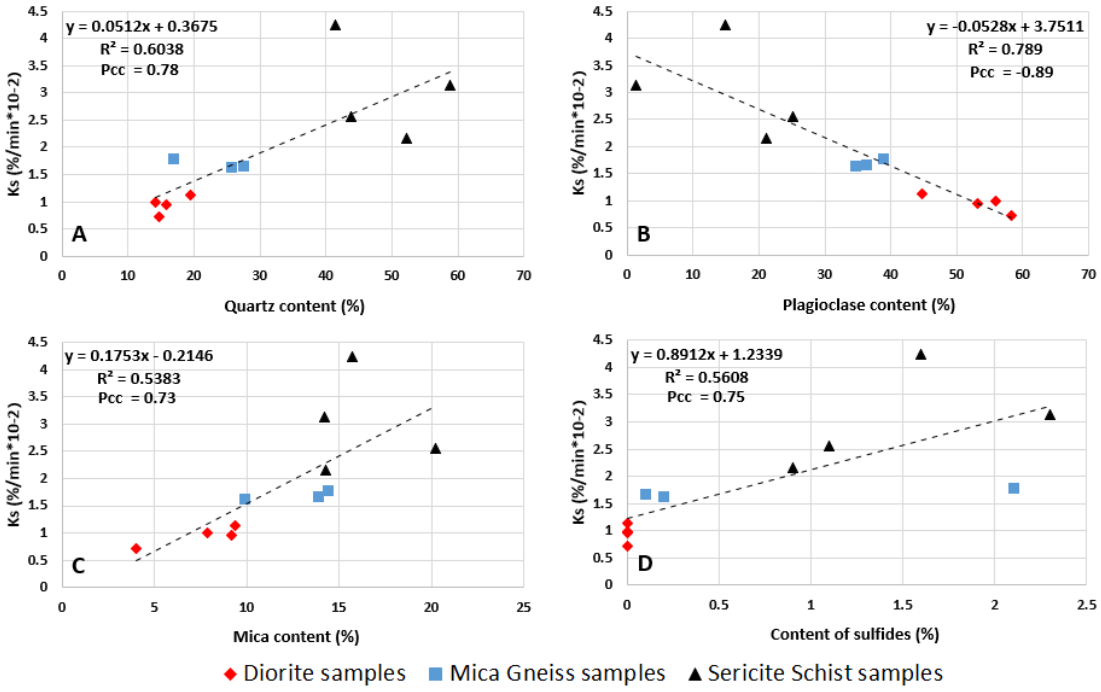

FIG 6 – Correlation plots between different mineral phases identified by XRD (bulk samples) and the respective k_s-values. In each case, the Pearson correlation coefficient (Pcc) and the model of a linear trendline with its respective R^2-value are given.

Relating the k_s-values to the proportions of the mineral phases of the three size classes analysed by QEMSCAN led to similar results (Figure 7). Strong positive and negative correlations were found between k_s-values and mineral phases across all size classes, particularly for the main mineral phases plagioclase, quartz, and sulfides. However, for the mica minerals, a Pearson correlation coefficient above 0.5 was only found within the 45–90 µm size fraction, which is due to the sericite schist 1 sample forming an outlier (Figure 7c), having approximately 50 per cent less mica content (Figure 5) as compared to the other sericite schist samples.

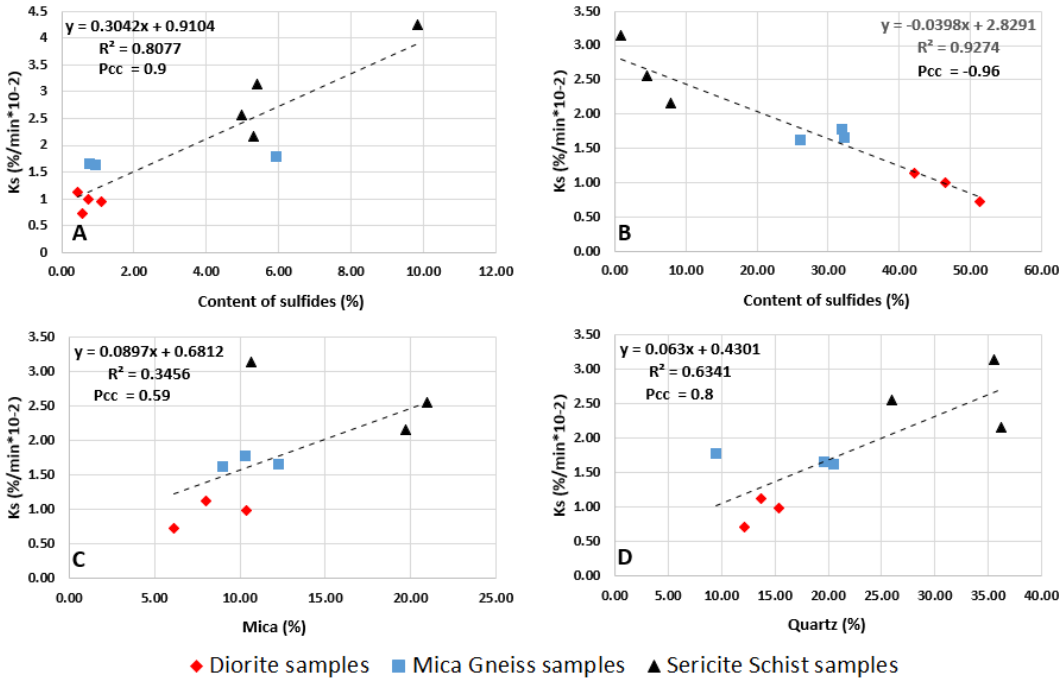

FIG 7 – Correlation plots between mineral phases identified by QEMSCAN and the respective k_s-values from different size fractions: Content of sulfides (bulk sample, A), plagioclase (90–190 µm, B), mica (45–90 µm, C) and quartz (0–45 µm, D).

Overall, the strongest correlation between mineral phase and k_s with a Pearson correlation coefficient of -0.96 was found for plagioclase in the 90–180 µm size class (Figure 7b). In the case of mineral phases such as K-feldspars and amphiboles, no significant correlations between mineral content and grindability indices were distinguished.

The chemical composition acquired by XRF powder analysis enabled the investigation of the relationship between grindability indices and the chemical composition of the bulk samples. Significant positive and negative correlations were observed between chemical data and k_s-values (Figure 8). The strongest correlations were found for Al_2O_3 and CaO, with Pearson correlation coefficients of -0.86. Negative correlations were detected in the cases of S and Fe. A further but less significant correlation was found for Al_2O_3 and CaO, resulting in a Pearson Correlation Coefficient of 0.64. As previously observed, the data points corresponding to sericite schist samples show more spread around the line of best fit.

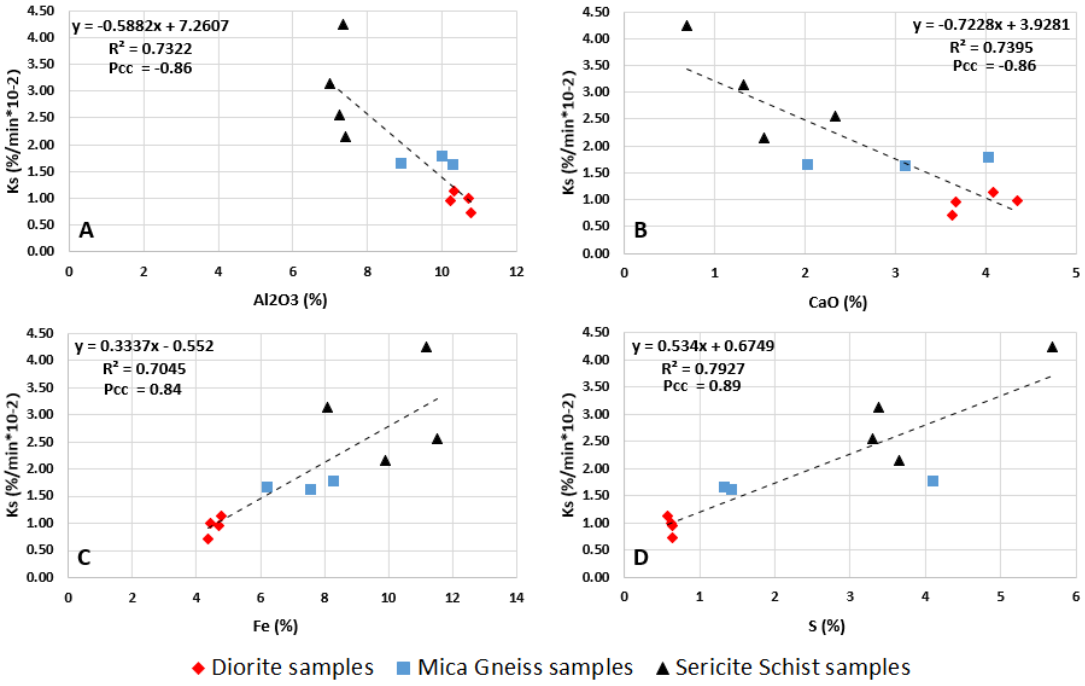

FIG 8 – Correlation plots between k_s-values and chemical data.

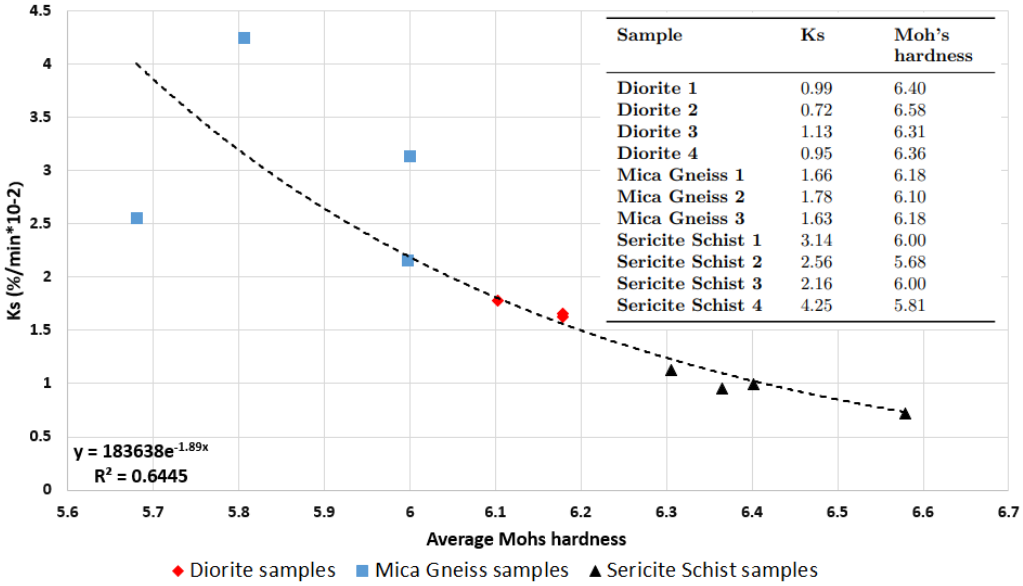
Mineral hardness and grindability

An approach from Mwanga (2016) was applied to calculate each sample's weighted average Mohs hardness based on the modal mineralogy acquired from XRD analyses. The hardness values for each mineral phase were obtained from the mineralogy database of webmineral.com and other relevant literature.

Aiming to investigate the relationship between k_s and Mohs hardness, the corresponding values for each sample were plotted in a correlation plot (Figure 9). The table embedded within Figure 9 lists the different mineral specimens with their respective k_s and Mohs hardness values. The negative correlation between the data indicates that an increasing average hardness leads to a decreasing mass loss regarding abrasion. Hence, and according to the information provided previously, the higher a sample's average Mohs hardness, the lower the percentage mass loss of the pebbles and the greater the proportions of generated fines within the grinding product. Since k_s and Mohs hardness are inversely correlated, the relationship between Mohs hardness and modal mineralogy is reciprocal. For example, the correlation between k_s and plagioclase content is negative, so the average Mohs hardness and plagioclase content are positively correlated. Consequently, average Mohs hardness increases with increasing plagioclase content.



Sample	Ks	Moh's hardness
Diorite 1	0.99	6.40
Diorite 2	0.72	6.58
Diorite 3	1.13	6.31
Diorite 4	0.95	6.36
Mica Gneiss 1	1.66	6.18
Mica Gneiss 2	1.78	6.10
Mica Gneiss 3	1.63	6.18
Sericite Schist 1	3.14	6.00
Sericite Schist 2	2.56	5.68
Sericite Schist 3	2.16	6.00
Sericite Schist 4	4.25	5.81

FIG 9 – Scatterplot between k_s-values and average Moh's hardness calculated from mineral proportions reported by XRD.

Mineral liberation

A mineral liberation analysis was performed on the 0–45, 45–90, and 90–180 µm particle size fractions. Kumar *et al* (2021) considered particles with a liberation degree above 95 per cent as fully liberated. For the present study, this approach was adopted, and four liberation classes were created for the data obtained by QEMSCAN: >= 95 per cent, 80–95 per cent, 30–80 per cent, <=30 per cent.

At Aitik, as is the case for the majority of sulfide deposits, chalcopyrite frequently occurs in association with pyrite and pyrrhotite (Wanhainen, Billström, and Martinsson, 2006). Since the flotation process at Aitik aims at separating the chalcopyrite grains liberated from pyrite, pyrrhotite, and other main gangue minerals such as plagioclase, quartz, K-feldspars, and micas, the focus of the liberation study was set on these mineral phases.

It was observed that the proportions of fully liberated plagioclase and mica grains within sericite schist samples are generally lower across all size fractions when compared to diorite and mica gneiss samples (Figure 10). The liberation data showed that, in general, 92 per cent of pyrite/pyrrhotite and 91 per cent of quartz within the sampled size fractions were fully liberated, indicating approximately equal liberation within these size classes. The degree of liberation of chalcopyrite was the lowest in the 90–180 µm size class of the diorite samples. Fully liberated chalcopyrite grains with proportions of up to 90 per cent by mass were observed in the 0–45 and 45–90 µm size fractions of all samples, indicating that the liberation size of chalcopyrite grains is below 90 µm. However, on several occasions, the degree of liberation within the 45–90 µm size class was higher than in the 0–45 µm size class. However, the apparent higher degree of liberation within this size class may be due to touching particles in the sample.

For the gangue minerals plagioclase, K-feldspars, and quartz, a clear trend of increasing mineral liberation with decreasing particle size was distinguished, indicating that the liberation size of these mineral phases is below 90 µm. Attempting to scrutinise how mineral liberation, k_s-values, and mineral content affect each other, a correlation analysis was performed. Only a single significant positive correlation was detected between mineral content and liberation: the higher the plagioclase content, the higher the % mass of fully liberated plagioclase grains within the sample. This observation seems reasonable since the likelihood of liberated mineral grains increases with increased mineral content. Strong negative correlations between % fully liberated plagioclase grains and k_s-values suggest that as the material loss due to abrasion increases, the proportions of fully liberated mineral grains decrease (Figure 11). This relationship agrees with the general observation of sericite schist samples having a lower degree of liberation of the plagioclase mineral phase.

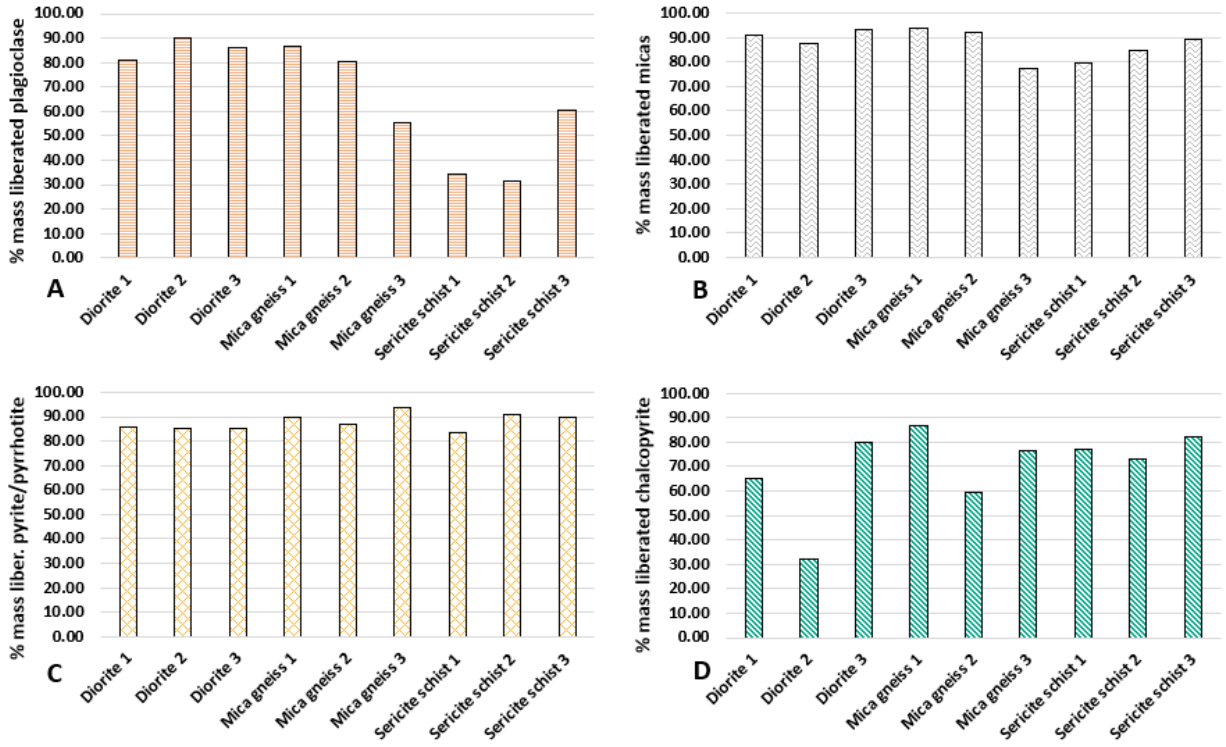


FIG 10 – % of fully liberated minerals grains of selected mineral phases: Plagioclase (90–180 µm, A), micas (45–90 µm, B), pyrite/pyrrhotite (0–45 µm, C), chalcopyrite (90–180 µm, D).

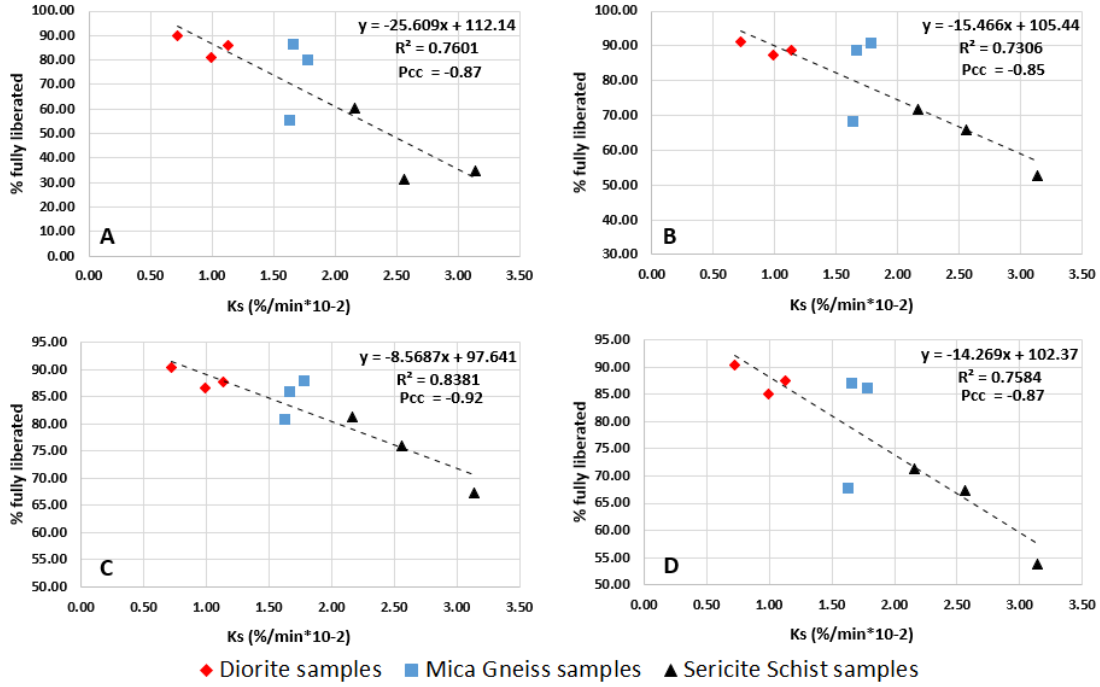

FIG 11 – Correlation plot between k_s-values and % fully liberated plagioclase particles in the 90–180 µm (A), 45–90 µm (B), and 0–45 µm (C) size classes and a combination of all size classes (D).

Preferential wear of mineral phases

The tendency of the mineral phases to accumulate in specific size classes was investigated. Accordingly, the modal mineralogy of the mill discharge after different grinding times and the bulk modal mineralogy were compared. Hence, any significant and systematic change in mineral composition within a particle size class may indicate preferential wear.

Considering the samples analysed with QEMSCAN, diorite 3, mica gneiss 2, and sericite schist 1 yielded the highest k_s-values (compare diagram inset of Figure 2). The elevated mass loss of these samples was expected to increase the likelihood of finding evidence for the preferential wear of mineral phases. Figure 12 shows the ratios between the mineral proportions after 150 and 60 minutes of grinding time and under consideration of the bulk mineral samples ordered by particle size classes. Generally, the mineral ratios are well below or above 1, indicating a notable difference in mineral composition after 150 minutes of grinding time (Figure 12a). The mineral ratios do not remain constant within the same size class, meaning the same mineral is deposited in different proportions. However, as for the 0–45 µm fractions, it was observed that the mineral ratios are approaching a value of 1, indicating that the mineral composition of the fine size fractions after 60 and 150 minutes of grinding are similar. Therefore, fine particles are abraded in a more homogenous and constant manner, resulting in comparable mineral compositions at different grinding times.

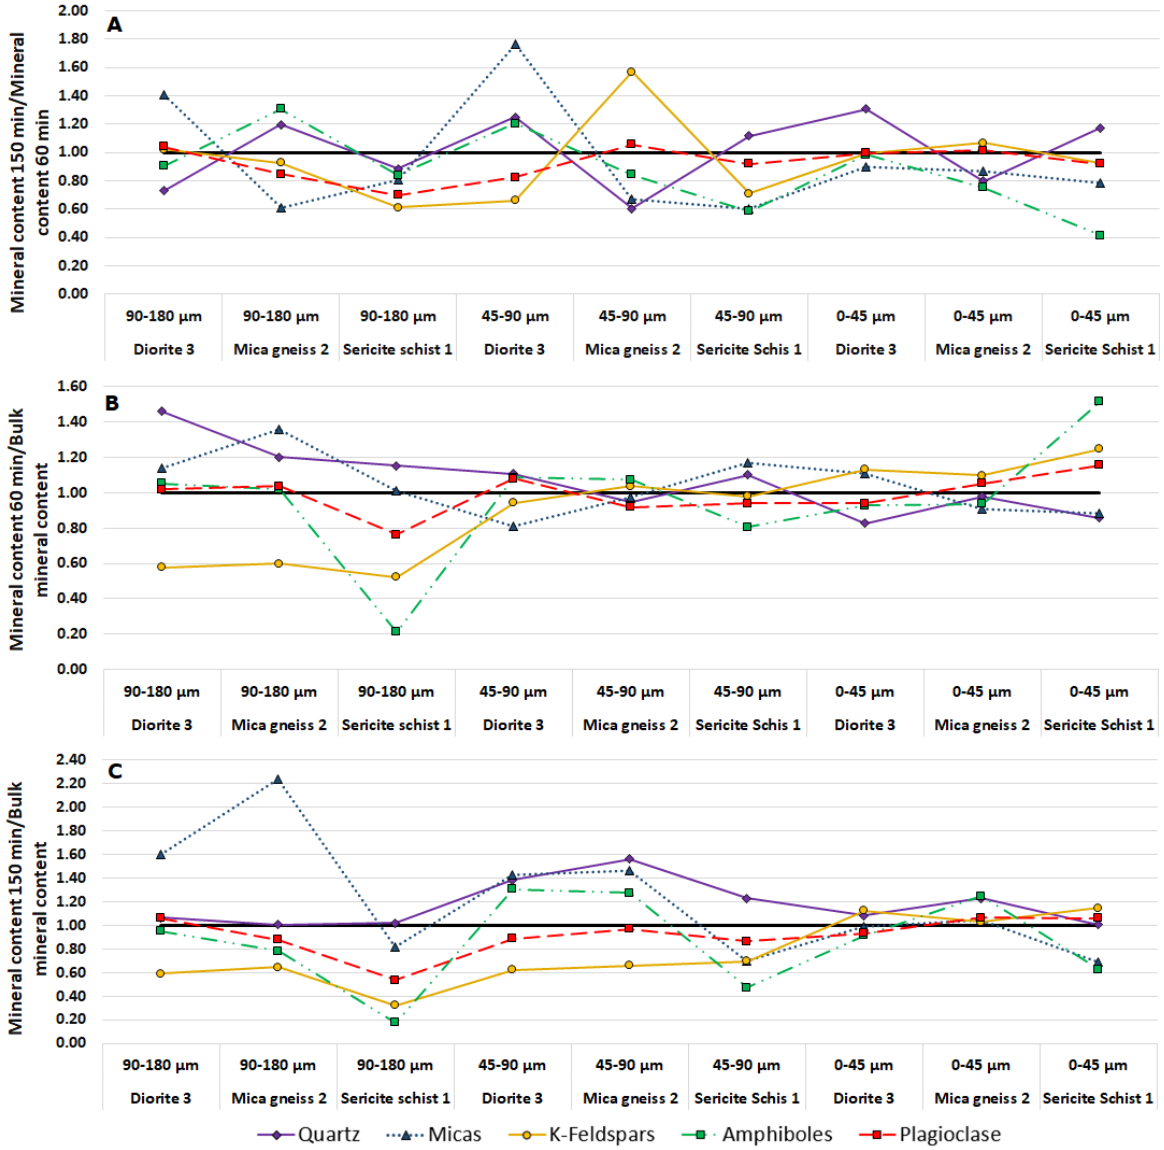

FIG 12 – Ratios of selected mineral phases: After 150 minutes versus 60 minutes of grinding (A), after 60 minutes of grinding versus bulk mineral content (B), and after 150 minutes of grinding versus bulk mineral content (C).

Concerning the mineralogy of the bulk samples (Figures 12b and 12c), the curves show ratios close to 1 for the medium and fine size classes. The divergence regarding the coarse size fractions is more pronounced. These results indicate that the grinding action leads to a constant and homogeneous abrasion of minerals so that the modal mineralogy approaches the bulk mineralogy. When comparing the mineral proportions resulting from different grinding times, it was indicated that K-Feldspars

preferentially compose the 0–45 µm size class. Contrastingly, micas became more abundant towards the coarse size fraction. The grade of chalcopyrite increased towards the 0–45 µm size fraction, whereas the opposite applied to pyrite/pyrrhotite. Considering that the mentioned mineral phases preferentially compose the same size fractions after 60 and 150 minutes of grinding time indicates a constant and homogeneous abrasion process.

DISCUSSION

For each rock type, the results of the wear tests show varying degrees of per cent weight loss over time, hence the visible spreads of the curves in Figure 2 result. Considering that sample texture and grain size were selected to be equal for each rock type, it is likely that differences in mineral composition are the main contributor. However, errors related to the test procedure and the impact of the sample's natural variability on the results cannot be eliminated. More grindability tests are necessary to obtain more accurate data. Even though samples were taken from three different rock types, considerable differences in mineral assemblage for samples from the same rock type may occur. Table 1 and Figure 1 indicate that the spatial distance between the chosen samples was relatively large. Thus, compositional differences regarding mineralogy are likely to influence grinding behaviour. In other words, the rock's resistance to abrasive grinding varies within and across Aitik's rock types. Likewise, the ore properties, in this case, the mineral composition, of samples 1 and 4 must be similar, as both samples exhibit very similar k_s-values of 0.99 and 0.95. Indeed, Figure 5 confirms the similar mineral composition of these samples. Considering that the invested grinding energy is equal for all samples and the similarity in texture and grain size, it is possible that other factors, such as a variation in mineral assemblage, impact grinding behaviour. A mechanism that may have influenced test results negatively is the pre-wear procedure: In case this procedure failed to remove the pebble's asperities and edges, the chipping breakage mechanism continued to be active during the wear tests releasing material and influencing the k_s-value. During grinding, the surface-specific wear rate of a particle decreases over time since the surface becomes increasingly rounded as the chipping and attrition breakage mechanisms remove edges and asperities (King, 2012). In other words, the mass loss of a particle due to chipping decreases with increasing grinding time. If sufficiently rounded pebbles are subjected to the wear tests, the abrasion mechanism becomes the dominant breakage mechanism. However, it was impossible to verify that all samples reached the required degree of roundness. Hence, k_s-values may have been influenced by this mechanism.

The grinding product's particle size distribution curves were used to investigate the relationship between k_s-values and particle size. The results showed that coarser particles are generated from samples with high k_s-values as grinding time increases. However, this observation relies on a relatively small sample population and only a few of the rock types present at Aitik. Furthermore, after 60 or even 150 minutes of grinding within the laboratory mill, over-grinding may occur, resulting in the unnecessary breakage of mineral particles (Kawatra, 2006). Thus, the significance of this observation is questionable, as the retention time inside Aitik's AG mill is between 7 and 10 minutes only (Isaksson, personal communication, February 12, 2021). Hence, in Aitik's comminution circuit, due to relatively short grinding times, certain rock types are possibly prone to producing increasingly coarse particles. However, since the target P_{80} of the feed for the flotation circuit of Aitik's processing plant is approximately 180 µm, no negative consequences are expected. Naturally, the proportions of generated fines increase with grinding time as particles are continuously reduced in size. While the coarse particles of the test batch increase in roundness due to abrasion, less material is abraded from their surfaces. Thus, the mineral surfaces become smoother, and eventually, less material is abraded over time. The material, which is abraded from the pebble's surfaces during the wear tests, is mixed with the -3.15 mm fraction that composes the mill charge. These circumstances tend to bias the test results. The fact that more material is abraded from sericite schist samples, while at the same time generating lower proportions of fines as compared to diorite and mica gneiss samples, indicates that the sample's mineral composition directly influences the smoothness of the pebble's surface. Thus, a smoother surface is less prone to being affected by abrasion. When conducting the laboratory tests, diorite samples exhibited a very smooth surface. Considering the relatively small number of samples selected for each rock type, no meaningful correlations between k_s-values and modal mineralogy were detectable. Thus, the data for all samples was plotted into a single diagram. Hence, as a result, it was not possible to make clear statements about the relationship between k_s

and the modal mineralogy of a specific rock type. However, Figure 6 depicts apparent rock type-specific trends for sericite schist and diorite. For example, taking into account only the data points of the mica gneiss samples in Figure 6b or Figure 7c, it seems as if the correlation between k_s and sulfide content is positive instead of negative. Nonetheless, additional data points for these rock types would be necessary to verify this observation.

Correlation analysis of the detected mineral phases and k_s-values showed that the major mineral phases govern the wear behaviour of the pebbles during autogenous grinding. Although the results derived from both techniques did not coincide entirely, similar correlations with the grindability indices were observed. These correlations seem reasonable, as some samples comprise >50 per cent of a single mineral phase. However, sulfides were shown to correlate with the grindability indices even though their proportions are generally below 5 per cent by weight. Strong negative correlations were observed between plagioclase, mica, quartz, and sulfides (Figure 5). Additionally, quartz, micas, and sulfides were shown to correlate positively with k_s, whereas plagioclase was found to have the strongest negative correlation with the k_s-values (Figure 5). This observation is reasonable since an increasing plagioclase content is accompanied by a decrease in the proportions of quartz and micas, amongst others, resulting in a decreasing k_s-value. Thus, plagioclase may be the actual steering force in terms of grindability. No correlations were observed for K-Feldspars in all size fractions. For some samples, high correlations of titanite, apatite, chlorites, and barite were detected. However, the mineral content of these phases is typically below 0.5 per cent. Hence, the influence of these mineral phases on grindability is unlikely. The correlations between k_s-values and the chemical composition of the samples (Figure 8) are meaningful. Elements such as Al or Fe occur in several minerals identified during this study. However, they cannot be related to a specific mineral. Fe, which positively correlates with k_s, is mainly present in biotite, amphiboles, and sulfides. Both micas and sulfides have shown positive correlations with the grindability indices, whereas amphiboles have shown no correlation. Therefore, the positive correlations between the grindability indices and Fe are likely due to the biotite and sulfide content. Sulfur has shown a positive correlation and is principally present in chalcopyrite, pyrite, and pyrrhotite, which, when grouped, have shown a positive correlation. Aluminium oxide (negative correlation) is, amongst several others, a compound of the minerals of the plagioclase and mica groups. However, considering that plagioclase is the main mineral phase within the samples, the negative correlation of aluminium oxide is probably attributed to the strong negative correlation between grindability indices and plagioclase. The negative correlation between plagioclase and micas supports this assumption. Calcium oxide occurs in plagioclase, amphiboles, and clinopyroxenes. However, amphiboles and clinopyroxenes are only minor mineral phases. Hence, the positive correlation of calcium oxide is possibly related to the negative correlation between plagioclase and grindability indices.

Mineral liberation encompasses random and non-random breakage (Gaudin, 1939, as cited in Guldris Leon, Hogmalm and Bengtsson, 2020). The former occurs due to the random formation and propagation of fractures within the mineral grain induced by comminution action, whereas the latter is associated with fracture propagation along the boundaries of the mineral. It is unknown which of the mentioned mechanisms was predominant during the wear tests conducted within this study. However, considering that abrasion constantly scrubs material off the pebble's surface, it is likely that random breakage prevails. In general terms, high proportions of fully liberated minerals were observed across all sampled size fractions. This observation may be linked to the relatively long grinding times of over 60 minutes, as mentioned further above, liberating most mineral grains. The data showed that the degree of liberation of plagioclase and mica is generally lower within sericite schist samples (Figure 11). This behaviour may be related to the high k_s-values of this sample type and the higher proportions of coarse particles generated during grinding. Hence, these coarse particles are less likely to be fully liberated. Plagioclase and mica minerals are known to have one plane of perfect cleavage, along which preferential breakage may occur. However, the tendency of less fully liberated particles was only observed for sericite schist and not for other samples containing these two mineral phases. In the case of chalcopyrite, the degree of liberation within the 45–90 µm size class was higher than in the 0–45 µm size classes. This occurrence may be due to chalcopyrite's liberation size falling within the 45–90 µm size class or fine particles from the 0–45 µm fraction sticking to the surface of liberated chalcopyrite grains. The latter would result in the QEMCAN-analysis not being able to identify these particles as liberated. The reasons why solely plagioclase content correlates with k_s are unknown.

Concerning the preferential wear of mineral phases, Figure 12 suggests that the observed mineral ratios change within the same size class, meaning that different proportions of minerals are deposited. For example, in the 45–90 µm fraction, after 150 minutes of grinding time, the quartz content of the diorite has increased, whereas it strongly decreased in the case of mica gneiss, only to rise once more for sericite schist (Figure 12a). However, this development may also be attributable to the mineral phases appearing in different proportions within the rock types. However, as for the 0–45 µm fractions, the mineral ratios are approaching one, indicating that the mineral composition of the fine size fractions after 60 and 150 minutes of grinding are more alike each other. Therefore, fine particles are abraded in a more homogenous and constant manner, resulting in similar mineral compositions at different grinding times.

CONCLUSIONS

The following conclusions can be drawn from the performed work:

- Abrasive grinding tests were performed on samples derived from rock types of the Aitik mine: diorite, mica gneiss, and sericite schist. Divergent degrees of grindability, expressed through the wear index k_s, were reported within and across the rock types. The abrasion resistance decreased from diorite over mica gneiss to sericite schist samples.
- Sieve analyses of the grinding products showed that particle size distribution varied according to rock type. High k_s-values generated a high % weight loss and a relatively coarse grinding product, whereas low k_s-values implied a low % weight loss and a finer grinding product.
- Results from XRD and QEMSCAN indicated the presence of similar mineral phases in the selected samples, though mineral content varied throughout the rock types. Plagioclase, quartz, K-Feldspars, and micas were identified as the main mineral phases, followed by minor amounts of amphiboles, chlorites, clinopyroxenes, and sulfides. Correlation analyses showed strong correlations between the main mineral phases and the k_s-values. It was determined that decreasing mica, quartz, and sulfides content and increasing plagioclase content result in a low k_s-value and vice versa. Plagioclase content is likely to dominate the response to abrasive grinding.
- The sample's chemical composition provided by XRF appeared to correlate with the respective k_s-values, supporting the findings mentioned above.
- A negative correlation between the weighted average Mohs hardness calculated from the sample's modal mineralogies and the grindability indices was found. Hence, it was proposed that a higher Mohs hardness results in a finer grinding product, oppositional to the k_s-values. Since k_s is interpretable as a measure of abrasiveness, it can be stated that an increase in sample hardness results in a lower abrasiveness and vice versa.
- There was little evidence for the preferential wear of specific mineral phases. However, it was observed that abrasive grinding results in a continuous and consistent removal of mineral particles from the sample's surface.
- The applied abrasion breakage mechanism leads to a high degree of liberation of gangue minerals and chalcopyrite. The only significant correlations between k_s and liberation parameters were found for plagioclase. With an increasing k_s-value, the liberation of plagioclase grains decreases.

ACKNOWLEDGEMENTS

The authors appreciate Boliden Mineral's provision of sample material from the Aitik mine and the financial support concerning sample analysis. Furthermore, the authors thank Boliden for granting access to the company's mineral laboratory for conducting wear tests and investigations by automated mineralogy. The assistance from Boliden's laboratory personnel concerning sample preparation is greatly appreciated. Thank you to Peter Karlsson from Aitik Boliden for assisting regarding sample selection and dispatching to Boliden.

ABSTRACT

Online analysis of continuous and batch processes has seen a dramatic increase in recent years, with examples ranging from petrochemicals to pharmaceuticals, to industrial biotechnology and food and drink. The particularly challenging environment of alumina processing has meant that instrumentation needs specific features and characteristics to be truly suitable, features such as: robustness, resistance to caustic conditions both in the analyte and the ambient environment, and reliability for long-term continuous use. Here we present the development of a novel FTIR spectrometer that achieves these requirements through the use of a static optics arrangement of mirrors, and stable diamond-tipped light-pipe probe.

Firstly we give a very brief explanation of spectroscopic analysis, and the difference between FTIR and other infrared methodologies. Next we outline the novel arrangement of mirrors required to produce an interferogram without moving mirrors, and compare the benefits and drawbacks of this approach instead of conventional designs.

We then share the results of laboratory analysis of synthetic Bayer liquors, with detection limits for aluminium hydroxide, sodium hydroxide, sodium carbonate and various sodium salts of organic acids. We then share the results of analysis on production samples, both in idealised laboratory conditions and then online in the process itself.

Lastly we present work on in situ ultrasonic descaling solutions to avoid scale build-up and provide continuous cleaning of the probe – preventing the need for probe removal and manual cleaning.

INTRODUCTION

Online process analytical technology (PAT) is an important area of development in a wide range of industrial processes (Bakeev, 2008; Chew and Sharratt, 2010) and a key element of Industry 4.0 – the commonly accepted fourth industrial revolution we are currently experiencing. Traditional instrumentation (such as pH and temperature probes) is being complimented with more advanced techniques such as spectroscopy.

Spectroscopy can be defined as the interaction of light with matter, and the wavelength and energy of the light absorbed determines the underlying interaction studied. A full explanation of all the different spectroscopic techniques and wavelengths is beyond the scope of this article and is available elsewhere (Atkins, De Paula and Keeler, 2006). The majority of PAT implementations make use of vibrational spectroscopy – namely near-infrared (NIR), Raman and mid-infrared Fourier transform (FTIR) spectroscopies. The work shown in this article uses a static optics FTIR spectrometer. A brief summary of conventional and static optics interferometers is explained below.

Conventional FTIR interferometer design

Conventional FTIR instruments make use of a Michelson interferometer (Michelson and Morely, 1887), as shown in Figure 1. The light is created by a light source (1), such as a silicon carbide infrared emitter. This light is shone onto a beam splitter (2) which sends half the light onto a stationary mirror (3) and the other half onto a moving mirror (4). The light that runs on the stationary path always has the same distance to travel, whilst the path length of the light on the moving mirror changes over time. The light is then recombined at the beam splitter (2) before interacting with the sample and finally landing on a detector (5). The detector is a single pixel of material such as lithium tantalite, deuterated triglycine sulfate or mercury cadmium telluride. The difference in path lengths (caused

by the moving mirror) creates an interference pattern that changes over time (as the mirror moves).This interference pattern is subjected to a Fourier transform (the ‘FT’ in ‘FTIR’) which ultimately creates a spectrum.

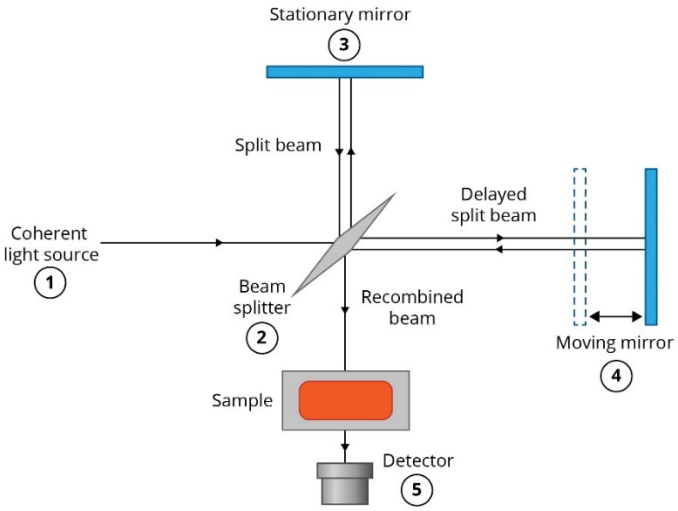

FIG 1 – A schematic of a Michelson interferometer showing light path from the light source through the pair of mirrors, the sample and eventually onto a single-pixel detector.

Static optics FTIR interferometer design

The static optics instrument design outline here makes use of a Sagnac interferometer (Sagnac, 1913), as shown in Figure 2. In this instance, the light (from a low powered source) runs through the sample first, before hitting a beam splitter (1). Half the light is reflected to run anti-clockwise through a pair of curved mirrors (2) whilst the other half is transmitted through the beam splitter to run clockwise through the pair of mirrors. Both beams of light are then incident onto a detector array (3) creating an interference pattern with respect to space directly onto the array. This interference pattern is subjected to the same Fourier transform mathematics as conventional designs.

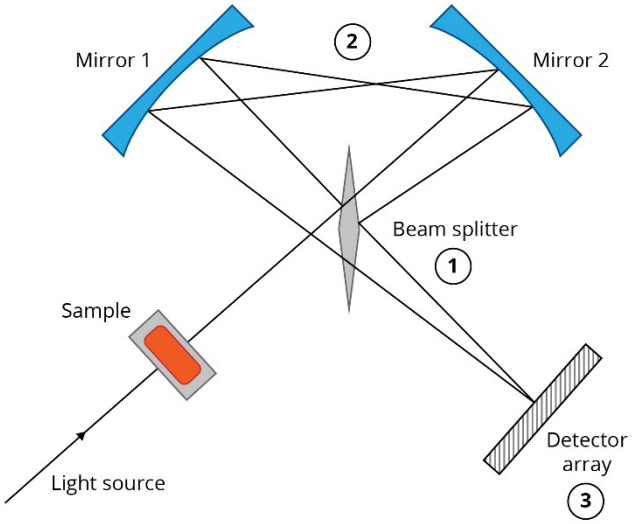

FIG 2 – A schematic of the modified Sagnac interferometer showing the light path through the sample, then the ‘Sagnac loop’ before the detector array.

The use of a ‘Sagnac loop’ of mirrors removes the need for moving mirrors and enables the use of secured mirrors onto an industrial baseplate. Ultimately this translates into a design that is significantly more resilient to vibration, as if one aspect of the optical design vibrates then the whole assembly vibrates – resulting in no change in the interference pattern and final spectrum.

RESULTS AND DISCUSSION

Detailed description of initial stage laboratory testing of synthetic Bayer liquors has been described previously (Speed and Wood, 2020). Briefly, a range of laboratory reference samples was made, and these were used to build a calibration curve using partial least squares (PLS) (Wold, Sjöström and Eriksson, 2001) methodology. Laboratory samples were prepared as follows: stock solutions of 607.5 g L^{-1} sodium hydroxide (NaOH), 75 g L^{-1} sodium carbonate (Na_2CO_3) and 155 g L^{-1} aluminium hydroxide ($Al(OH)_3$) dissolved in 328 g L^{-1} NaOH solution. These were mixed and diluted with additional water as appropriate to make a 'Design of Experiment' sample set for calibration.

A table of collated laboratory performance is shown below in Table 1. The results are reported as RMSECV (root mean squared error of cross validation) which is the average error during calibration. It is also a good approximation to limit of detection (LoD) for a calibration. It is highly affected by the absolute concentration range studied – in general higher concentration values have a higher RMSECV.

TABLE 1

Table of performance for laboratory calibrations of synthetic Bayer liquor.

Chemical name	RMSECV/g L^{-1}
Sodium hydroxide	7.38
Sodium aluminate	4.69
Sodium carbonate	1.36
Sodium oxalate	0.11
Sodium acetate	0.26
Sodium formate	0.27
Sodium succinate	0.31

Online process results

Following successful laboratory studies an online installation was performed directly into the spent liquor line in an alumina refinery in Europe. The instrument was installed using a welded flange directly into a side loop from the main process stream. This gives the ability to remove and inspect the instrument from time to time if required without affecting the daily production schedule of the refinery.

Spectra were recorded continuously with a 120 s averaging time, over one year. Calibrations were performed using spectra collected online from the instrument using reference data provided by the refinery, with primary laboratory quantitative analysis performed using a range of techniques such as ion chromatography (IC) and titration. Chemometric calibrations were built on the spectroscopic data using a combination of PLS and support vector regression (SVR) methods (Smola and Scholkopf, 1998).

A collated table of results for online process calibration using real world samples is shown below in Table 2. This table includes the RMSECV but also RMSEP (root mean squared error of prediction) which is a validation error – ie the average error predicting the concentration of samples not included in the calibration at all – and RPD (residual predictive deviation), defined as the standard deviation of reference data divided by the RMSEP. This allows the user to understand the capability of the calibration to be used for real-time control. Values greater than three are good for screening, greater than five show a strong and highly performing calibration suitable for quality control and above eight are good for analytical analyses (Conzen, 2014).

TABLE 2

Table of results for online calibration results.

Chemical name	RMSECV/g L^{-1}	RMSEP/g L^{-1}	RPD
Sodium hydroxide	1.76	1.12	1.97
Sodium aluminate	1.61	1.87	1.86
Sodium carbonate	1.07	0.36	6.33
Sodium oxalate	0.115	0.096	1.07
Sodium succinate	0.050	Not enough data	Not enough data
Sodium formate	0.067	0.10	Not enough data

The output of these calibrations for the inorganic compounds is shown below in Figure 3. The measurement is shown as a continuous line with the offline laboratory sampling overlaid. It is clear that the laboratory data shows good agreement with the majority of the online measurements, but there are several laboratory measurements that do not agree, and moreover do not agree with the trend of the measurement before or afterwards. Work is ongoing to determine whether these data points are in fact laboratory or human error, or whether the calibration needs refining to reflect these measurements.

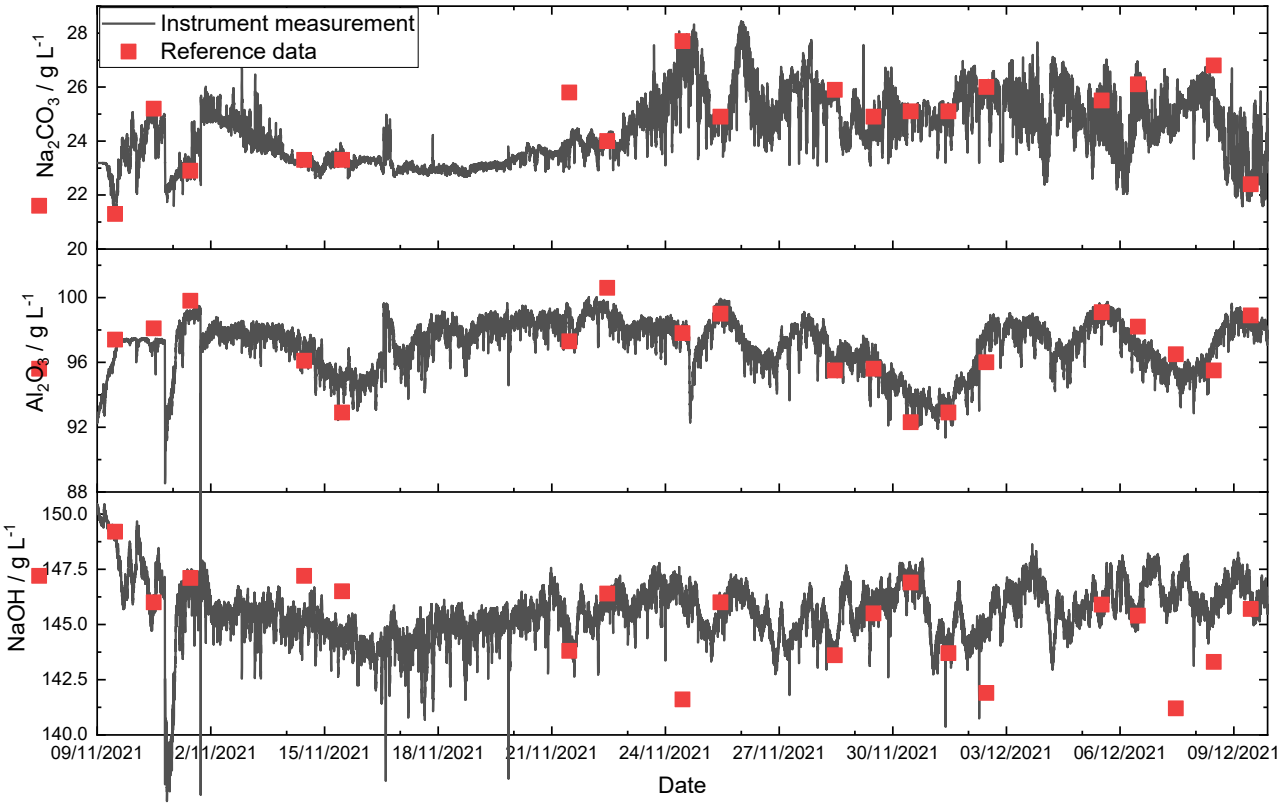

FIG 3 – Graph of spectrometer measurements over time overlaid with reference data from laboratory for inorganic compounds of interest for November and December 2021.

It should be noted that the 'spikes' seen in the data above are in fact real measurements caused by washing of the filters installed nearby to the instrument where periodic dilution of the liquor lasts for approximately 30 min. This appears as a 'spike' on the data above because of the timescale used.

The calibration for organic salts is shown below in Figure 4. It shows a good agreement between the oxalate reference values and instrument measurement, clearly highlighting the peaks and troughs in concentration over time. The succinate and formate concentrations are more stable, but increasing

succinate concentrations from January 20 through to 25 is clearly evident and would have been missed purely with offline sampling.

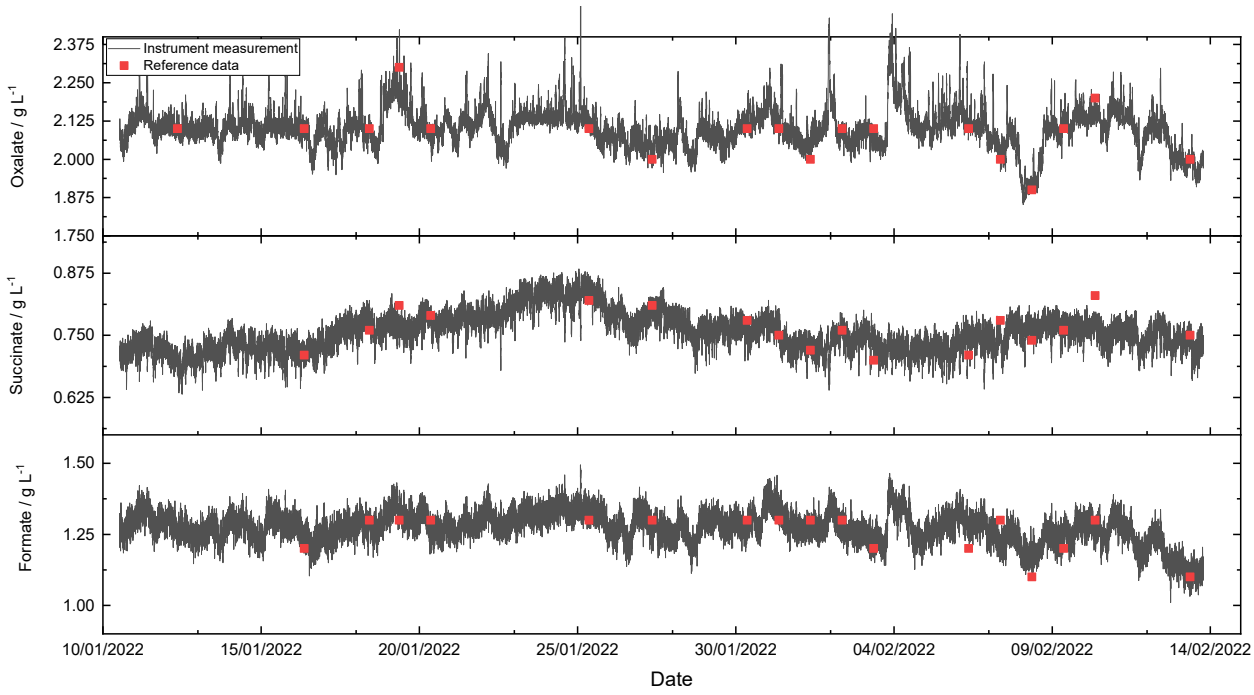

FIG 4 – Graph of spectrometer measurements over time overlaid with reference data from laboratory for organic compounds of interest for January 2022.

Preliminary descaling results

The spectrometer probe has been designed with an attenuated total reflectance (ATR) sensing tip that requires contact with the liquid to be studied. A potential issue with this is the formation of scale on the end of the probe, which could prevent the wetting of the diamond ATR element. The instrument presented here has been installed in a spent liquor stream for greater than 12 months without scale formation, but use in other locations in alumina refineries are highly likely to scale. Preliminary results have shown that scale can be removed from the end of the probe using an ultrasonic pulse. This is shown in Figure 5 – where the intensity of water, dissolved $Al(OH)_3$ and precipitated Gibbsite scale are measured before, during and after an ultrasonic pulse.

These results are very encouraging, but do require an ultrasonic generator strong enough to permeate through the pipework around the probe. Work by the author in the pulping sector has investigated the formation of pirssonite scale (a calcium, sodium carbonate mineral) on the end of the probe during use, and it is possible to identify its formation using FTIR spectroscopy, and then easily remove it using 1 M hydrochloric acid (HCl) solution in approximately 1 hr.

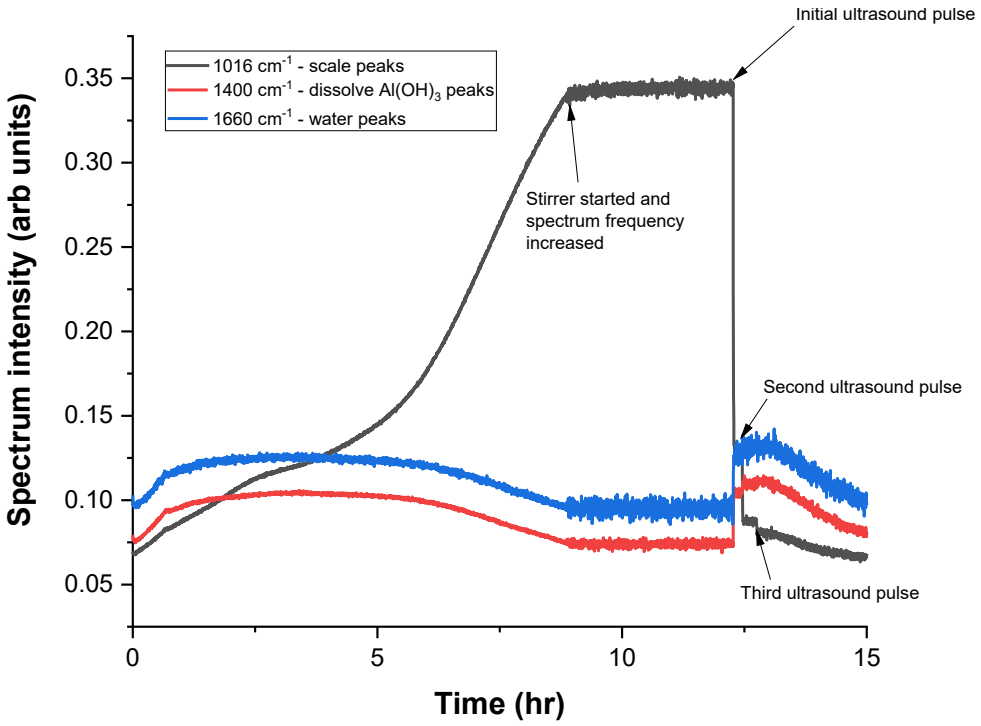

FIG 5 – Intensity of peaks for scale (1016 cm^{-1}), dissolved $Al(OH)_3$ (1400 cm^{-1}) and water (1660 cm^{-1}) at various stages throughout the experiment. (It can be seen that the scanning frequency is 10 s overnight and is increased to 1 s frequency during the ultrasound pulsing).

CONCLUSIONS

This work shows that FTIR spectroscopy is an effective tool for the measuring of alumina refining, and that robust and reliable measurements can be achieved when conventional interferometry is replaced with Sagnac interferometry. It is possible to measure dissolved alumina to an accuracy of 1.61 g L^{-1}, sodium hydroxide with 1.76 g L^{-1} and sodium carbonate to a level of 1.07 g L^{-1}. Moreover it is also possible to simultaneously measure different organic acids with the same instrument, with oxalic, formic and succinic acid measurements of 0.115, 0.067 and 0.050 g L^{-1} limits of detection respectively.

Lastly, the use of ultrasonic cleaning has been demonstrated to remove scale from the tip of the instrument with no damage or interference to the working of the instrument itself. However a 12 month installation in spent liquor has not resulted in any scale forming on the probe, showing that some applications are robust to scale formation and may not need any intervention.

Advances in mineral processing – comminution

A standardised method for the precise quantification of practical minimum comminution energy

ABSTRACT

This paper explores development of a novel ore characterisation method for the precise measurement of practical minimum comminution energy. A monolayer of particles with a narrow size distribution is broken using a precision rolls crusher (PRC); an ore characterisation device developed to overcome the shortcomings of conventional tests. For energy measurement, PRC uses two shaft-mounted rotary torque transducers. These transducers acquire precise torque and angular speed data in response to the load applied to the rotating shafts during breakage events, which is converted into energy. The test progressively crushes feed particles down to final product size in many controlled breakage stages. The generation of fines in each breakage stage is then plotted as a function of input energy. The inverse of the gradient of this plot provides the size specific energy (SSE) in kWh/t of material generated below a predefined marker size; -75 µm in this case. The PRC has potential to evolve as a geometallurgical ore characterisation test—it is simple, fast, requires small sample mass (200–300 g), covers a wide feed particle size range (10 mm to 115 µm), and provides ideal SSE measurements that can be used for the calibration of on-site production equipment.

INTRODUCTION

The endemic issue of not achieving the design throughput in comminution circuits relates to the selection of incorrect design criteria and the use of inaccurate models (Bueno *et al*, 2015). Incorrect design criteria include poor quality of test work, misinterpretation of results, and orebody variability. Orebody variability is based on spatial changes in geological structures and physical properties of the minerals present within the resource. Ore characterisation comes first in the design process, and it needs to be executed carefully as this underpins the entire circuit design. Since comminution is accountable on average for 37 per cent of mine energy consumption (Ballantyne and Powell, 2014), quality test work in ore characterisation is of significant importance. Ore characterisation provides useful information in understanding rock breakage behaviour and in establishing the relationship between input energy and size reduction. The traditional approach in ore characterisation involves testing representative reference samples across the orebody. Using geometallurgical principles, these reference samples can be used to establish spatial geometallurgical domains (Dunham and Vann, 2007; Lund, 2014). Combining these geometallurgical domains with the mine plan can provide a year-by-year estimate of the feed material that can be used for comminution circuit design. To allow for more extensive geometallurgical campaigns, ore characterisation needs to be fast, economical, and should have low sample requirements. Various characterisation methods have been developed to date. A comprehensive review has been reported by Mwanga *et al* (2015) and Chandramohan *et al* (2015) except for two recent developments by Böttcher *et al* (2021) and Bueno *et al* (2021). Widely used tests include the Bond work index test (Bond, 1952), drop weight test (DWT) (Napier-Munn, 1996), rotary breakage test (RBT) (Shi *et al*, 2006), SAG mill comminution (SMC) test (Morrell, 2004), Starkey SPI test (Starkey *et al*, 1994; Starkey and Dobby, 1996), and Starkey SAG design test (Starkey *et al*, 2006). These tests can be used to provide relatively risk-

free designs by using well-understood benchmarks developed over decades of operation. However, the required large sample size and test cost mean these tests are prohibitory in fully addressing ore variability, which can lead to results that are not representative for some ore types.

The fundamental comminution laws report an exponential increase in energy consumption at the fine particle size range (Hukki, 1961). Therefore, methods are required for accurate measurement of energy in the fines as it covers the major portion of energy consumption. However, the issue is the unavailability of a suitable method to quantify the energy requirements of individual, fine particles. In practice, many comminution models use values of A x b determined through DWT or RBT on the coarser particle size range, and Bond rod and ball milling tests in the fine end (Lane *et al*, 2013; Powell *et al*, 2014). Although various attempts have been made to measure the energy consumption of fine particles. These include micro compression testing of single particles by Farias *et al* (2014) and Romeis *et al* (2015), the application of the nano-indentation method to measure the fracture energy distribution of ultrafine particles by Schilde and Kwade (2012), Impact testing of particles beds by Barrios *et al* (2011), application of JK rotary breakage tester and Schonert device to determine size specific energy by Ballantyne *et al* (2015), and monolayer impact breakage using modified SILC test (Tavares and King, 1998) by Reja (2017) and using a mini drop weight by Yu *et al* (2019). However, all of these methods require tedious experimental work and extensive time, making their use impractical for geometallurgical sample testing.

Well-controlled single particle breakage under compression is the most effective way of determining primary fracture energy (Schönert, 1971) as it relates to the strain energy required for inducing bulk fracture within a particle (Tavares and King, 1998; Tavares, 2007; Tavares *et al*, 2020). However, this method is only proficient for coarse particles. Generally, single particle slow compression of small particles (<250 μm) is not suitable for industrial applications due to extensive cost and time requirements. Secondly, it provides limited information on the resulting progeny distribution. The recent application by Böttcher *et al* (2021) of breakage in monolayers based off the design of Powell, has shown promising results for particles below 150 μm. Particles were broken between a set of rigidly mounted rolls, and the breakage response was recorded as a profile of compression forces along the entire length of roll, referred to there as line load, expressed in N/mm. The line load was used to calculate compression stress that should be comparable to the particle strength measured by single particle compression testing, for instance measured by Schönert (1991).

The standard practice in the mining industry to determine the efficiency of a comminution unit is using a ratio between the operating work index and the Bond work index. The P_{80}-based methods have an underlying assumption that the feed and product distributions need to be parallel in log-log space (Bond, 1952). This makes application of the Bond test inappropriate for modern comminution equipment such as SAG mills, which produce considerably more fines relative to the P_{80} value than a ball mill; and stirred media mills, which produce a steeper size distribution with less reduction of the P_{80} size (Ballantyne *et al*, 2021). The test outcomes therefore can be misleading – an example is the incorrectly calculated inefficiency of the SAG mill relative to a ball mill when assessed using the Bond test.

Powell *et al* (2003–2010) proposed size specific energy (SSE) as an alternate method to measure ore competence. Size specific energy refers to the amount of energy consumed in generating material below a certain marker size (Powell *et al*, 2003–2010; Ballantyne *et al*, 2015). Typically, 75 μm is used as a standard marker size and SSE75 is measured. Musa and Morrison (2009) reported that for typical circuits that involve AG/SAG, HPGR, or ball milling, 75 μm material is a suitable marker size to benchmark equipment performance because material below this size contains 80 per cent surface area of the new surfaces generated. The application of SSE eradicates limitations of P_{80}-based tests and depends more on the generation of fines rather than P_{80}. The concept of size specific energy has been in use since the beginning of the 20th century when Davis (1919) used this method to measure the efficiency of the ball mill. Ballantyne *et al* (2015) established a linear relationship between specific energy and production of minus 75 microns material by breaking particles from a wide particle size range on JKRBT and Schonert devices. Reja (2017) applied the SSE method to determine minimum comminution energy by breaking a monolayer of particles using an impact load cell. And more recently, Ballantyne and Giblett (2019) reported that the SSE approach is an effective way to determine the efficiency of comminution circuits and individual equipment. However, determining SSE using single particle impact breakage, as in DWT

or JKRBT is still questionable. Studies in comminution testing and ore characterisation suggest that conventional single particle breakage tests such as the Drop Weight Tester (DWT) and the equivalent Rotatory Breakage Tester (RBT) have limited ability to provide a precise and accurate measure of the SSE. These devices are limited in a number of ways:

- inaccurate application and measurement of low energy impact
- insufficient generation of fines (sub 100 µm) for use in calculating the SSE
- inability to apply appropriate energies to small particles (below 5 mm)
- unable to achieve the ideal of primary fracture only.

Therefore, the development of a suitable method that employs the SSE method using single particle breakage and can be used to benchmark other lab-scale equipment, and industrial comminution devices and circuits is critical. This will allow the determination of practical minimum energy requirements for comminuting different types of ores on-site and will provide the opportunity to uplift the baseline performance of the comminution circuits by identifying underperforming units. Figure 1 shows a comparison between the specific energy measured on-site versus using bulk grindability tests, and single particle breakage for the same amount of material produced below 75 µm. The 'Missing data' in the graph represents the data gap that existing single particle breakage methods fail to populate.

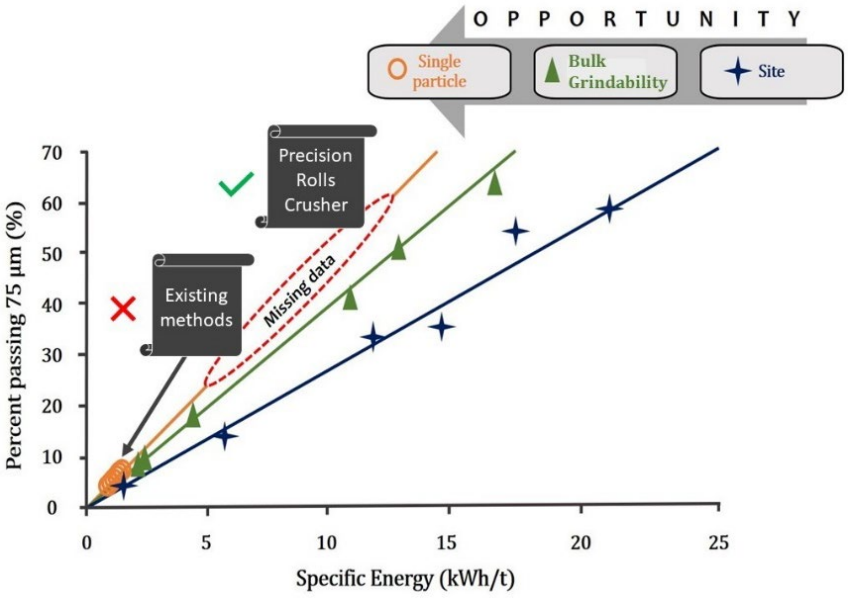

FIG 1 – Comparison of specific energy measured on-site versus specific energy measured using bulk grindability tests and single-particle breakage tests for the same generation of -75 µm material (modified from Reja, 2017).

This publication explores the development of a novel ore characterisation method that will provide practical minimum energy requirements in comminution. This method can potentially be used to benchmark operations, assess the energy efficiency of individual units and full-scale grinding circuits, and calibrate productivity improvements. Additionally, the method will be suited to characterising small samples for geometallurgy characterisation.

PRECISION ROLLS CRUSHER

The Precision Rolls Crusher (PRC) is a modern ore characterisation device being developed at the JKMRC, Sustainable Minerals Institute, The University of Queensland for the determination of practical minimum comminution energy. In 2017, a Buaermaeister rolls testing equipment, used in the food industry, was adopted as a prototype for testing the principle. Numerous modifications have been made in-house to make it suitable for comminution testing. Some preliminary test work was conducted internally to explore equipment suitability for ore characterisation. The equipment specifications are listed in Table 1. The concept of a rigidly mounted rolls mill was explored in the

1990s when Furstenau and his peers used similar equipment to study mathematical descriptions of single particle comminution, and for understanding particle interactions and energy dissipation (Fuerstenau *et al*, 1990, 1996; Gutsche *et al*, 1993).

TABLE 1

Specifications of precision rolls crusher.

Manufacturer	Bauermeister
Model	LRC250
Crusher dimensions (L × W × H)	1.4 m × 0.8 m × 1.4 m
Crusher weight	490 Kg
Power supply	415 volts (3 phase supply), 3 kW connected load (1.5 kW for each motor), 50 Hz power frequency
Roll diameter	250 mm
Roll width	80 mm
Roll speed	Individually controlled by frequency converter, 0–12 m/s (0–900 rev/min)
Motor	Induction motor (model 76646 manufactured by SEW-EURODRIVE, Germany)
Motor power frequency	50 Hz
Motor speed	1461 rev/min

A schematic of the PRC is shown in Figure 2. The PRC uses a set of counter-rotating stainless-steel rolls to crush rock particles. Each roll has a diameter of 250 mm and is 80 mm wide. The rolls have a smooth surface and can be controlled to a fixed gap using an adjustable gap assembly. The rolls are driven by 1.5 kW induction motors and are attached to each roll through shafts. Precise rotary torque sensors are installed on each shaft to record the response of rock breakage. The sensors were added with an additional feature of angular speed logging.

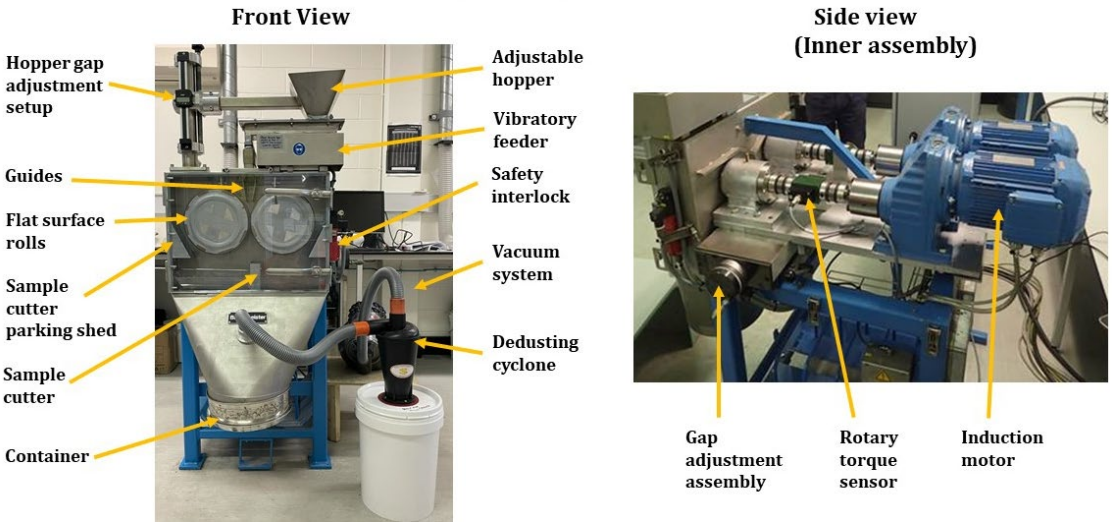

FIG 2 – Schematic of precision rolls crusher.

The Precision Rolls Crusher is fed with a small sample mass of approximately 200–300 g using a rectangular discharge hopper that sits on top of a vibratory feeder. The hopper gap height is adjusted by a dedicated digital hopper gap adjustment set-up to control the feed rate. The vibratory feeder is used to transport the ore particles to fall freely into the breakage zone. A pair of guides are installed to constrain the trajectory of any falling particles on the periphery of the flow and direct them towards

the centre of the rolls gap. The current dimensions of the guides limit the feed particles to below 11.5 mm. The crusher chamber has a plexiglass door that can be locked using a pair of cross-lock handles. A safety interlock is installed on the door that breaks the electrical circuit and stops the machine if the door is opened while the machine is functioning. This prevents the risk of injury. In addition, PRC also has an emergency stop button on the control panel. A sample cutter is installed underneath the set of rolls, to extract representative samples from the rolls product. The sample cutter stays under a parking shed when unattended. Another shed of the same dimension is installed on the opposite side for symmetrical airflow inside the mill chamber. On the inner side of the door, two plastic flaps are attached to the bottom to prevent sample loss when the door is opened for sample recovery. These flaps act as collection chutes and prevent fine dust on the door from spilling during cleaning. Air fines that are generated during breakage are collected using a dedusting cyclone set-up. The dedusting cyclone provides a sharp cut point of the rolls product and delivers almost 100 per cent of the air fines to the cyclone underflow, which allows convenient recovery of fines from the underflow bucket with minimal sample loss. The coarse breakage product is collected in a steel container attached to the bottom of the mill chamber.

A central control panel is used to operate the machine. The panel houses the electrical system of the PRC. It also has a graphic user interface that displays machine inputs. Rolls speed and feed rate are digital inputs to the control unit, while the gap width is adjusted manually. Gap adjustment is made by moving the moveable roll relative to the fixed roll. The moveable roll with its entire assembly is mounted on a sliding table that moves across by rotating a crank attached to the assembly. The changes in the gap can also be monitored on the control unit interface. A lever is used to lock the moveable roll at the desired gap width.

PRINCIPLES OF BREAKAGE

A standard test in the PRC is conducted using an appropriate reduction ratio (RR) between the gap width and particle top size that supplies adequate compression energy required to induce body fracture of individual particles. In practice, after the first pass, the RR is the ratio of rolls gap over the previous rolls gap. The breakage is achieved by testing a uniformly distributed monolayer of particles in a way that the gap is reduced progressively over sequential passes following a constant reduction ratio, and the product is recycled between passes. By doing so, the particles that are smaller than the gap pass through the rolls without breakage, while large particles break, and the breakage response is recorded in the form of torque and angular speed data. The recirculating material does not need screening between passes as was required to perform a similar kind of test work using impact breakage on JKRBT (Ballantyne *et al*, 2015). The test workflow is illustrated in Figure 3.

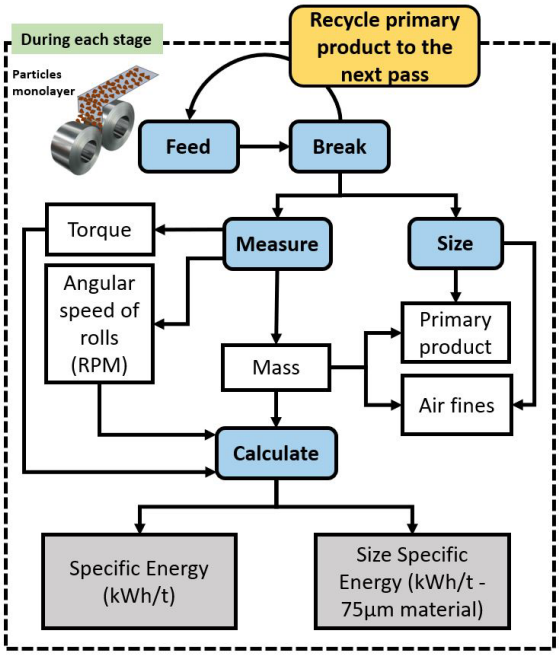

FIG 3 – Process flow in PRC.

A data logging program was developed in LabView 2017 software that takes user inputs to run the experiment, monitors the outputs such as torque and angular speed in real-time, and logs that data automatically to the desired location in computer memory. The data have been acquired at the sampling rate of 400 Hz using data acquisition devices manufactured by National Instruments. A MATLAB script was written to process the acquired data and convert that into energy in kWh. Equation 1 is used to calculate net torque energy during a breakage event. The area under the curve in the torque-time signal is integrated to get cumulative energy consumption during a breakage event (Figure 4). Before each experiment, torque data is logged for approximately 20 seconds at no-load. The average of that data gives no-load torque value that is subtracted from each torque measurement logged during the experiment. This allows discounting no-load torque from the acquired data. Adding cumulative energies for left and right rolls gives the overall energy consumption of a breakage event in the PRC. Dividing the torque energy by feed mass results in specific energy in kWh/t.

$$Net\ torque\ Energy(kWh) = \frac{\pi\left(\frac{\omega}{30}\right)\int_{t_0}^{t_1}[\tau(t)-\tau_0(t)]dt}{3600} \quad (1)$$

Where:

τ = Torque (Nm)

τ_0 = No-load torque

ω = Angular speed (rev/min)

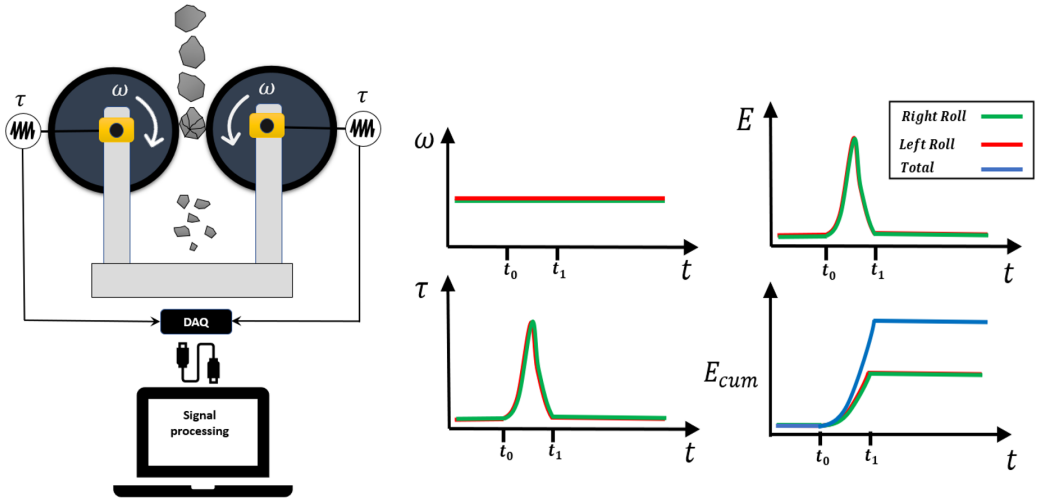

FIG 4 – Concept of breakage and energy logging in PRC.

The PRC employs the concept of SSE at 75 µm marker size. In addition to the accurate measurement of energy for SSE determination, it is equally important to effectively recover the mass of fines generated as both are inputs to SSE formulation ie SSE = Breakage Energy (kWh)/Fines generated below 75 microns (tons of -75 µm material). In a plot of specific energy versus percent new 75 µm generated, the inverse slope of the trend line forced to pass through zero gives SSE (Ballantyne *et al*, 2015).

Mass of material below 75 µm is measured both from the primary rolls product and from the air fines. Air fines that are generated inside the mill are collected during each pass of breakage by the dedusting cyclone and report to the cyclone underflow bucket at 100 per cent below 100 µm. These fines accumulate over a batch of three passes and are recovered after every third consecutive pass. Similarly, a sample from the primary product stream is cut every third pass, although it does not cumulate masses from the previous passes. The extracted sample mass of primary material in the cutter is not added back to the recycled mass, therefore, the extracted mass needs to be adjusted for specific energy calculations. Air fines collected in the vacuum are sized using a sonic sifter, a mechanical sizing method that is well suited to size small samples relatively quickly (Wolcott, 1977).

Breakage of particles in the PRC is analogous to testing particles between two flat parallel plates given that the feed rate is kept very low, and the particles are spread out uniformly along the roll

length to avoid interaction. The latter is achieved using an adjustable feed hopper that ensures a monolayer of particles leaves the feeder. Furthermore, the ratio of roll diameter to particle size is rather large which almost eradicates the effect of rolls curvature on particles and makes the concept similar to the compression of particles in a press. However, the strain rate in PRC cannot be controlled as in slow compression.

The validity of particle monolayer breakage relative to a single particle breakage was verified through a comparative analysis of specific energies and size distributions of the resulting progeny when particles were broken in the form of monolayer and singly on PRC (Figure 5). Particles of size class +6.7 mm -8 mm from a hard rock homogenous sample were chosen for the study. Results showed a match of specific energies within one standard deviation. Also, the resulting progeny distributions from both cases overlapped (Figure 5).

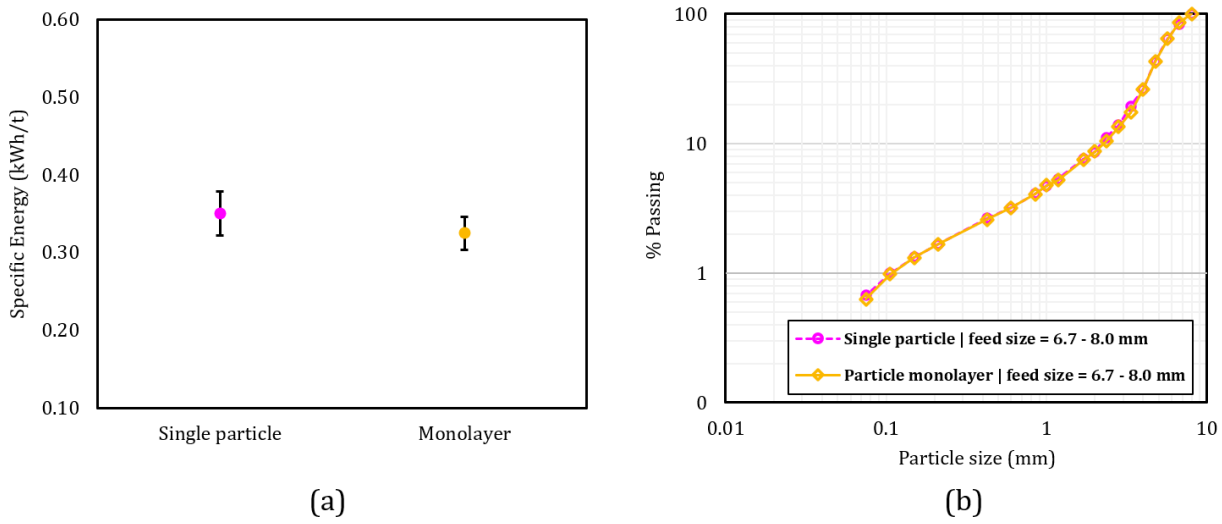

FIG 5 – (a) Comparison of specific energy measurement for the breakage of particle monolayer and single particles (b) Resulting progeny distributions.

Additionally, high-speed filming was used to ensure the breakage of particles singly, however, particles below 1.7 mm could not be captured by the camera due to the limitation of camera resolution. For coarse particles, ie >1.7 mm, it was observed that particles were falling individually in the breakage zone with little to no interaction with other particles. However, when the particles get smaller in size, their population density on the feeder increases which might result in particle interactions. This interaction seems to be random between particles of different sizes. Since knowledge of fine particle interactions in the breakage zone is relatively vague, it can however be hypothesised that generally a large population of particles smaller than the gap sweep through and leave behind a well spread-out layer of only those particles that then breaks normally. Nevertheless, it is still acknowledged that various factors may cause such interactions in the breakage zone, for instance, individual particle geometry, the mass difference between particles, surrounding distance from the other particles, collision during the free fall, etc.

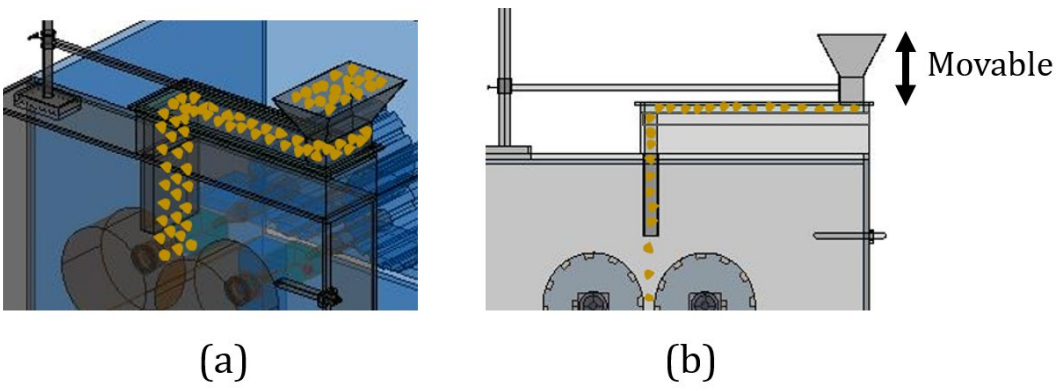

FIG 6 – Particles monolayer formation on the feeder (a) 3D view (b) Front view.

The effect of change in feed rate on specific energy was investigated by breaking particles from three different size fractions, at a range of feed rates that the equipment could reasonably be operated. The results show that breakage specific energy is independent of feed rate for the range tested for all the size fractions tested (Figure 7). The absolute specific energy for each size was dependent on the chosen reduction for that size, so holds no particular significance. High feed rates in the vibratory feeders increase vibrations and so the particle interactions. But since the monolayer was well controlled at hopper discharge (Figure 6), increased feed rates did not affect energy measurements that could otherwise have reflected particle interactions in the breakage zone. The independence from feed rate over almost an order of magnitude in sizes, gives confidence to this being the case for the finer feeds down to 150 µm.

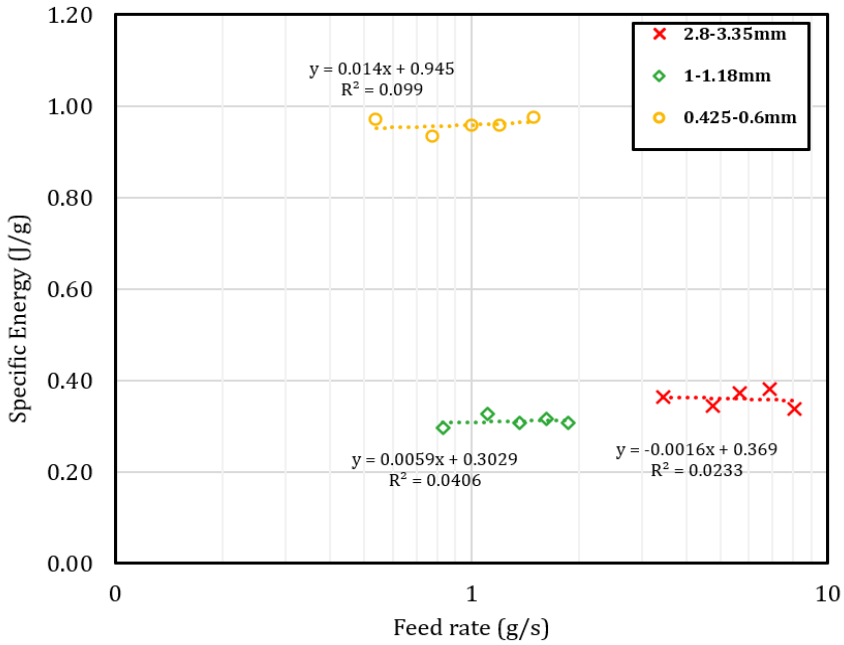

FIG 7 – Specific energy as a function of change in feed rate.

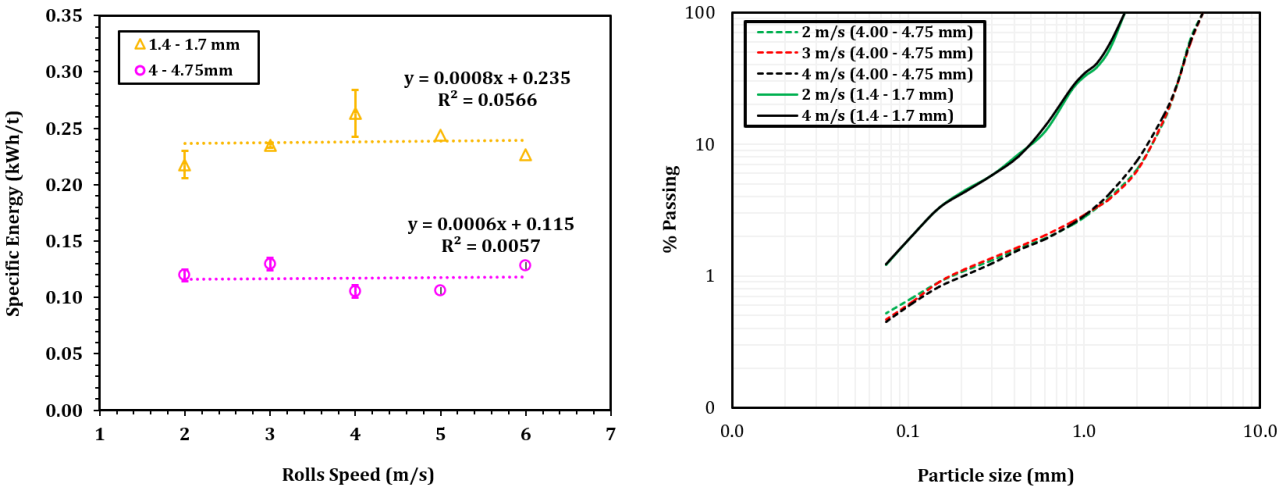
Based on the concern that slip between the particle and the rolls surface as the particle enters the nipping zone could induce an additional breakage mode of sliding abrasion, the influence of varying the speed of the rolls was investigated. The free-fall velocity of the particle was measured using a high-speed camera at a value of 2 m/s. A range of rolls surface speeds of 2–6 m/s was tested for two particle size ranges: +1.4 mm -1.7 mm and +4.00 mm -4.75 mm. Results presented in Figure 8 illustrate that there is no trend in the specific energy value across the range of rolls speed tested. Also, an overlap of corresponding progeny distributions was observed (Figure 8), which is evidence that the change in speed does not affect the breakage event. This indicates that particles most likely do not experience any significant slip due to static friction dominating as the particle enters the nipping breakage zone, as reported by Lieberwirth *et al* (2017). Although no sensitivity to rolls speed was measured, the tip velocity of the spinning rolls was set to the fall velocity of the particles to ensure that differential slip and attrition could be avoided. Additionally, a pair of guides were installed underneath the feeder fall point to direct particles to follow a path towards the centre of the rolls gap, avoiding undesirable bouncing of the particles which can lead to bypassing the breakage zone or interference with other particles.



(a) (b)

FIG 8 – (a) Feed rate as a function of change in rolls speed (b) Progeny distributions at varying rolls speed.

In contrast to user-defined input energy for impact tests, the input energy is a response to the ore competence and degree of reduction in breakage. Thus for the PRC, the specific energy input is recorded as a response to breakage. This response varies depending on the intensity of compression which can be controlled by changing the gap between rolls for particles of fixed size. To test the influence of reduction ratio on breakage energy, progeny size, and SSE, a comparative trial was conducted against ideal single particle breakage.

The SILC uses double-sided impact to break a single particle at a time. A sample of at least 30 particles is selected from a narrow size class to provide a distribution of breakage energies, and the median energy E_{50} represents the energy at primary fracture (Tavares and King, 1998). The SILC was used to measure primary fracture energy and the corresponding progeny distribution was measured. Particles from the same ore type were broken in the PRC using various reduction ratios. The procedure was applied as illustrated in Figure 9 with the objective to find a reduction ratio where progeny distributions matched those from the SILC. Matching results would indicate that primary fracture was being achieved in the PRC.

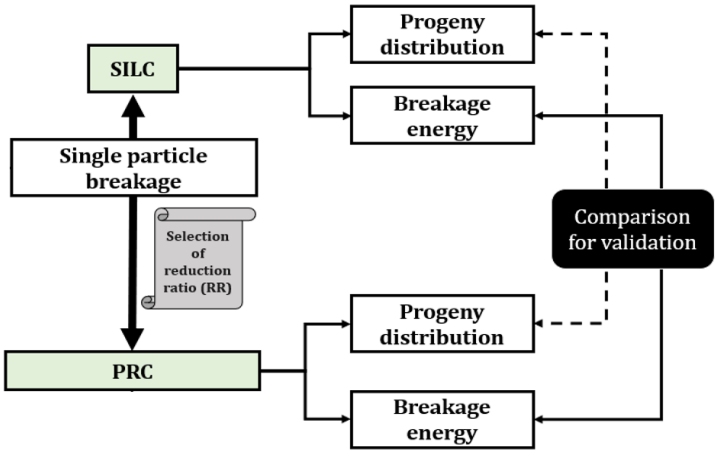


FIG 9 – Experimental approach for the selection of appropriate reduction ratio in PRC.

A rock sample from the size range +6.7 mm -8.0 mm was broken on both SILC and PRC. Results showed that the progeny distributions from PRC were similar to those of the SILC at RR = 0.8 (Figure 10), and close at the fine end below 500 µm. interestingly, the PRC product resulted in slightly steeper size distribution, potentially indicating that there is less secondary breakage than in the SILC device. Table 2 shows the corresponding gaps and nominal feed sizes for different

reduction ratios. The corresponding energy consumption of PRC at RR = 0.80 was slightly lower than SILC input energy, which is calculated using the potential energy of the ball related to the mass of the ball and drop height. The selection of input energy is entirely user-dependent; however, it is generally chosen to be the minimum required to repeatedly induce a bulk fracture of a particle. On the other hand, absorbed energy (E_{50}) is an absolute minimum measure of energy, calculated based on the first peak of the force-time profile captured from the SILC device, representing energy absorbed to first fracture. This does not include any subsequent breakage the rock may undergo.

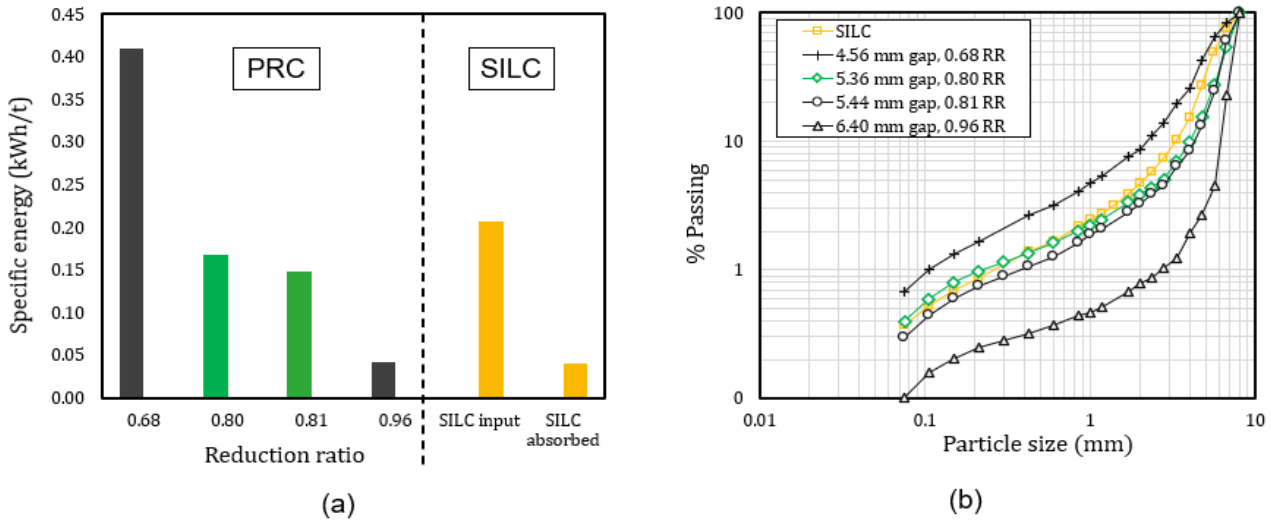

FIG 10 – Comparison of (a) specific energy and (b) resulting progeny distributions of single particle breakage in SILC versus single particle breakage in PRC at various reduction ratios.

TABLE 2

Reduction ratio and corresponding gap widths – PRC versus SILC.

Equipment	Nominal particle size (mm)	Reduction ratio (gap/particle size)	Gap width (mm)
SILC	6.7	NA	NA
PRC		0.68	4.56
		0.80	5.36
		0.81	5.44
		0.96	6.40

A similar kind of test work was conducted on a rock sample having flaky particles and the appropriate reduction ratio was found to be 0.74. As the RR is currently calculated on square-mesh screen size as opposed to the more appropriate minimum particle dimension, it is expected that the more flaky the particle the lower the reduction ratio value to achieve the same degree of compression.

Breaking a population of particles in PRC from a particular size fraction in the form of a monolayer provides statistically significant data on fracture energy considering that each particle is broken singly. The scale of energy measured in PRC is different from E_{50}. The impact load cell has a relative advantage of capturing the heterogeneity at the particle scale. This heterogeneity is acknowledged as the shape, mineralogy, and flaw density can affect the breakage energy of particles even within the same size class (Tavares and King, 1998; Tavares *et al*, 2020). In the PRC, the overall energy required to break a known mass of particles of the same size corresponds to the summation of fracture energies of individual particles. The resolution of measurements in PRC decreases for finer particle sizes. Therefore, the quality of sensors needs to be considered. A set of new torque sensors have been purchased and are being installed to achieve the required resolution.

EXPERIMENTAL

A homogenous hard rock sample was tested for the preliminary test work. Around 300 g of material from a mono-sized fraction of +6.7 mm -8 mm was progressively crushed down to a gap width of 115 µm. A standard operating procedure of the experiment is as follows:

- Equipment warmup – approximately 15 to 30 minutes.
- Setting up experimental parameters such as, gap width, feed rate, and rolls speed.
- Adjusting hopper gap to allow monolayer formation of feed particles on the feeder.
- Logging torque and rolls speed data during a breakage event, including no-load logging before and after, for approximately 20 seconds each.
- Extraction of samples from the primary product of rolls.
- Collection of air fines using a dedusting cyclone.
- Adjusting gap width for the next pass of sequential breakage, and recycling product from the last pass.
- Repeating the process for each progressive gap setting until the desired minimum gap is reached.

Since the method is still under development, the current methodology will be improved. Future improvements include automating the sample cutter which would reduce the dust loss that currently happens due to cleaning and transferring the material when the door is open. In addition, it would also speed up the process as the sample will be collected without the door being opened.

PRELIMINARY RESULTS AND DISCUSSION

The product generated from breaking a monolayer of particles in PRC resulted in a sequential parallel appearance function. Figure 11 illustrates the resulting percent passing as a function of progressive gap reduction. These distributions were calculated on the representative samples of primary products that were collected every third pass of sequential breakage. This appears to be an ideal primary breakage appearance function that can be directly implemented in mechanistic comminution models. Provided that the progeny distribution is parallel, the intermediate steps of sample extraction can be ignored in the future, and rather only the final product can be a focus. This will make the test relatively fast.

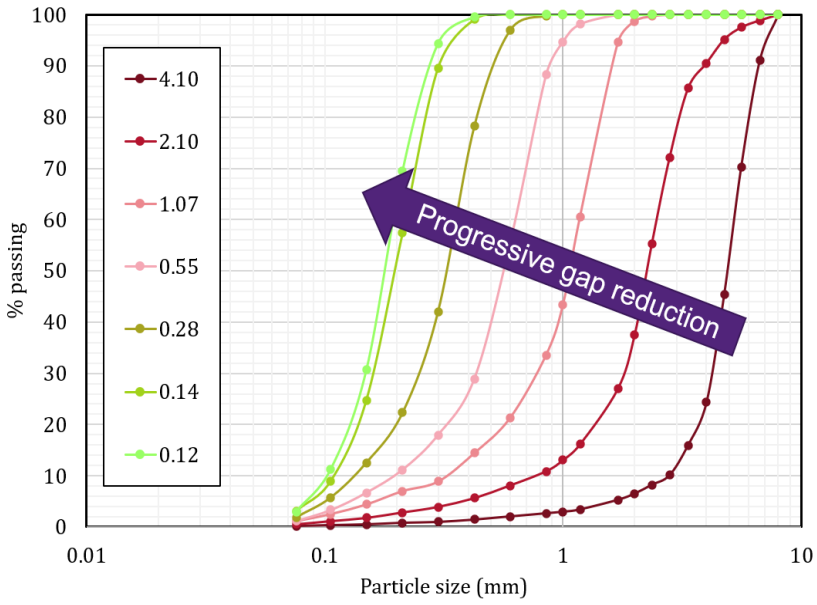

FIG 11 – Parallel progression in the appearance function as particle size or the corresponding gap width decreases.

Plotting gap width versus cumulative specific energy that was consumed to break the feed sample to the desired product size demonstrated an increase in energy consumption as a function of decreasing gap width (Figure 12). The plot fitted a logarithmic model that seems to be fitting reasonably well with an R^2 of 0.99; however, the underlying reason for the logarithmic model fit is still under investigation.

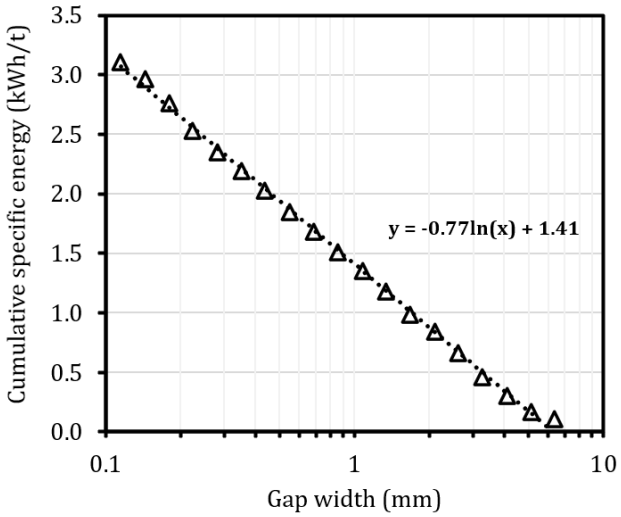

FIG 12 – Specific energy as a function of change in gap width. The dashed line represents logarithmic model fit.

Specific energy versus percent fines generated was plotted (Figure 13). The percent fines generated rather than 75 µm was plotted because the data was captured when the vacuum set-up was being installed and the cut point was not effectively set-up which resulted in some coarse material reporting to the dedusting cyclone underflow. However, it was observed that the amount of oversize (plus 75 µm) material reported to the fines was tiny, below 2 per cent of the fines content, and thus less than 1.5 per cent of the total fines product. Results in Figure 13 exhibited an increasing trend of energy consumption for the production of fines. As shown in Figure 1, a linear trend is typically expected when plotting fines generated versus cumulative specific energy. However, in these tests, this relationship is developed by progressively breaking single coarse particles down to fine particles. Therefore, feed particle size is impacting this relationship as the reduction ratio to produce -75 µm is greater for coarser particles.

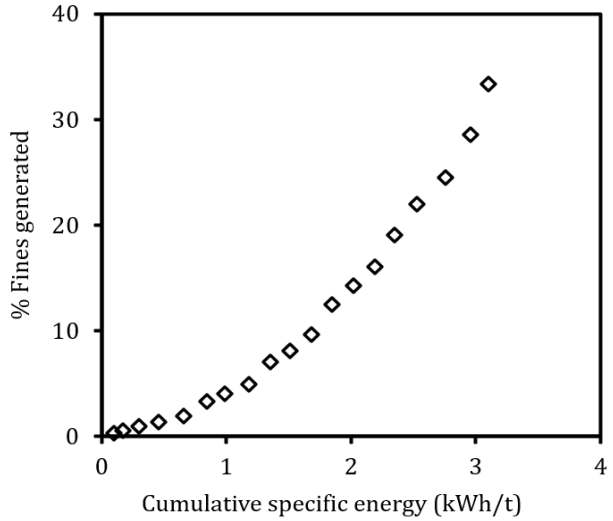

FIG 13 – Plot of specific energy versus percent passing fines generated.

The effect of initial feed size on size specific energy was investigated (Figure 14). The initial feed size was found to influence the size specific energy ie an increase in size specific energy with the

particle size was observed, which was more pronounced at the coarser end. The results are in agreement with a study conducted by Ballantyne *et al* (2015). The reason for this decrease in SSE for finer particle sizes is the lower reduction ratio.

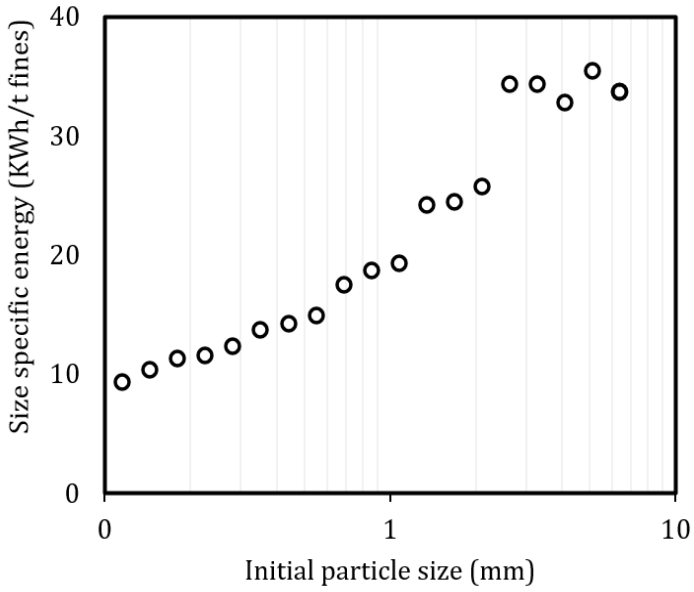

FIG 14 – Relationship between initial particle size and size specific energy.

CONCLUSIONS

The precision rolls crusher, a novel ore characterisation method that uses the concept of SSE to determine practical minimum comminution energy requirements was developed. The feasibility of monolayer breakage of particles that produces similar breakage results to single particle was proven. Also, the primary fracture of ore particles in PRC was targeted through the selection of an appropriate reduction ratio that generated relatively similar progenies as in breakage under impact to achieve primary fracture energy in the short impact load cell. In addition, the influence of various experimental variables such as feed rate and rolls speed was also investigated.

Even in its current initial set-up, the test is relatively fast, inexpensive, and requires a small sample of under 200 g, so has a potential to be used for geometallurgical variability programs. This can supplement recent developments such as Geopyora (Bueno *et al*, 2021), and the double roller mill used for fine particle characterisation. It is capable of capturing the primary ore characteristics, mostly independent of the grinding environment fairly similar to single particle breakage in compression and impact load cell. The ideal practical energy measurements are well suited to benchmark on-site equipment given the test is conducted on the same ore type. The stagewise product obtained from PRC can be used for liberation analysis, and the degree of liberation can therefore be linked to a robust energy measure ie SSE. The generation of ideal appearance function can be used directly in mechanistic comminution models. After some technological improvements to accelerate the testing rate, this device has a foreseeable future for being used in accurate ore characterisation for geometallurgical modelling of orebodies.

ABSTRACT

Dry milling circuits that include high pressure grinding rolls (HPGR) or vertical roller mills (VRM) and air classification have replaced dry ball milling in cement production, but how do they compare to wet milling and classification circuits in mineral processing plants? Two case studies are presented that compare the energy efficiency, wear, liberation and capital cost of dry and wet milling circuits. In both case studies the VRM and HPGR consume half the energy of a wet tumbling mill for the same duty. However, the dry classification system tends to significantly erode the energy benefits. A number of improvement opportunities are presented that have the potential to improve the energy and capital efficiency of dry milling circuits. These improvement opportunities focus on the dry classification system that consumes significant energy in heating and fan power requirements and requires a large proportion of the footprint.

INTRODUCTION

Designing the most cost-effective comminution circuit requires consideration of the ore characterisation, required capacity, power price, grind size and recovery drivers. Wet milling circuits utilising semi-autogenous (SAG), and ball mills are pervasive in the industry as they provide a low capital cost, low risk option that can be employed for a wide range of applications. Ball consumption can be reduced through autogenous (AG) and pebble milling circuits and power consumption can be reduced by using high pressure grinding rolls (HPGR). These technologies are well understood, provide acceptable risk and are known to add significant value given the right project conditions. Extending dry crushing via HPGR or vertical roller mills (VRM) to produce fine particle size distributions has the potential to further reduce power and media consumption. This paper describes the application of dry fine crushing in the minerals industry, how these technologies could be de-risked and the estimated value of these technologies through two case studies.

Fine dry crushing technologies are widely used in cement plants and other industrial minerals plants. However, until recently HPGRs were only considered in tertiary crushing applications prior to ball milling in mineral processing plants (Lane *et al*, 2019). In Australia in the last two years the West Musgrave project and the Iron Bridge project announced they will progress with dry fine crushing to final product size.

The West Musgrave project has partnered with Loesche to develop two parallel VRMs treating nominally 5 Mt/a each. Oz minerals stated that the decision to pursue VRMs in the feasibility study was due to a circa-15 per cent reduction in power consumption and a circa-2 per cent improvement in nickel recovery.

The 67 Mt/a Iron Bridge project (Fortescue, 2019), currently under construction, contains two stages of HPGR with the second stage closed with air classification (Figure 1). The dual HPGR circuit resulted in a 30 per cent reduction in energy consumption and wet tailings (Weir, 2019).

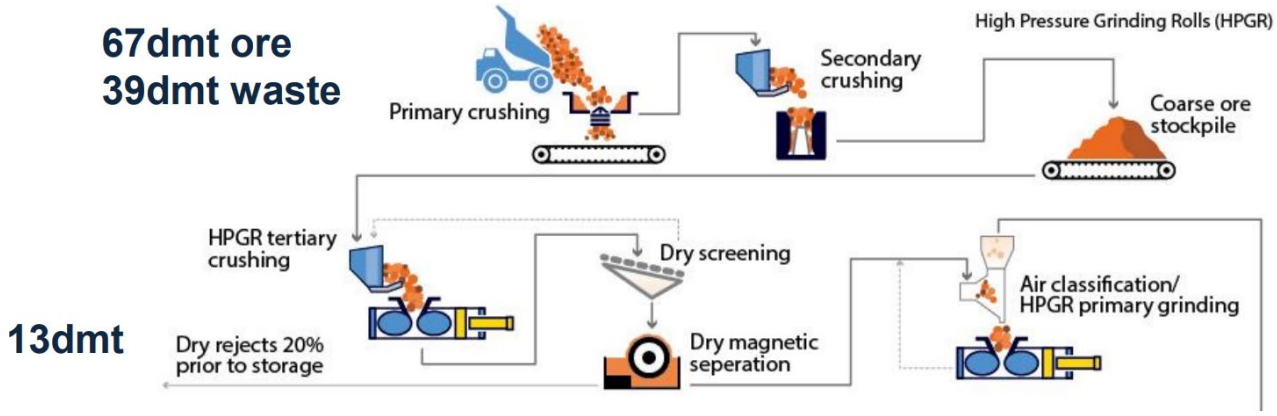

FIG 1 – Iron Bridge dual HPGR circuit configuration (Morrell, 2022).

The operating principal of the HPGR is two counter-rotating rolls compress the material inducing high pressure breakage. One roll is fixed while the other roll is subjected to a pressure and allowed freedom to move (Figure 2). The VRM is similar to a HPGR in that it is a dry compression crusher, the difference in breakage is largely related to the pressing force which is smaller in the VRM, Instead of the two driven opposing rolls of a HPGR, the VRM has a table that is pressurised against rotatable rolls that are not driven.

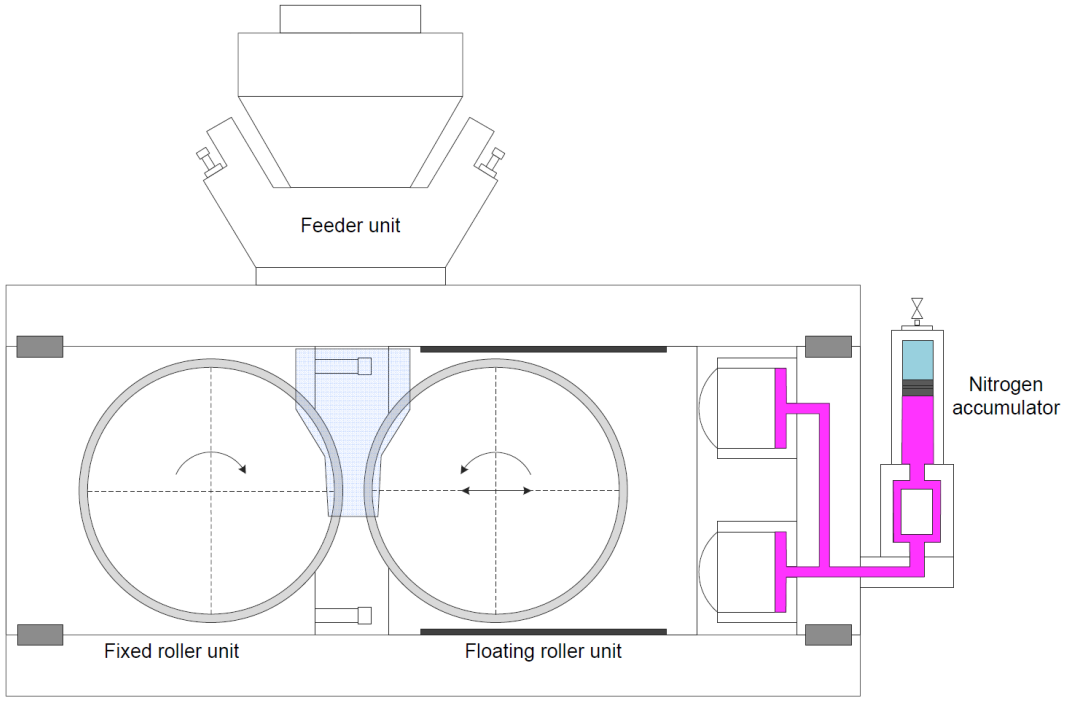

FIG 2 – HPGR schematic (Quist and Evertsson, 2012).

Air classification is required to produce the fine, dry products from both VRM and HPGR circuits. There are two types of air classification available: static and dynamic (Figure 3). Static classification is carried out in a cross-flow separator, where a stream of material cascading over plates is cross-swept by air flow, which removes the finer particles. In a dynamic classifier, the air flow loaded with fine ore particles is passed through the vane slots of a rotating cage wheel. Depending on the air flow and the rotational speed of the cage wheel, the coarser particles are thrown back and collected through a middlings outlet, whereas the fines are swept through the cage wheel with the air flow. The fines are then collected in a system of gas cyclones and dust collectors and form the final product of the classification operation.

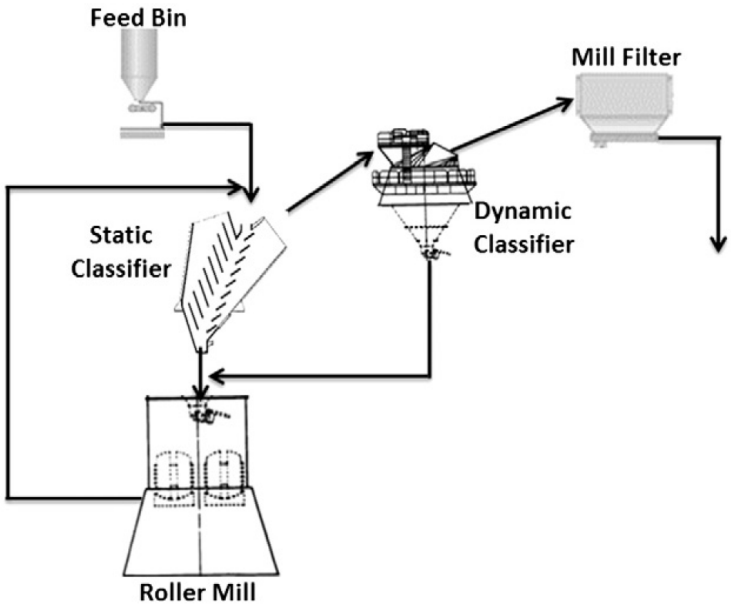

FIG 3 – Schematic of static and dynamic air classification in closed circuit with a VRM in overflow mode (Altun *et al*, 2015).

Both the HPGR and VRM can operate with a dry air classification system. In the case of the VRM the air classification is integral to the unit (Figure 4). The feed material is fed via a rotary star feeder and falls by means of an inclined chute onto the rotating grinding table. The grinding, drying and classification of the grinding material is performed inside the mill.

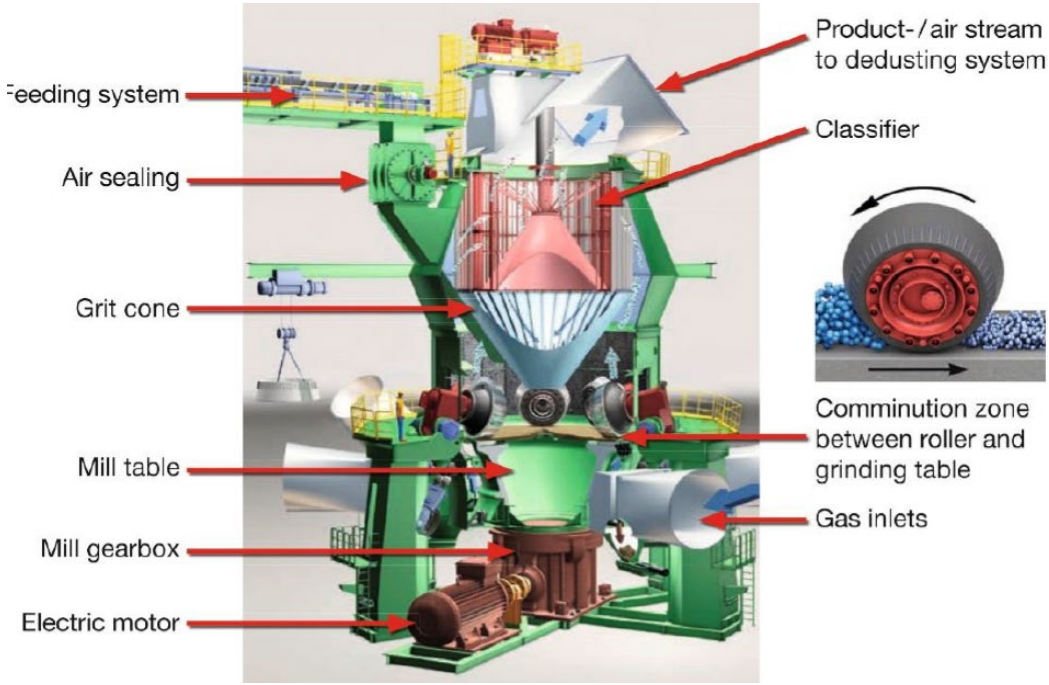

FIG 4 – VRM illustrating major milling components and control measures (Altun *et al*, 2018).

Many previous investigations have been completed that show the potential energy savings of dry fine crushing. Table 1 presents five case studies that have been published on the energy efficiency of VRM circuits. The efficiency of the circuits is presented in relation to the equivalent specific energy requirements calculated from the Bond work indices. The comminution specific energy for these case studies is between 56 per cent and 75 per cent of the Bond specific energy. Unfortunately, fewer case studies have been published related to dry fine crushing utilising a HPGR. However, it is anticipated that the energy efficiency factors will be similar considering the similar breakage and classification environments.

TABLE 1

Summary of previous studies into the energy efficiency of dry fine crushing. *reported HPGR circuit specific energy, not Bond Specific Energy as the base.

Parameter	Unit	Gamsberg (Airflow)	Gamsberg (Overflow)	Copper ore	Turkish Gold	Mogalakwena

Fan Specific Energy	kWh/t	5.6	2.5	7.2	-	-
Reference		(van Drunick *et al*, 2010)	(van Drunick *et al*, 2010)	(Altun *et al*, 2015)	(Altun *et al*, 2018)	(Altun *et al*, 2018)

CASE STUDY 1

Case study 1 considered a plant grinding very hard ore (Bond ball mill work index BWi of 33.5 kWh/t) from an F_{80} of 6.5 mm to a P_{80} of 75 µm. Three comminution technologies were reviewed in this study:

1. Wet ball milling.
2. Dry high pressure grinding roll (HPGR) and air classification.
3. Dry vertical roller mill (VRM) and air classification.

The ball mill sizing was based on the ore characterisation test work, specifically the Bond ball mill work index. There is no equivalent reliable small scale ore characterisation test that can be used for HPGR and VRM sizing. Therefore, the HPGR and VRM sizing was based on the pilot HPGR test results. A series of three locked cycle tests were conducted with an HPGR in closed circuit with air classification. The specific energy requirement for the HPGR circuit was calculated from the average operating work index for the three cycles. In comparison to the ball mill, the HPGR test work found that dry comminution required 45 per cent of the energy (Table 2). Due to the similarity in the breakage and classification mechanisms, the energy efficiency of the HPGR and VRM were assumed to be similar.

TABLE 2

Ball mill and HPGR/VRM design criteria.

Parameter	Unit	Ball milling	HPGR/ VRM
Bond ball mill work index	kWh/t	33.5	
Grinding circuit feed size, F_{80}	mm	6.5	
Grinding circuit product size, P_{80}	µm	75	
Specific comminution energy, design	kWh/t	35.0	15.7
Nominal circulating load	%	250	800

The large specific energy reduction was related solely to the comminution requirements. However, dry classification requires significant power for the fan to hydraulically transport the mill products to the classifier as well as the fine product to the product storage bin. In addition to the fan power, heating energy is required to ensure a low moisture feed to the classifier. For this case study, the required heating energy was extremely high due to the high (14 per cent by weight) moisture levels in the feed stock. The high moisture content is a substantial issue for dry milling as it increases capital cost and energy consumption. The high moisture is likely due to ice and snow collected from the uncovered stockpiles and may be able to be reduced in the comminution circuit design. Without design mitigation, a hot gas generator with an equivalent power of 147 kWh/t was required, effectively swamping the reduction in comminution energy.

The direct capital cost of the dry grinding scenarios was between 21 per cent and 68 per cent higher than the wet ball milling option. The HPGR and VRM options provided lower electrical energy consumption, improved storage prior to separation, modular design and the potential of increased recovery due to improved liberation, reduced surface oxidation and reduced density bias in classification. However, these strengths were not enough to outweigh the higher capital cost and higher risk associated with moisture levels and wear from metal components in the feed.

CASE STUDY 2

Case study 2 considered a high-capacity milling circuit (110 kt/d) treating competent (A*b ~ 30) hard (BWi ~15 kWh/t) ore. The study considered five comminution circuit options, this paper focuses on the outcomes from the SAG and ball mill circuit and the two-stage HPGR and dry classification circuit. Due to the ore hardness, the SAG-based circuit considered a secondary crushed feed to improve the capital and energy efficiency of the circuit (2CSAB).

The dual-stage HPGR circuit considers a primary gyratory crusher and coarse ore stockpile followed by closed-circuit secondary crushing and a fine ore stockpile. The coarse HPGR is closed with dry screens and the fine HPGR is closed with air classification prior to flotation (Figure 5). Although the HPGR circuit can be configured in a single stage, the fan energy and the classifier wear is reduced in the dual-stage configuration.

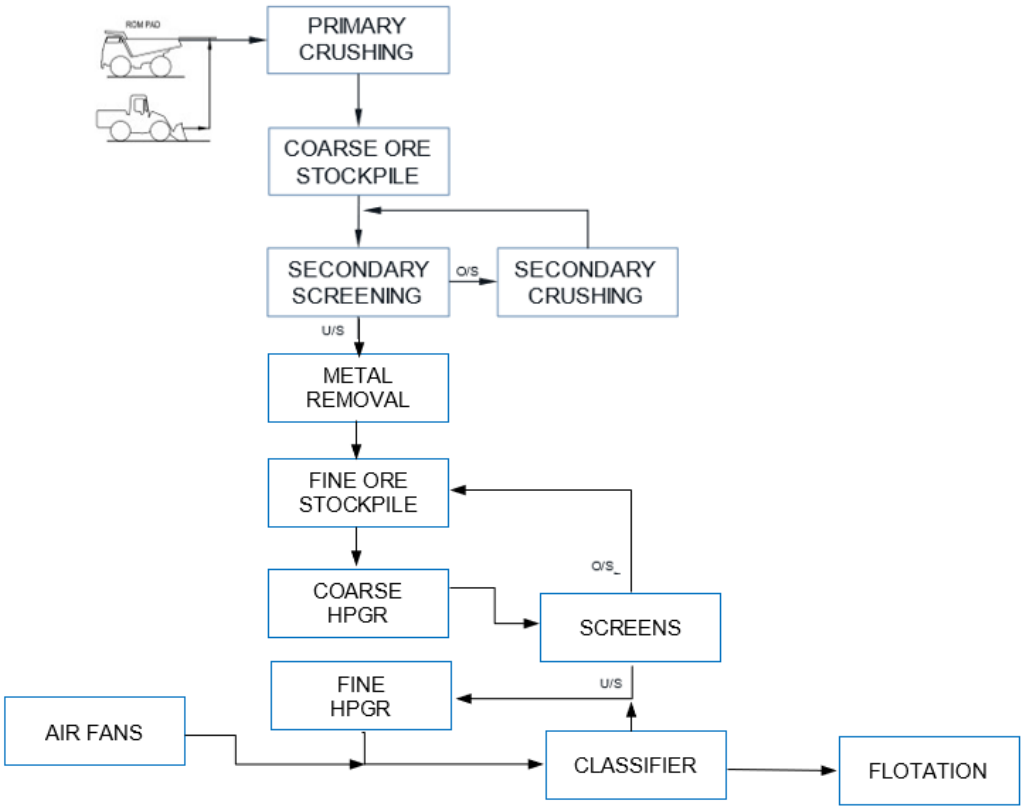

FIG 5 – Dual stage HPGR circuit considered for Case Study 2.

Order of magnitude economic analysis was completed for the two circuit configurations to determine which configuration should progress to the next stage of the study. The dual HPGR circuit reduced the energy consumption from the 2CSABC circuit by 36 per cent, inclusive of ancillary energy associated with fans, conveyors and pumps. The relative capital cost was 16 per cent higher for the dual HPGR circuit. However, due to the high price of electricity in this case study, the operating cost reduced by US$1.19/t for the dual HPGR circuit. This resulted in a very short payback period and showed that the dual HPGR circuit has the potential to add significant value to this project.

TABLE 3

2CSAB and HPGR design criteria.

Parameter	Unit	2CSAB	Dual HPGR
Grinding circuit feed size, F_{80}	mm	102	
Grinding circuit product size, P_{80}	µm	350	
Specific comminution energy	kWh/t	11.3	6.1
Specific ancillary energy	kWh/t	1.3	1.9
Total specific energy	kWh/t	12.6	8.0
Relative capital cost	%	0	+16
Relative operating cost	US$/t	0	-1.19

In addition to the financial analysis, the process/technology risk, the greenhouse gas emissions and readiness for the next study phase were evaluated. The collective result from this analysis was that the lower-risk HPGR ball milling circuit will progress to the next phase of the project as the economics were similar to the dual HPGR circuit, the risk was lower and the technology readiness was higher.

DISCUSSION

In comparison to SAG milling circuits, dry fine crushing circuits (HPGR and VRM) have the potential to almost halve the comminution energy. This power reduction is enhanced for competent, hard ores. However, the energy associated with ancillary equipment such as the fans and hot gas generation can significantly reduce the benefits in comminution energy reduction. Reducing the classification energy should be a major focus in dry fine crushing circuit design. However, this needs to be mindful of the fact that classification efficiency, fan energy consumption, comminution efficiency and downstream recovery performance are all interrelated.

Therefore, efficient size classification must be maintained while simultaneously reducing energy consumption. Some potential solutions to this problem are presented below:

1. For the VRM, the pressure drop can be reduced by operating in overflow mode, thereby not requiring the fan to pneumatically transport the coarse particles up to the classifier.
2. For dual stage circuits, the first stage can be extended finer by employing smaller aperture dry screens being developed by suppliers such as Derrick and Liwell.
3. Employing efficient wet classifiers such as screws and fine screens should be explored where the oversize product is 80–90 per cent solids by weight. With the dry new circuit feed, the % solids in the VRM/HPGR feed should be lower than 10 per cent and should not impact performance dramatically.

CONCLUSIONS

Dry fine crushing utilising High Pressure Grinding Rolls and Vertical Roller Mills should be explored for projects with hard ores and high electrical energy costs. The reduction in power and media consumption have the potential to significantly reduce operating cost and greenhouse gas emissions in compared to conventional tumbling mill circuits. The reduction in comminution energy has the potential to be eroded by high energy consumption in the classification circuit. However, this can be

reduced by utilising improved design principles. The benefit of dry fine crushing on recovery should be investigated and included in the economic benefit of the circuit configuration to obtain a more accurate economic analysis.

HPGR and VRM dry fine crushing circuits have similar comminution characteristics. However, the applications of the two systems are quite different and lend themselves to be applied in different project settings. The fully enclosed, modular VRM and classifier design will be most applicable to low-capacity projects such as the dual 5 Mt/a circuits at West Musgrave. On the other hand, the separate air classification and the large proven HPGR equipment design means these circuits are initially more applicable for higher capacity projects such as the 67 Mt/a Iron Bridge project. However, the development of these technologies over time will likely see the reduction of this differential.

ACKNOWLEDGEMENTS

Thanks to Ausenco for supporting the publication of this work and Ausenco's global comminution group for the collaborative, collegial technical discussions that have contributed to the outcomes of this work.

ABSTRACT

Much practical experience has been gathered in the last 30 years of application of high-pressure grinding rolls (HPGR) integrated with ball milling in size reduction of fine iron ore concentrates. The company Vale S.A, in Complexo de Tubarão (Brazil), was one of the pioneers applying the technology prior to pelletisation with an outstanding size reduction energy efficiency in the circuit and a significant increment in the specific surface area of the product. Recent studies by the authors demonstrated benefits of modelling and simulation to improve the performance of HPGRs in this particular application, with the model being able to describe HPGR performance under different operating conditions and under variations of feed size distribution. Despite these important advances, this modelling approach has only been used offline and under steady-state conditions. The present work applies the modified Torres and Casali model proposed by the authors in pseudo-dynamic simulations. The ability of the model to predict the characteristics of the product in real-time is evaluated using data available online for the pellet feed preparation circuit. Results demonstrated the model capabilities to map the physical operation and give a realistic representation of the process. Additionally, the model is demonstrated to be able to support the pellet feed production by providing extended real-time information of the process, making it a useful tool for improvement of the operational strategies and process stability.

INTRODUCTION

High-pressure grinding rolls (HPGR) reached great popularity in the last 30 years of application in the minerals industry. The company Vale S.A, in the Complexo de Tubarão (Vitória, Brazil), was one of the pioneers using this technology for pressing iron ore concentrates in integrated circuits with ball milling (Van der Meer, 1997), where the HPGR usually operates in the regrinding prior to pellet formation in the so-called pellet feed preparation stage. The success of HPGRs in this type of application can be summarised by their capabilities to improve the Blaine specific surface area (BSA) coupled with a high throughput and low specific energy consumption (Van der Meer, 2010; Abazarpoor *et al*, 2018; Campos *et al*, 2019a). In this particular circuit configuration, the HPGR represents the interface between the end of the pellet feed preparation circuit and the beginning of the pellet formation process (Campos *et al*, 2019a), so that the technology occupies a key position in potentially absorbing disturbances caused in upstream operations and producing a qualified iron ore pellet feed to the downstream process.

Aiming to support operations, advances in the mathematical modelling describing HPGR performance followed, at least in parts, the improvement in the technology over the last 40 years (Rashidi *et al*, 2017). Among several works considering simplest and empirical modelling approaches (Chelgani *et al*, 2021), going through phenomenological models (Morrell *et al*, 1997; Torres and Casali, 2009; Dundar *et al*, 2013) and more in-depth descriptions with simulations using the discrete element method (Barrios and Tavares, 2016; Cleary and Sinnott, 2021; Rodriguez *et al*, 2021, 2022), improvements have been made possible in operations. New dynamic modelling approaches have been proposed, showing potential to be used as model predictive control in industrial-scale HPGRs (Numbi and Xia, 2015; Johansson and Evertsson, 2019; Vyhmeister *et al*, 2019) and to help improve understanding towards process integration. Nevertheless, the simplicity

of some of the descriptions and the very limited level of validation of some of these approaches raise several questions regarding their applicability. In the particular case of interest in the present work regarding pressing iron ore concentrates, published works by the authors (Campos *et al*, 2019b, 2021) proposed and demonstrated the validity of several modifications to the phenomenological HPGR model proposed by Torres and Casali (2009), applying it to both pilot – and industrial-scale HPGRs operating under a range of conditions. However, applications were limited to offline simulations and to steady state conditions.

Indeed, the new digital transformation in the minerals industry is shifting traditional operation towards new approaches that are able to correlate dynamic modelling with industrial demands from real-time simulations. Robust models providing rapid and accurate responses coupled with an integration into the plant network and real-time information between the physical operation and the digital models will, potentially, allow predicting variations within the process besides being the basis of a robust model-predictive control. Despite these potential improvements, several key challenges still remain when it comes to HPGR full process integration and multi-scale dynamic modelling within pellet feed preparation circuits for long periods.

The present work proposes a new modelling approach integrated with real-time information and uses it in pseudo-dynamic simulations of size reduction of iron ore concentrates in an industrial-scale HPGR. Model prediction is investigated in a period of a year of operation and applied to describe HPGR performance under different roll surface wear conditions. A new method is proposed and applied to improve model prediction when dealing with worn rolls.

MODELLING BACKGROUND

Among the main phenomenological mathematical models that are able to describe the HPGR performance (Morrell *et al*, 1997; Torres and Casali, 2009; Dundar *et al*, 2013), the approach proposed by Torres and Casali (2009) is able to predict power consumption and throughput on the basis of physical equations on the operations, besides describing the size reduction based on the population balance model. Recent works by the authors identified some limitations on the model when dealing with Brazilian iron ores and proposed some particular modifications to model equations with the aim of improving prediction (Campos *et al*, 2019b, 2021).

Briefly, the so-called modified Torres and Casali model (Campos *et al*, 2019b, 2021) relies on the plug flow model to calculate the HPGR throughput as:

$$Q = U_g L \chi_g \rho_g \left(\frac{100}{100 - \delta}\right) \tag{1}$$

where U_g is the material velocity, χ_g is the operating gap, *L* is the roll length, ρ_g is the flake density and δ is a parameter representing the proportion of material ejected by the edge of the rolls given by:

$$\ln\left(\frac{\delta}{\varphi}\right) = -\upsilon \frac{\chi_g}{D}\left(\frac{U}{U_{max}}\right)^{\tau} \tag{2}$$

where *D* is the roll diameter, *U* is the roll velocity, U_{max} is the maximum roll velocity allowed for the machine and φ, υ and τ are fitting parameters. The material velocity in Equation 1 is estimated as:

$$U_g = \frac{U \rho_a \chi_c}{\rho_g \chi_g} \tag{3}$$

where ρ_a is the bulk density and χ_c is the critical size given by $\chi_c = \chi_g + D\left(1 - \cos \alpha_{ip}\right)$.

The power consumption prediction is carried out based on the torque for both rollers multiplied by the angular roll velocity as:

$$P = 2F_m \sin\left(\frac{\kappa \alpha_{ip}}{2}\right) U \tag{4}$$

where α_{ip} is the nip angle, κ is a fitting parameter that allows adjusting the estimate of the nip angle and F_m is the compressive force applied to the particle bed (Torres and Casali, 2009):

$$F_m = p_m \frac{D}{2} L \tag{5}$$

where p_m is the hydraulic pressure.

Finally, the size reduction can be predicted from an analytical solution of the population balance model which allows to calculate the product size distribution ($w_{i,k}$) for N_b section along the axial roll position (Torres and Casali, 2009):

$$w_{i,k} = \sum_{j=1}^{i} A_{ij,k} exp\left(-\frac{S_{j,k}}{U_g} z^*\right) \tag{6}$$

where z^* is the distance between the beginning of the compression region and the extrusion zone (Torres and Casali, 2009) and $S_{j,k}$ is the breakage rate for each size class *j* and section *k*. The analytical solution uses the non-normalisable breakage function (King, 2001) and the specific selection function approach (Herbst and Fuerstenau, 1980) to solve the differential equations. The cumulative non-normalisable breakage function is given by:

$$\begin{aligned} B_{ij} &= \phi\left(\frac{x_i}{x_j}\right)^{\gamma} + (1-\phi)\left(\frac{x_i}{x_j}\right)^{\beta} \quad \text{for } x_i \geq \omega \\ B_{ij} &= \phi\left(\frac{x_i}{\omega}\right)^{\eta}\left(\frac{x_i}{x_j}\right)^{\gamma} + (1-\phi)\left(\frac{x_i}{x_j}\right)^{\beta} \quad \text{for } x_i < \omega \end{aligned} \tag{7}$$

where x_i is the particle size, γ, β, ϕ, ω and η are fitting parameters and b_{ij} is the distributed breakage function calculated from $b_{ij} = B_{i-1,j} - B_{ij}$. The breakage rate, on the other hand, is given by:

$$S_{i,k} = s_i^E \frac{P_k}{H_k} \Psi\left(\frac{P}{Q}\right) \tag{8}$$

where H_k is a constant Hold-up along the roll length, P_k is the power profile and s_i^E is the specific selection function:

$$\ln\left(s_i^E / s_1^E\right) = \xi_1 \ln(\hat{x}_i / \hat{x}_1) + \xi_2 [\ln(\hat{x}_i / \hat{x}_1)]^2 \tag{9}$$

where s_1^E, ξ_1 and ξ_2 are fitting parameters, $\hat{x}_i$ is the representative size calculated from $\hat{x}_i = \sqrt{x_i x_{i-1}}$ and $\hat{x}_1$ is a reference size given by the top size class.

The power profile in Equation 8 allows the model to predict the variation of the product size distribution along the roll length, which is a key feature in HPGR operations. The power profile is then given as:

$$P_k = 2F_m \sin\left(\frac{\kappa \alpha_{ip}}{2}\right) U \frac{P'_k}{\sum_{j=1}^{N_B} P'_j} \tag{10}$$

where P'_k is calculated on the basis of the Fourier Transform and allows the model to describe shape profiles that vary from trapezoidal to a parabolic (Campos *et al*, 2021):

$$P'_k = \frac{4}{\pi} \sum_{n=1}^{100} \frac{1 - \cos n\pi}{2n} e^{-\mu(n^2\pi^2)} \sin n\pi \bar{y}_k \tag{11}$$

where μ is a fitting parameter.

In order to account for the drop of energy efficiency when the specific energies are raised in HPGR operation, a damping parameter multiplying the breakage rate in Equation 8 was proposed (Campos *et al*, 2021):

$$\Psi(E_i) = exp\left[-\left(\frac{E_i}{E'}\right)^{\Lambda}\right] \tag{12}$$

where E_i is the specific input energy, E' is a parameter, called energy densification, and Λ is a second fitting parameter.

MATERIALS AND METHODS

HPGR operation

An industrial-scale HPGR from one of the pelletising plants from Complexo de Tubarão from Vale S.A (Vitória, Brazil) was selected as case study in the present work. The HPGR operates in an integrated circuit with ball milling and is at the boundary between the end of the pellet feed preparation stage and the beginning of the pellet formation process (Campos *et al*, 2021). The machine was connected to a process information management system (PIMS) in order to capture information on throughput, power consumption, operating pressure, roll peripheral velocity and operating gap. Operating gap was measured using a gap sensor positioned on both edges of the rolls.

Operation is often carried out with a feed moisture content of 8 ± 0.5 per cent, which is closer to the maximum that is tolerated for pressing iron ore concentrates (Van der Meer, 1997). Table 1 summarises the main HPGR settings and range allowed for the operating conditions. Given the large roll dimensions, this HPGR faces a particular issue operating below the designed capacity since the feed hopper does not allow to keep the HPGR operating in a choke fed condition and, therefore, drives the machine to operate under roll peripheral velocities lower than the original value allowed (Table 1).

TABLE 1

Summary of the main HPGR settings and operating ranges.

Variable	Value
Roll diameter (m)	2.25
Roll length (m)	1.55
Specific force (N/mm²)	0.5–5.5
Operating pressure (bar)	20–180
Roll velocity (m/s)	0.2–2.01
Operating gap (mm)*	5–15
Nominal throughput (t/h)	400–1200
Total power consumption (kW)	500–3600

As previous investigated by the authors (Campos *et al*, 2021), the HPGR is fed with a blend of four different iron ore concentrates mainly composed of hematite with minor amounts of quartz as contaminant. Specific gravity of the feed was measured by Helium Pycnometerry, being equal to 4.9 t/m³. The bulk density was determined from the ratio between the sample mass in a known volume after vibration and given as 3.0 t/m³, whereas the flake density was measured using preserved flakes from Archimedes principle and given as 3.54 t/m³.

In order to ensure a careful investigation about HPGR operation when machine is under different roll wear patterns, measurements of the distance between the top of the studs and a metal strip placed in the front of the rolls along the axial position were carried out as presented in Figure 1. This distance between the roll surface and the metal strip was measured periodically in 63 studs selected in both rollers using a digital calliper. It is worth mentioning that the authors recognise that recent works presented more reliable and accurate approaches to measure the wear pattern from online systems (Burchardt and Mackert, 2019), but the approach adopted in the present work was also used and already validated elsewhere (Rodriguez *et al*, 2021).

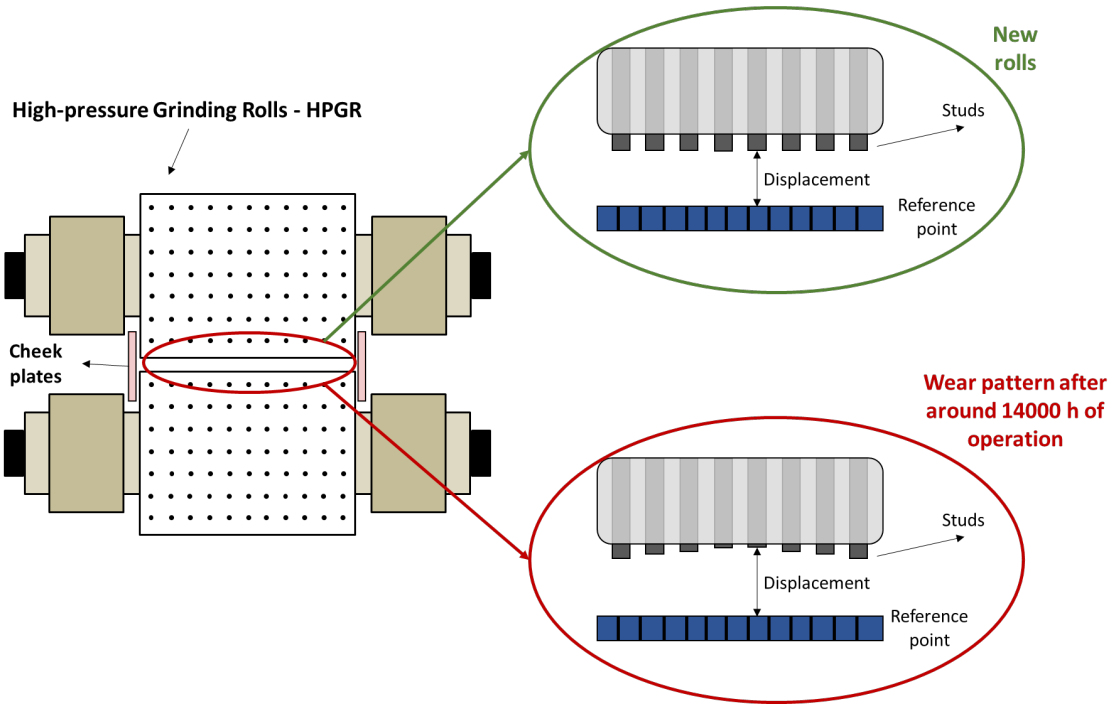

FIG 1 – Schematic diagram showing the experimental device used to measure the distance between a reference position and the top of 63 studs along the roll length. The green circle presents the rolls in the beginning of the wear life, whereas the red circle presents an illustration of the worn profile after 14 000 hours of operation, which is usually the total wear lifetime.

Data collection

A period of 12 months was selected with information recorded in a frequency of 5 min from PIMS, which corresponds to around 105 120 data points for a total of five variables in HPGR operation. Assuming no information about HPGR feed and product in real-time, samples were gathered from the process every four hours in the entire period evaluated. A sampler was used to collect material, whereas BSA was measured in laboratory using a PCBlaine-Star (Zünderwerke Ernst Brün GmbH). A total of 2190 points were recorded in this second data set.

To ensure that the data collected from the process was reliable, two steps were used in the present work. First, considering the lack of uniformity in the sampling rates between the PIMS data set and the laboratory data set, a regularisation between both was necessary. For this purpose, the BSA measurement was assumed as an average of the last four hours within the process and, therefore, its value repeated for these previous four hours considering the frequency of 5 min adopted in the PIMS data set. Considering the new regularised data, the second step relied on cleaning the data to avoid missing values, outliers, measurement disturbances and low accuracy in all process variables. Data deletion strategy was adopted to overcome missing values, which is a valid approach when the amount of missing data is only a negligible fraction of the entire data set. In order to remove outliers, a preliminary operation consisted of removing data when they do not satisfy physical conditions and usual operating ranges presented in Table 1. Outliers were also identified and removed when a value for a data point was more than three scaled median absolute relative deviations from the median (MAD). After data reconciliation and data cleaning a set of 65 193 data points for each HPGR variable was then used for modelling and simulation.

Model implementation

The modified Torres and Casali model (Campos *et al*, 2019b, 2021) was implemented in Matlab™ (version R2021b, Mathworks Inc) to perform all the simulations. A nonlinear optimisation method was used to calibrate the breakage parameters (Table 1), which basically relies in a function available in Matlab, called *fminsearch*, able to find the minimum of a multivariable scalar function using the Nelder-Mead method from an initial estimation. The objective function consisted of the sum of the differences of the logarithms of the experimental and the fitted values of the particle size distribution of a reference test (Base Case) in cumulative form using the least squares method:

$$f_{obj} = \sum_{i=1}^{N} \left[\log\left(W_{Calc}^{HPGR}(i)\right) - \log\left(W_{Exp}^{HPGR}(i)\right) \right]^2 \quad (13)$$

where N is the number of size classes, W_{Calc}^{HPGR} and W_{Exp}^{HPGR} are, respectively, the calculated and experimental fraction passing in size *i*. The objective function was proposed in the logarithmic form in order to ensure a more reliable description of the fine part of the size distribution, since the present work aims to quantify this part of the distribution accurately.

The online model structure relied on the application of the Modified Torres and Casali model coupled with real-time information about HPGR operating conditions and feed characteristics. Predictions are evaluated on the basis of the absolute relative deviation from measurements and from time series comparisons.

RESULTS

Process results

Data collected from PIMS and filtered following each step presented in the Section 'HPGR operation' was analysed in the entire period. Statistical analysis provided detailed information about operating conditions and HPGR performance variables, which were analysed in light of global variation in the entire period and local variations when dealing with each specific month.

Rolls wear patterns were carefully investigated in the entire period. Figure 2 shows wear profiles in the beginning, middle and end of rolls lifetime. A trapezoidal (also named 'bathtub') profile already discussed and investigated elsewhere (Gardula *et al*, 2015; Burchardt and Mackert, 2019; Rodriguez *et al*, 2021), is evident in the beginning, whereas a parabolic profile is reached when the HPGR is closer to 14 000 hours of operation, which is typically the maximum lifetime for the rolls in operation. Wear profiles were concave and more intensive wear occurred in the middle of the rolls, besides presenting modest wear on the edge region up to the middle lifetime and a significant edge effect when the parabolic wear profile was achieved in the end of its lifetime. Results are lined up with previous investigations carried out using DEM (Rodriguez *et al*, 2021) and from industrial-scale measurements for pressing iron ores (Nejad and Sam, 2017).

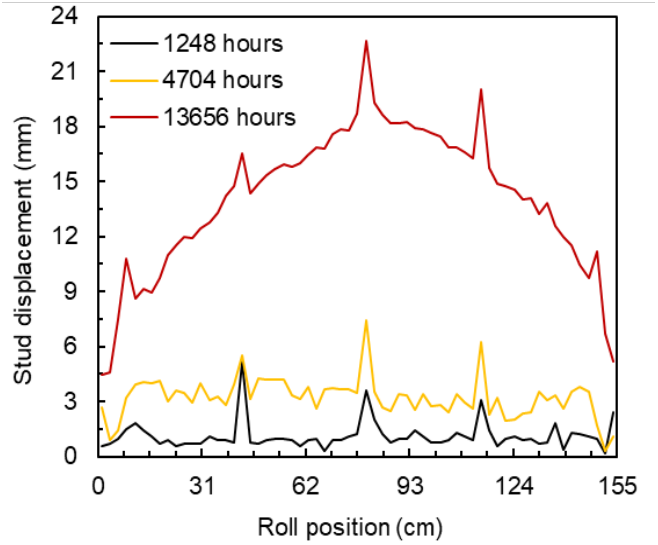

FIG 2 – Roll wear patterns registered from the beginning of operation up to the end of roll wear lifetime with nearly 14 000 hours of operation.

Figure 3 presents the average variation of operating pressure (a) and roll peripheral velocity (b) in the twelve months investigated, whereas vertical lines represent the standard deviation for each month. Figure 3a shows the minor global variation of the roll peripheral velocity, in which average values varied from 1.00 to 1.04 m/s. The very small standard deviation for each month (up to 0.04 m/s) also confirms that this process variable varies within a very narrow range of operating conditions. As discussed in Section 'HPGR operation', the HPGR investigated does not allow to

ensure a choke fed condition when dealing with high throughputs (higher than 650 t/h), thus imposing nearly constant roll velocities throughout its operation. Additionally, Figure 3a allows to conclude a potential improvement study in the HPGR performance since the roll velocity is a well-known controlled variable used to change throughput and power consumption of HPGRs (Johansson and Evertsson, 2019; Vyhmeister *et al*, 2019). Operating pressure, which is the key variable used to improve size reduction, presented monthly averages from 56.7 to 66.9 bar and standard deviations for each month up to 7.1 bar (Figure 3b). Local variation in the operating pressure in each month can be related to the control strategy adopted in order to maintain constant the torque in both rollers, besides potentially absorbing variations in the feed size distribution. A slight, but still important, global variation can be identified after the fifth month. Assuming the drop in size reduction caused by the worn rolls (Figure 2), the increase in operating pressure can be explained, at least in part, as an operational strategy used to overcome this issue.

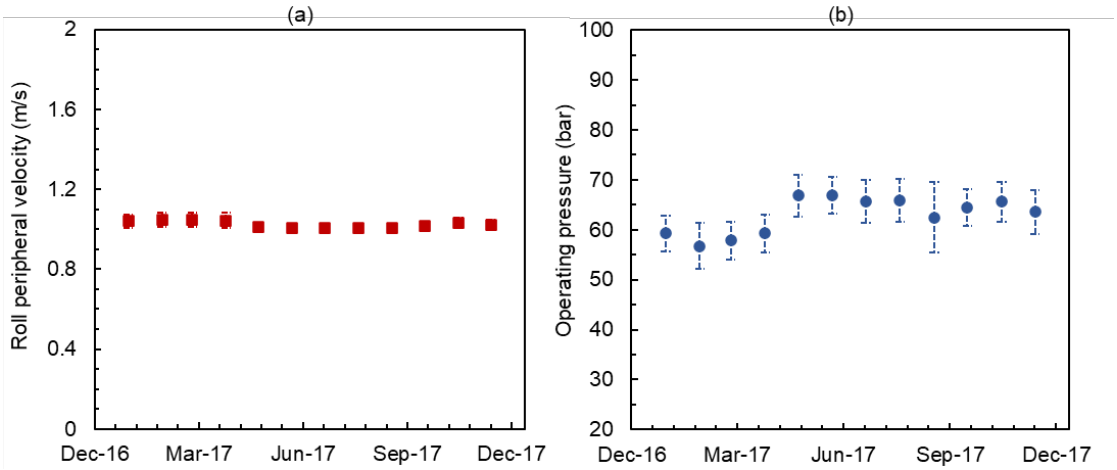

FIG 3 – Month-to-month variation of operating pressure (a) and roll peripheral velocity (b) over a period of 12 months. Markers are the average values for each month and vertical lines present the standard deviations within each month.

Variation of the average value of the measured operating gap in each month is presented in Figure 4. Results showed significant changes in the entire period with average values ranging from 13.0 to 5.1 mm. Unlike the well-known trend between operating pressure and operating gap (Daniel, 2002; Barrios and Tavares, 2016), the minor increase of pressure in Figure 3b does not have a clear relationship with the significant reduction in operating gap. In association to Figures 2 and 3b, the reduction of the operating gap and the poor relationship with operating pressure can be again explained on the basis of roll wear (Figure 2). Indeed, taking into account the approach used to determine the operating gap (Section 'HPGR operation') and the usual concave profile of the rolls (Figure 2), it is worth mentioning that measurements of operating gap are only associated to the distance between rollers in the edge, thus not accounting for the parabolic (or bathtub) profile in the centre region. Results from Figure 4 allow to state that operating gap is not a reliable variable in the process when dealing with worn rollers, although it remains valid as an indicator of roll condition.

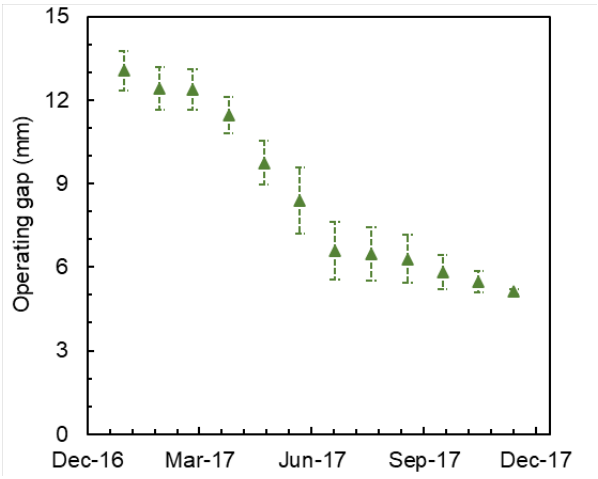

FIG 4 – Month-to-month variation of operating gap over a period of 12 months. Green triangles represent the average values and vertical lines present the standard deviations within each month.

Month-to-month variation of throughput and power consumption in the period investigated are shown in Figure 5. Minor global variations can be seen in the throughput with average values from 531 to 623 t/h. Standard deviation values for each month (vertical lines) reaching 52 t/h also demonstrate that the HPGR throughput varying within a narrow range of operating conditions. Results from Figure 5a are mainly governed by the roll peripheral velocity (Figure 3a), thus explaining its small changes.

On the other hand, Figure 5b presents both average values (from 1523 to 1483 kW) and standard deviations (up to 175 kW) for HPGR power with important variations. Comparing results from Figure 5b and Figure 3b it is possible to argue that power consumption for this HPGR is mainly determined by changes in operating pressure.

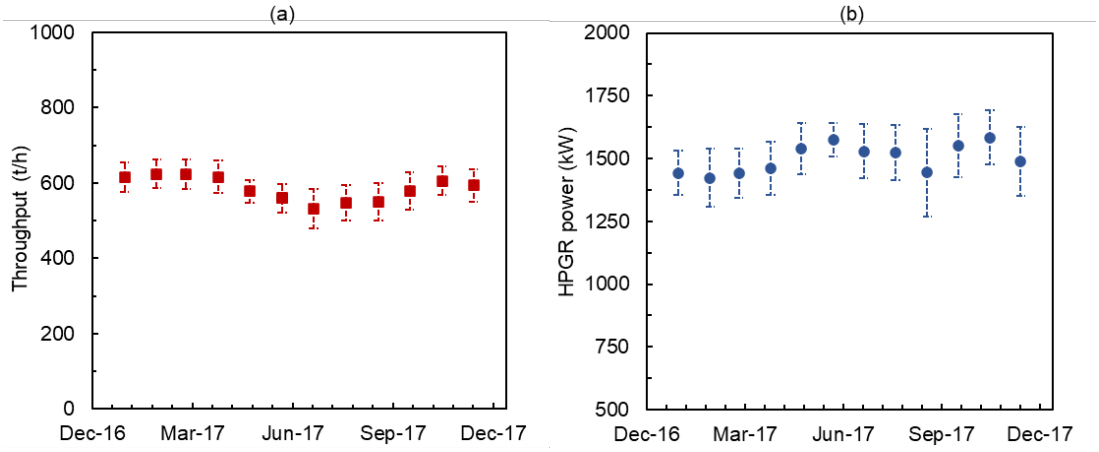

FIG 5 – Month-to-month variation of throughput (a) and power consumption (b) over a period of 12 months. Markers represent the average value, whereas vertical lines are the standard deviations within each month.

Data from laboratory analyses characterising the HPGR feed and product are presented in Figure 6. Important month-to-month variations are evident, with the average value for each month varying from 1550 to 1650 cm²/g in the HPGR feed and from 1770 to 1910 cm²/g in the HPGR product. Important variations within each month, evident from the high standard deviations, also demonstrate the significant changes in both feed and product size. Moreover, results from Figure 6 show that the product BSA is highly influenced by the feed BSA and, beyond the improvement in the product surface area, it is almost ever following the trend imposed by the feed.

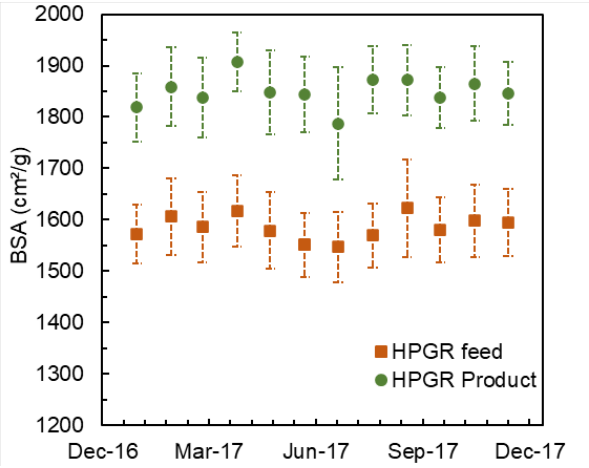

FIG 6 – Month-to-month variation of Blaine specific surface areas of the feed and product of the HPGR over a period of 12 months. Markers represent the average value, whereas vertical lines are the standard deviations within each month.

Power consumption and throughput predictions

Results from Figure 7 compare model predictions and experiments in the entire period assessed for power consumption (a) and throughput (b). Good agreement was reached for the first four months (close to 3000 hours of operation) with average absolute relative deviation from measurements up to 5.8 per cent for the throughput and 6.3 per cent for the power consumption. This period corresponds to the same period when the HGPR was operating from the beginning of lifetime until a point when the roll wear pattern reached a bathtub profile (Figure 2). Although already exhibiting a bathtub wear profile, results from Figure 7 demonstrate the ability of the model in providing good predictions of power and throughput. Under these conditions, the nip angle parameter (κ in Equation 4) was fixed in 2.75. On the other hand, in the case of the throughput model (Equation 2), two parameters were maintained equal to those previous calibration by the authors and given by $\varphi = 100$ and $\tau = 0.1$ (Campos *et al*, 2021), whereas the remaining parameter was fitted ($\upsilon = 550$).

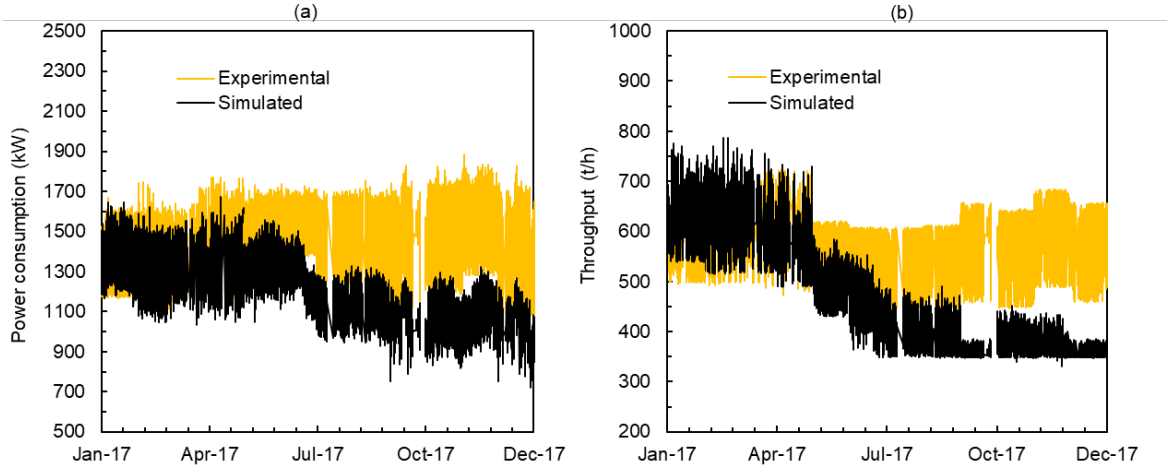

FIG 7 – Comparison of experimental and predicted values for power consumption (a) and throughput (b) in the twelve months investigated. Data is presented for every 5 min of operation.

With the aim of improving the model prediction when dealing with different roll wear patterns (briefly discussed in the Introduction), the present work proposes an algorithm to recalibrate selected parameters of the Modified Torres and Casali model. The step-by-step approach used to recalibrate the model is illustrated in Figure 8, which shows that it consists in a progressive analysis used to verify power consumption and throughput predictions, respectively. A value of absolute relative deviation from measurements of 10 per cent for both power and throughput is used as threshold for model accuracy. If the absolute relative deviation from measurements is higher than 10 per cent for more than one hour of operation, the approach allows the model to recalibrate selected model

parameters, as discussed previously. Parameter optimisation is performed from the difference between calculated and experimental values for a reference test selected in the previous hour of operation using the least square method. Parameter κ in Equation 4 was selected to be recalibrated in the power consumption model, whereas parameter υ was selected for the throughput model (Equation 2).

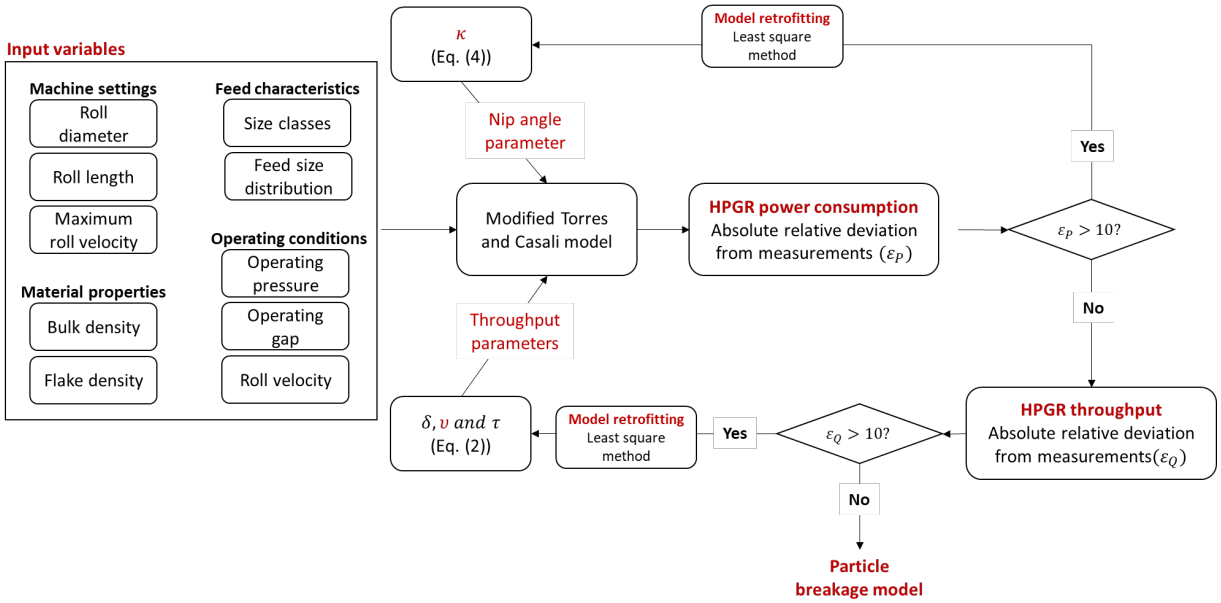

FIG 8 – Approach used to recalibrate model parameters based on the deviations in model prediction owing to roll wear. ε_Q and ε_P are the absolute relative deviation from measurements for the throughput and power consumption, respectively.

Figure 9 then presents the comparison between model and experiments when the approach presented in Figure 8 was applied. Results showed very good agreement over the entire period, with absolute relative deviations of simulations to measurements up to 4.8 per cent for power consumption and 6.0 per cent for throughput. The approach adopted seems to be able to circumvent the bias in the model prediction when dealing with worn rolls, as well as minor variations in feed competence. Nevertheless, results from Figure 9b shows the model limited the ranges of predicted values for HPGR throughput from October to December 2017. These poor predictions may be explained, at least in part, by the simplified assumption of recalibrating some model parameters to compensate the error of the operating gap measurement, which may be regarded as a disadvantage of the algorithm.

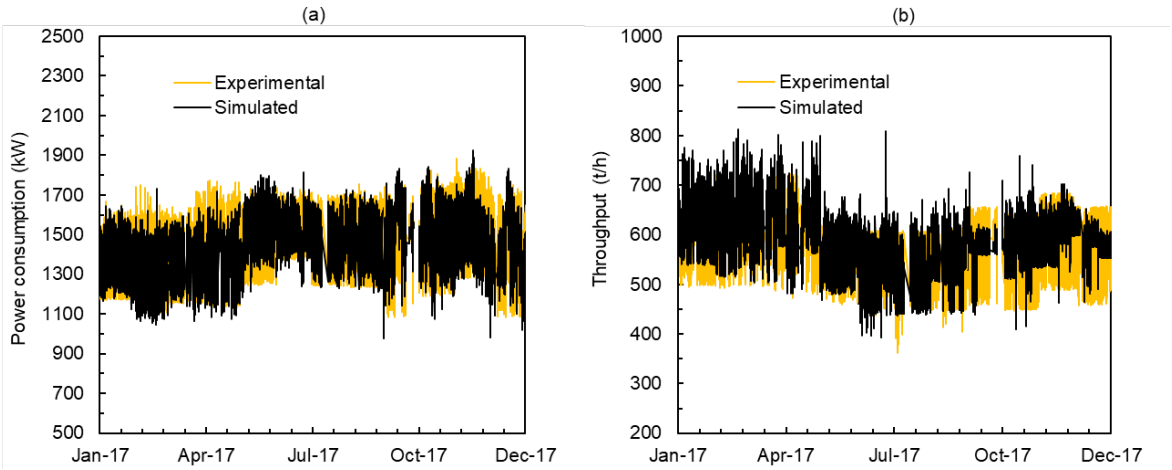

FIG 9 – Comparison between experimental and predicted power consumption (a) and throughput (b) in a period of twelve months assessed after applying the calibration approach depicted in Figure 8. Data is presented for every 5 min of operation.

Size reduction model

Feed size distribution prediction

To ensure a reliable assessment of the size reduction in the entire period, data from laboratory analyses were reconciled with supervisory system data. Reconciliation assumed that the measurement made of the BSA would be a process average over the last four hours, so that this value was repeated for the four hours prior to the measurement. Additionally, taking into account the key model requirement of using the complete feed size distribution as an input, the present work proposes that the feed sizes follows a Rosin-Rammler distribution function, given by:

$$P_i = 1 - exp\left[-\left(\frac{x_i}{x^*}\right)^{\alpha}\right] \quad (14)$$

where x_i is particle size (mm) and x^* is a 62.3 per cent passing size (mm). Based on an extended database containing 162 measurements of BSA and size distributions presented elsewhere (Campos *et al*, 2021), a relationship was then proposed to calculate the size parameter x^* as a function of the Blaine specific surface area. Figure 10 presents the relationship between these two variables for 80 per cent of the database, which was randomly selected as calibration data set. The clear linear relationship between this parameter and BSA suggests that simple linear equation to describe it, represented by:

$$x^* = 126.5 - 0.0412BSA_{Alim} \quad (15)$$

where x^* is given in μm and BSA_{Alim} is the Blaine specific surface area (cm²/g) from the HPGR feed gathered from laboratory measurements. The parameter α in Equation 14 was set to the optimal constant value of 0.97. Predictions made using Equation 14 were then compared to the respective experimental size distributions for both calibration data sets (80 per cent used for training) and validation data set (the remaining 20 per cent of the original data set) using Equation 13. Results demonstrate the good predictive capabilities of the model with average values for the objective function for calibration and validation data sets of 0.04 and 0.06, respectively. Figure 10 still presents the region bounds by the dotted red lines with relative deviations between model (black line) and fitted sizes (green circles) up to 10 per cent.

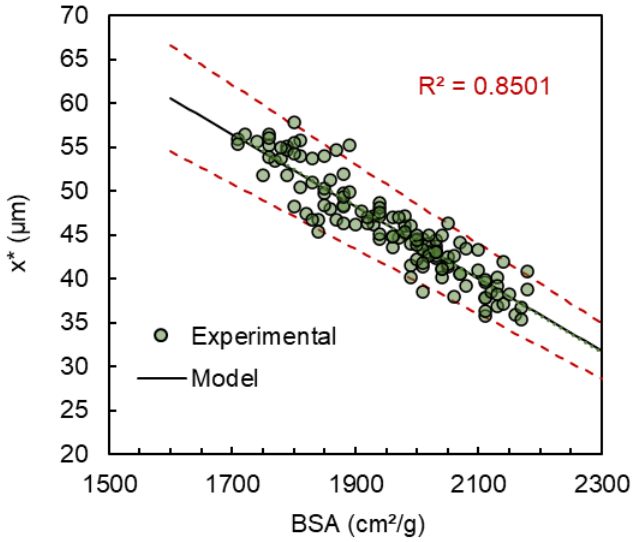

FIG 10 – Relationship between BSA for several measurements carried out elsewhere (Campos *et al*, 2021) and the critical size fitted in Equation 14. Green circles are values fitted from Equation 14 and the black line is the model fitting with Equation 15. The red dotted lines bound the region with relative deviations between black line and experiments up to 10 per cent.

Product BSA

In order to simulate the size reduction in the HPGR the breakage model was calibrated based on survey data. All five parameters from the breakage function (Equation 7) and two parameters from the selection function (Equation 9) were assumed to remain constant and equal to previous

calibration carried out by the authors (Campos *et al*, 2019b). The remaining parameter from the selection function (s_1^E) was then fitted on the basis of a reference test selected among the ones when the HPGR was operating under good wear conditions and in the beginning of roll life.

As such, considering the model presented in Equations 14 and 15 and the breakage parameter depicted above, Figure 11 presents the comparison between experimental and predicted values for the HPGR product BSA when considering a constant and average feed size distribution with 1550 cm²/g in a period of 740 hours of operation. This simplified assumption was adopted in order to check the real effect of the feed size distribution in the model prediction. Indeed, as discussed in Figure 6, there is a clear trend between both HGPR feed and product, being the second one strongly determined by the first. Analysing both results together allows to explain the poor agreement between model and experiments presented in Figure 11.

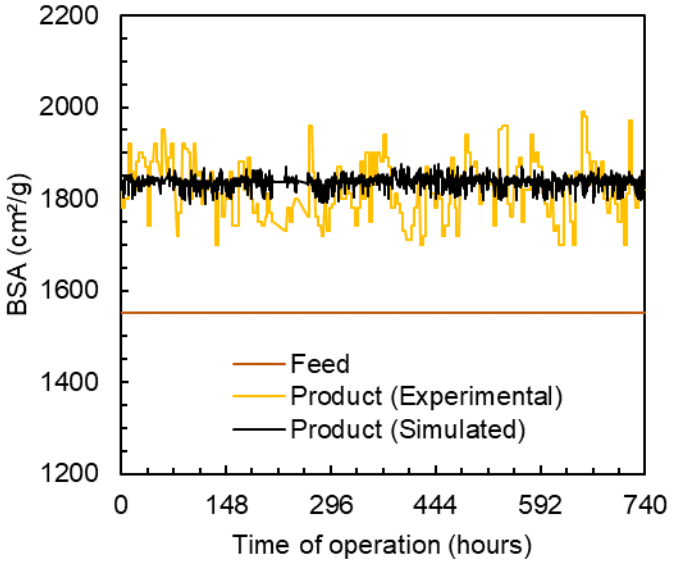

FIG 11 – Comparison between experimental and predicted value for the HPGR product BSA considering a fixed feed size distribution with 1550 cm²/g.

Figure 12 then presents a more complete version of the model dealing with the measured feed size distribution in real time. First it is worth highlighting the variation of the HPGR product over the entire period assessed following the trend imposed by the HPGR feed. Nevertheless, results from Figure 12 show the very good agreement between experimental and predicted values for the HPGR product BSA with average absolute relative deviation from measurements equal to 2.7 per cent. Results also allow to conclude that the model is able to capture key variations in the feed size distribution and accurately describe the HPGR product. Results for the twelve months assessed also presented good agreement with average absolute relative deviation from measurements of up to 5.3 per cent, but results were omitted for brevity. The predicted HPGR product BSA was calculated on the basis of the predicted product size distribution using a method proposed and calibrated previously by the authors (Campos *et al*, 2021).

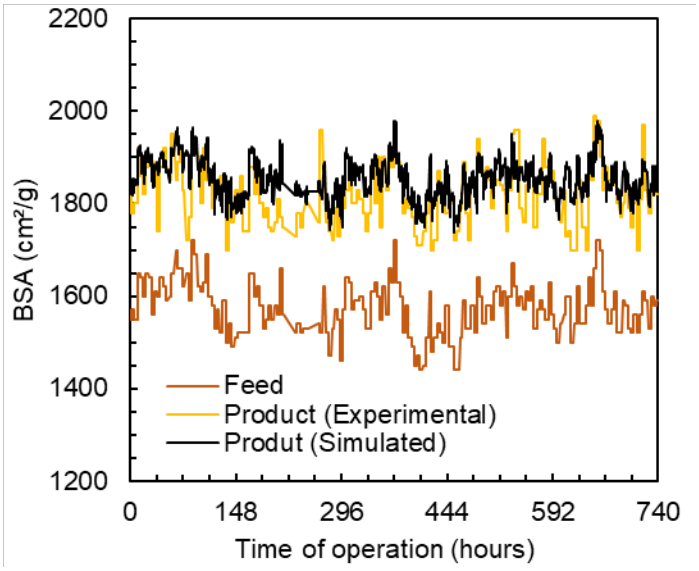

FIG 12 – Comparison of experimental and predicted values for the HPGR product BSA on the basis of the feed BSA measured every 4 hours.

CONCLUSIONS

The work relied on the application of the Modified Torres and Casali model as pseudo-dynamic approach to describe an industrial-scale HPGR pressing iron ore concentrates. Good agreement was reached to predict power consumption, throughput and product BSA when the HPGR was operating under good roll wear conditions.

Evidence of a bathtub wear profile and a wear parabolic profile after a period of 14 000 hours of operation was presented as a great challenge for model descriptions. Results highlighted an underestimation of power and throughput when the HPGR started operating under significant roll wear patterns. An algorithm was proposed to optimise selected model parameters with the aim of improving prediction for the HPGR with worn rolls which provided very good agreement between model and experiments.

A model was also proposed to convert the HPGR feed BSA into a cumulative feed size distribution. The model was validated under a wide range of measurements. Application of the breakage model using this new feature provided very good agreement between product BSA measured and predicted by the model.

Results showed feasibility of applying the model as a pseudo-dynamic model and coupled with real-time information to describe the HPGR performance in an industrial-scale plant pressing iron ore concentrates.

ABSTRACT

As the global demand for metal values expands, it becomes increasingly important to create more sustainable mining operations. Consequently, considerable research and technology development is required to produce processes which are both more energy efficient and have a minimal environmental impact. One potential technology is the utilisation of microwave pre-treatment to reduce the energy requirements in comminution. Microwaves can preferentially heat the valuable mineral phases in an ore and the resulting differential thermal expansion leads to the formation of microfractures along the grain boundaries. As a result of the preferential heating, ore competency is reduced, mineral liberation is enhanced, a coarser grind size can be employed, and plant throughput can be increased. Furthermore, microwave pre-treatment can be combined with advanced ore sorting, to decrease the quantity of gangue material processed downstream and hence reduce tailings production. Previous studies on the microwave treatment of ores over the last 30 years have mainly been limited to low power bench-scale studies and there is a paucity of information on pilot and/or commercial scale studies. In the present research, the microwave heating behaviours of over 40 ores have been studied at the bench-scale. These results were used to generate a database, from which a unique classification system was developed. This system was used to rank the amenability of any given ore for microwave pre-treatment. This knowledge can be employed to predict the performance of the ores in the high-power pilot scale tests and thus can be used as a pre-screening tool. The effects of high-power microwave pre-treatment on grindability and liberation were reported. Additionally, the ore sorting potential was evaluated using a combination of X-ray transmission (XRT) and microwave infrared (MW/IR).

INTRODUCTION

Conventional comminution circuits are extremely inefficient. A survey of three semi-autogenous grinding (SAG)/ball mill circuits by Bouchard *et al* (2019) revealed that 91 per cent of the energy input was lost, leaving only 9 per cent available for ore breakage. Given ever-increasing costs to mine depleting ore deposits coupled with more stringent environmental laws mandated by governments, it is exigent to develop more economic solutions. One possible solution is the application of microwaves for both assisted comminution and ore sorting (Bobicki *et al*, 2020; Forster *et al*, 2021; Olmsted *et al*, 2021).

In general, ores contain both valuable minerals and gangue (barren rock of little to no value). Many valuable minerals, such as sulfides and some metal oxides, heat very well in response to microwave irradiation. Typical gangue minerals, especially those containing large quantities of silica (SiO_2), are transparent to microwaves and do not heat. Selective heating causes differential thermal expansion, resulting in stress and strain across mineral grain boundaries, creating microfractures. It also generates distinctive heating patterns on the surfaces of the rocks. The three main benefits of microwave ore treatment are: ore competency reduction, increased liberation, and improved sortability, with significant variables being the frequency, power, temperature, dielectric properties, magnetic properties, load size, load mass, load position, and applicator type (Peng and Hwang, 2015).

Historically, the use of microwave energy to pre-treat minerals has focused on microwave-assisted comminution (Walkiewicz *et al*, 1991; Amankwah *et al*, 2005; Henda *et al*, 2005; Jones *et al*, 2005; Rizmanoski, 2011). Henda *et al* (2005) reported an uneconomical energy dose of 13 kWh/tonne from microwave pre-treatment and grinding. Here, the nickel and copper grades improved by 15 per cent

and 27 per cent, respectively, along with a recovery increase of 26 per cent. Therefore, although microwave pre-treatment and grinding alone may not be viable, downstream benefits may make a process worthwhile. The exploitation of the heat signature from microwave pre-treatment for ore sorting is more recent (eg Van Weert, Kondos and Gluck, 2009; Van Weert, Kondos and Wang, 2011; Ferrari-John *et al*, 2016; Batchelor *et al*, 2016, 2017; Naseh and Sam, 2019). Pioneering work by Van Weert and Kondos (2007) laid the foundation for this field by demonstrating that it is possible to use microwaves to readily heat sulfide ores and to use an infrared sensor as a sorting technique. However, one of their conclusions was that rocks shielded by surrounding rocks tended to heat up slowly. The authors recommended that scaling up requires the use of a belt instead of a shaft, which is contrary to a recent report from Holmes *et al* (2020), which suggested that a vertical system is appropriate for commercialisation. Despite the remarkable progress at the bench-scale (hundreds of studies), there is a lack of information regarding pilot and/or commercial scale studies on microwave-assisted comminution and sorting.

Three key parameters for successful application of microwave treatment at a larger scale are kinetics, penetration depth, and electronic control (Krieger, 1995). There is a trade-off between throughput and the energy input: a higher throughput reduces the energy input, but it also results in less grain boundary damage (Bradshaw *et al* (2011). Recently, a study has been conducted on the development and implementation of a continuous, pilot-scale, monomode microwave applicator that could deliver very high power (>100 kW) for very short times to produce ultra-low energy dosages of <0.7 kWh/t (Batchelor *et al*, 2017). This is because the electric field strength increases with microwave power. With this technique, for a copper porphyry ore, the same degree of liberation could be achieved at a grind size which was 50–60 µm greater than the untreated ore. Also the Ball mill work index was reduced by 3–9 per cent. Olmsted (2021) reported that high-power microwave pre-treatment of a gold sulfide ore improved gold recovery by 14 per cent after a leaching time of only 6 h. Anglo American PLC announced the development of a microwave-assisted comminution project at their Amandelbult platinum mine in South Africa, as part of their FutureSmart Mining™ program (Moore, 2021). In some of their preliminary test work, they reported hardness reductions of 5–25 per cent and 8–12 per cent for platinum and copper ores, respectively. The company is investigating installations at other facilities, starting with a pebble circuit at Los Bronces (Chile), followed by Mogalakwena (South Africa), Collahuasi (Northern Chile), and Quellaveco (Peru). This effort speaks very highly of the potential for microwave-assisted comminution in the mining industry.

The present work involves the study of the bench-scale heating behaviour of 42 unique ores to determine their amenability to microwave treatment. This test work resulted in a database, whereby a classification system was developed, which can be applied to rank any ore in one of four heating classes and determine its suitability for microwave pre-treatment. Select ores from this test program were tested at the pilot-scale using a 150 kW microwave system to determine the effects of microwaves on comminution, liberation of valuable minerals, and sorting potential.

MATERIALS AND METHODS

Materials

Table 1 presents the elemental analysis of the 42 ores investigated in the present study. There are many ore types including gold, silver, Ni/Cu, and Pb/Zn sulfides. Some of the oxide ores include chromite, and iron. There are also several silicate rich ores (Zn silicates, lithium, and kimberlite).

TABLE 1

Methods

Elemental composition

Inductively coupled plasma–optical emission spectrometry (ICP-OES) was used to determine the elemental composition of the head assays for the ore candidates and of selected rocks from sorting tests. For the head assays, representative crushed (2–3.35 mm) samples were pulverised into a fine powder and sent for analysis. For assays on rocks from the sorting tests, each rock was individually crushed and pulverised. All analyses were performed at XPS (Falconbridge, ON), where a subsample was split from the pulverised sample and digested via sodium peroxide fusion.

A Panalytical (Epsilon-1; 50 kV; Ag anode X-ray tube) XRF spectrometer was used to analyse the elemental composition of pulverised rock samples at Sepro Mineral Systems (Langley, BC). Each pulverised sample was riffled to between 10 and 15 g each, placed into a sample cup, and inserted into the system for analysis. The positive linear relationship with ICP-OES data was used to improve the accuracy of the XRF assays and to validate the methodology to be used for rapid XRF analysis of individual rocks in the pilot sorting tests.

Mineralogy and liberation

The SAG and BWI products form the grinding tests were sent for analysis using QEMSCAN. This technique allows for the determination of the mineralogy and liberation analysis of a sample. The samples of interest were split, mounted in epoxy, polished, carbon coated, and imaged. This analysis calculated the number, size, mineral composition, and associations of the particles. The liberation degree of target minerals (eg chalcopyrite, pentlandite, pyrrhotite, pyrite, sulfides, iron oxides) was represented as an area percent, indicative of the 2D surface fraction of the target mineral in a scanned particle. The particles observed on a single scan were grouped in liberation classes based on their area percent value as follows: locked (<30 per cent), low-grade middling (30–80 per cent), high-grade middling (80–95 per cent), liberated (>95 per cent) and free (100 per cent).

Bench-scale microwave heating behaviour tests

Microwave heating curves provide direct information on how a material responds to microwave irradiation. For each test, a 50 g sample of crushed (1.7–3.35 or 2–3.35 mm) ore was massed into a quartz crucible and placed into a BP-211 microwave oven (53.5 cm width × 25.1 cm height × 33 cm depth; Microwave Research and Applications, Illinois, USA). A top size of 3.35 mm was selected to match the feed size for typical ball mill grinding tests. Samples were exposed to 2450 MHz microwaves at 3.2 kW with time as the independent variable. After treatment, the quartz crucible was quickly removed from the microwave oven, and a Type-K thermocouple was inserted into the centre of the sample to measure the bulk temperature. Temperature was plotted against time to generate a microwave heating behaviour curve for each ore.

Pilot-scale microwave tests

The 915 MHz pilot-scale microwave system was designed and constructed by Thermowave (Danvers, MA, USA). It is equipped with two 75 kW transmitters. Multiple generators can provide a better excitation of modes yielding more uniformity compared to a single feed (Metaxas and Meredith, 1983). A water circulator dissipates any reflected microwave power, thereby preventing damage to the magnetron. The system is controlled via an HMI control panel equipped with an Allen Bradley PLC. The applicator is 1 m long, with a microwave transparent polypropylene bridge and a built-in arc sensor. The conveyor belt is made of microwave-transparent silicone/polyester and can reach speeds of up to 5 m/s. For all tests, the energy dosage in kWh/t was calculated prior to the test, and the tray packing, belt speed, and microwave power were varied to meet this value (eg 1–4 kWh/t electrical power). Immediately after processing, a FLIR A8300sc IR camera recorded a video of the sample trays and transferred the data via a Gigabit ethernet port connected to FLIR's Research IR software. In some of the monolayer sorting tests, the infrared videos were used to generate data for the ore sorting algorithm.

SAGDesign tests

Following microwave treatment, the sample was prepared for the SAGDesign test. Each ore required an initial reference grind (untreated material) before the microwave treated sample could be ground. The SAGDesign test was conducted using a laboratory SAG mill (Starkey, Hindstrom and Nadasdy, 2006). The grinding energy was determined for both a SAG mill (W_{SDT}) and a Bond Ball mill (S_d-BWI), both expressed in kWh/t. The W_{SDT} value estimates the energy consumption (kWh/t) of coarse grinding – SAG mill grinding from 80 per cent passing 152 mm to 80 per cent 1.7 mm. The BWI test (variability of ± 9 per cent) measured the energy required for fine grinding. The Bond mill used the ground product from the SAG mill test (T_{80} 1.7 mm) per the standard Starkey SAGDesign methodology.

RESULTS AND DISCUSSION

Bench-scale microwave heating behaviour of ores

The 42 ores tested were grouped into four classes (I–IV; Table 2) based on the bench-scale microwave heating behaviour (Figure 1). For the purposes of the current work, a formal definition of highly microwave amenable phases (HMAP)s is proposed. This includes the following minerals: bornite, chalcopyrite, galena, hematite, magnetite, molybdenite, pentlandite, pyrite, and pyrrhotite.

TABLE 2

Microwave heating classes, typical highly microwave-amenable phase (HMAP) content, and minimum, maximum, and mean initial (first 30 s) heating rates for 42 ores.

Heating Class		Typical HMAP Content (wt.%)	Initial Heating Rate (°C/min)		
			Minimum	Maximum	Mean
I	Poor	0–2	13	40	23
II	Fair	2–5	21	133	76
III	Good	5–20	105	339	159
IV	Excellent	>20†	150	829	559

† excluding massive sulfide ores

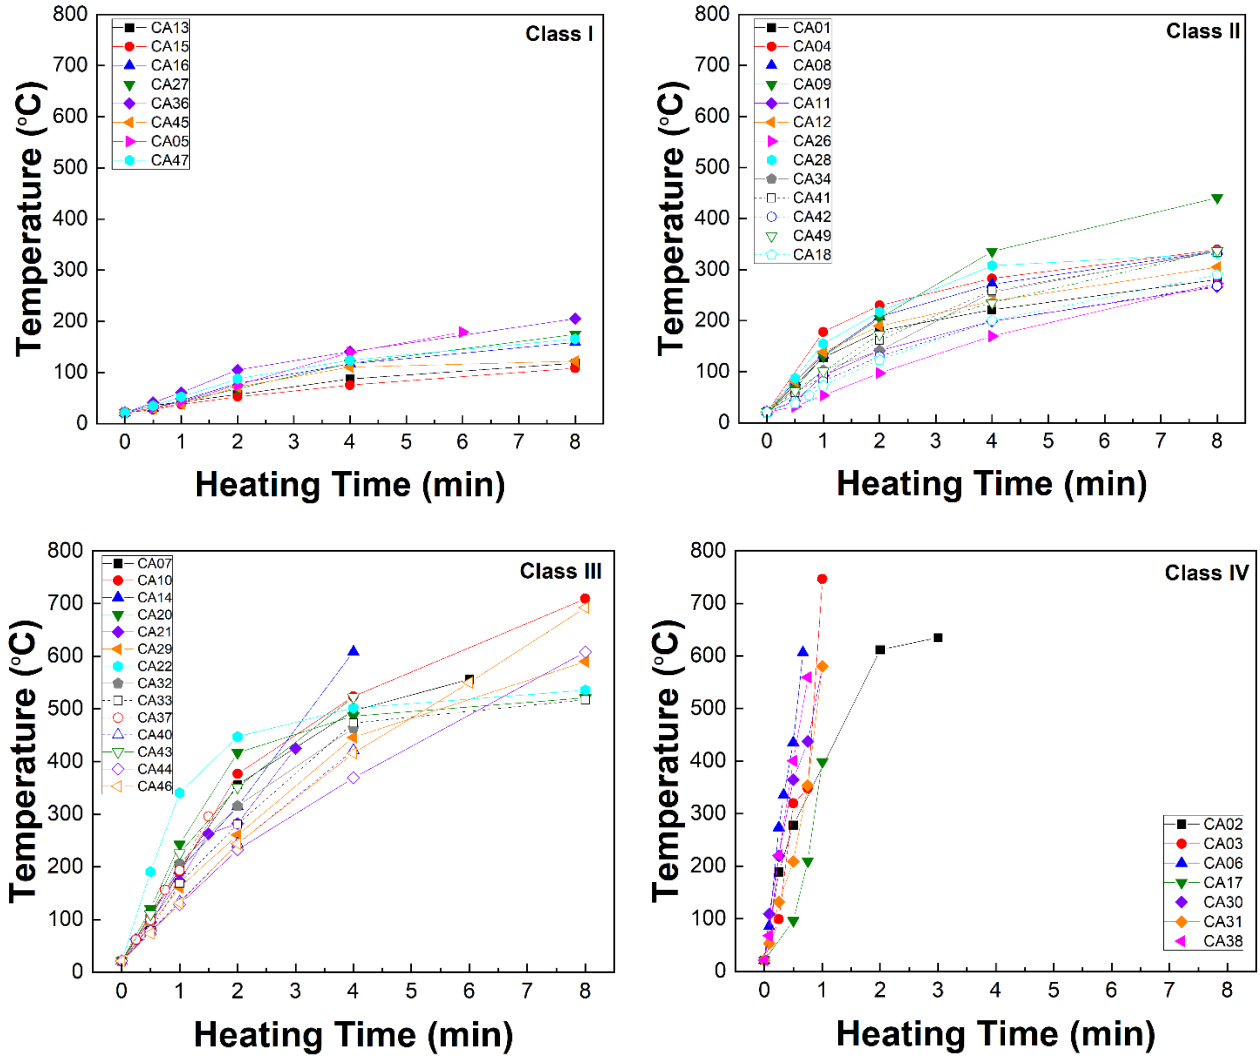

FIG 1 – Bench-scale heating behaviour curves for 50 g samples of 42 Class I–IV ores treated with 2450 MHz microwaves at 3.2 kW power; particle size 1.7–3.35 or 2–3.35 mm.

Class I ores showed limited heating, reaching a maximum temperature of roughly 200°C by 8 min. Despite this, grindability improvements are still possible. For example, Hredzak and Lovas (2005) reported that even relatively pure quartz (>99 per cent SiO_2) exhibited reductions in grindability after prolonged microwave heating. However, heating at low power (<5 kW) for a long period allows for thermal conduction between grains and particles. This additional heating mechanism reduces the temperature differential between grain boundaries of the various phases, thereby lessening the degree to which the ore will fracture. For comminution and ore sorting benefits, high heating rates are desirable. Hence, Class I ores are not ideal. Class II ores demonstrated moderate heating: most reached 250–300°C by 8 min. Class III ores exhibited high heating rates: most heated to >400°C after 4 min. Class IV ores had very high heating rates, with all ores reaching or exceeding 400°C within 1 min of treatment. However, none of these ores could be treated for the full 8 min due to thermal runaway and fusion of the samples. Furthermore, the power, particle size and the mass of the load will all affect the heating of any material. However, to achieve the maximum possible thermal gradient, the maximum power was applied. Future work will involve the exploration of these additional parameters.

In general, Class IV ores would be excellent candidates for pilot-scale microwave treatment. The very high heating rates would both initiate fractures in the ore (reducing competency and improving liberation) and provide a distinct thermal signature for sorting. Conversely, the low HMAP content of Class I ores would result in poor heat signatures. Class I ores are generally not amenable to the process. Class II and Class III ores can be expected to realise overall benefits, except ores with very conductive surfaces, which would reflect microwaves (eg massive sulfide ores). To facilitate comparison among the ores, the power was fixed at 3.2 kW for all the microwave heating behaviour tests. A lower power would have helped prevent thermal runaway (Huang and Lu, 2009) in some of the tests on the ores of a higher class. One of the major findings was that most of the gold sulfides are Class I ores (CA13, CA15, CA16, CA36, CA47), except for CA08 and CA14, which are Class II and Class III, respectively. CA08 contained roughly 2.4 wt.% iron sulfides (pyrite and chalcopyrite), and CA14 contained about 11 wt.% iron oxides. This proves that just a small increase in the amount of HMAP phases is enough to shift the curves to a higher class.

High-power microwave tests, comminution, and QEMSCAN of select ores

Ores CA30 (net textured sulfide ore), CA34 (gabbro rock), CA41 (Ni/Cu sulfide), and CA42 (Cu porphyry) were treated in the pilot-scale microwave system and subsequently tested using the grinding procedure according to the parameters in Table 3. The efficiency of conversion of electrical to microwave power was approximately 80 per cent which is on par with that reported by Tranquilla *et al* (1999). In many of the microwave assisted comminution tests, smaller particles (<25.4 mm) were added to the trays to mitigate arcing by reducing the void spacing between adjacent rocks. For the very soft copper porphyry ore (CA42), the W_{SDT} values of the microwave treated samples increased slightly after grinding, which may be indicative of improved breakage at the coarser particle size during grinding. A reduction in competency was not realised for this soft ore. Furthermore, the doubling of the electrical energy dose from 2 kWh/t to 4 kWh/t did not significantly reduce the ore competency either. However, improved liberation is still possible (see next section). In many of the grindability results presented, benefits are realised in the SAG portion of the SAGDesign test, as opposed to the Bond ball mill test (closing size based off process flow sheet).

TABLE 3

Microwave treatment parameters and SAGDesign comminution results for select ores.

†Olmsted (2021); *Ref-Reference Sample; MW-Microwave Treated Sample

QEMSCAN

Ni/Cu sulfide ore (CA30)

QEMSCAN liberation analysis was carried out on the SAG test product and two size fractions from the BWI test: >106 and <106 µm. For the <106 µm products, considering the top two liberation classes (>95 and 100 per cent), the minimal improvement in pentlandite liberation from microwave treatment was mostly due to a slight improvement for the free (100 per cent liberated) class (Figure 2a). However, for chalcopyrite, the amount of liberated plus free material was more than 2.4 times higher for the microwave-treated (36.3 per cent) than for the reference samples (14.9 per cent; Figure 2b). It is possible that a greater proportion of the chalcopyrite is hosted within the gangue silicate matrix, whereas the pentlandite is preferentially combined with gangue pyrrhotite, which is a HMAP. Therefore, the chalcopyrite-silicate would experience more intergranular fracturing than the pentlandite-pyrrhotite system.

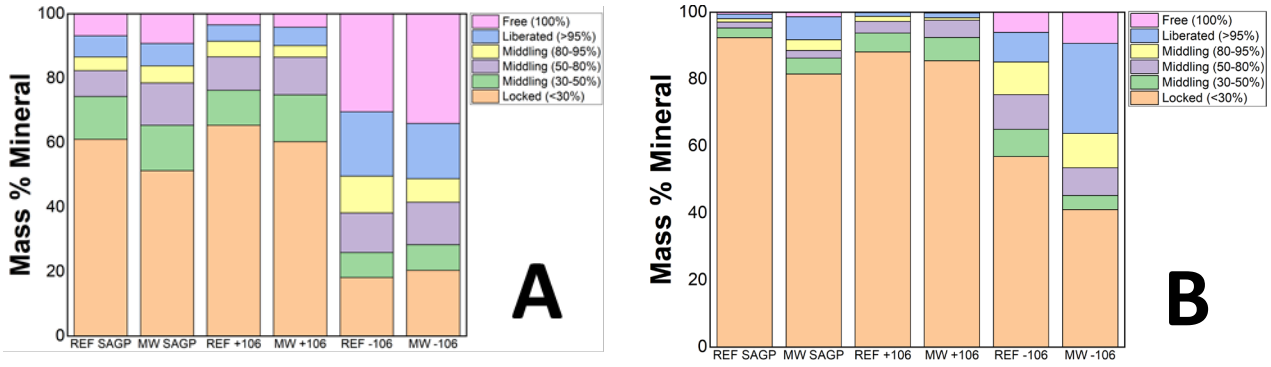

FIG 2 – Pentlandite (A) and chalcopyrite (B) liberation for reference (REF) and microwave-treated (MW) samples of CA30.

Copper porphyry ore (CA42)

Given the very low W_{SDT} for this ore (Table 3), microwave pre-treatment followed by comminution did not yield grinding energy savings. Instead, savings are expected to be realised in downstream flotation, where an improvement in the liberation of copper sulfide species should improve overall Cu recovery. Copper sulfide liberation (>95 per cent and 100 per cent) from the Bond ball mill

undersize products for Ref1 and 2 and MWT1 and 2 (Table 3) at both closing sizes showed a significant improvement after microwave pre-treatment (Figure 3). For the test with a closing size of 106 µm, microwave treatment increased liberation from 25 to 58 per cent. For the coarser closing size (212 µm), liberation was increased from 17 to 55 per cent.

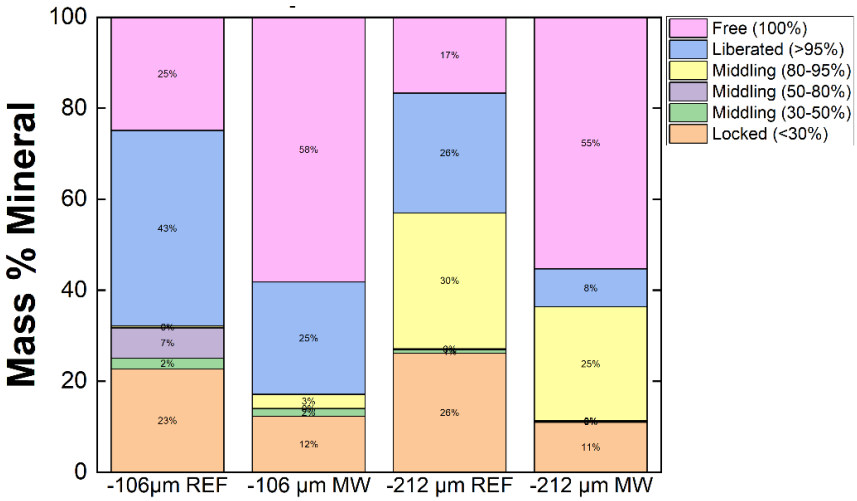

FIG 3 – Copper sulfide liberation analysis for reference and microwave treated samples at two closing sizes.

Monolayer sorting of nickel sulfide ore (CA30)/gangue rock (CA34) blend

CA30 and CA34 were from the same mine site, and therefore it was of interest to carry out a sorting test on a blend of these two materials. A 25.6 kg load comprising a 58/42 wt.% blend of CA30 (48 rocks)/CA34 (36 rocks) was treated at 75 kW power (2.2 kWh/t electrical energy dose). Many of the gangue rocks (white/grey) heated up, which is likely due to the larger penetration depth (Figure 4). Certain sections of the surfaces of the valuable rocks (darker in colour) were more conductive because they contained pentlandite, pyrrhotite, and chalcopyrite. Even if surface heating was high, there was less bulk heating for these rocks, given the lower penetration depths of their constituent sulfide minerals.

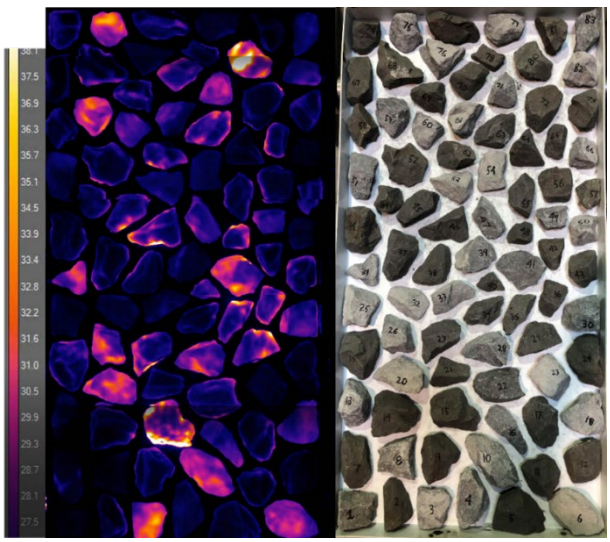

FIG 4 – Infrared and optical images of the sample tray of a 58/42 wt.% blend of CA30 (48 rocks) and CA34 (36 rocks) for the MWIR monolayer sorting test.

The infrared video was processed into multiple frames, and the pixels from the infrared heating pattern were then extracted and combined with the XRF and XRT analysis before being fed into a proprietary sorting algorithm which uses machine learning. Table 4 reports the mass split, recoveries, feed and product grades, and upgrade ratios for the nickel and copper. A mass rejection of 31.5 per cent yielded a nickel recovery of 98.7 per cent, and a corresponding upgrade ratio of

1.51. Mass rejection while maintaining high metal recovery directly translates into energy savings. A previous study by CanMicro found that the integration of ore sorting represents significant energy savings (Tian *et al*, 2021).

TABLE 4

Sorting analysis results for Ni/Cu (CA30) ore.

Component	Parameters	Value	Unit
Mass Split	Mass Rejected	34.50	%
	Mass Accepted	65.50	%
Nickel	Recovery	98.70	%
	Feed Grade	3.75	%
	Product Grade	5.65	%
	Upgrade Ratio	1.51	Ratio
Copper	Recovery	97.90	%
	Feed Grade	0.76	%
	Product Grade	1.13	%
	Upgrade Ratio	1.49	Ratio

CONCLUSIONS

A microwave heating behaviour database comprising of hundreds of bench-scale experiments on 42 ores was developed. Ores were classified into one of four heating behaviour classes, which is directly related to the wt.% of HMAP present in an ore: (poor, 0–2; fair, 2–5; good, 5–20; excellent, >20). This is the first comprehensive study on an array of ores spanning multiple commodities, especially sulfide ores.

Pilot-scale microwave tests were carried out on four selected ores. This involved treatment at high power (75 or 150 kW) for very short amounts of time. Appreciable reductions in the SAG W_{SDT} values were obtained on three out of the four ores. The ore (CA42) that did not achieve a reduction in grinding energy but still demonstrated substantial improvements in the liberation of the copper sulfide mineral species. This reveals that while comminution test work may not immediately show energy savings, this loss can be reclaimed in downstream unit operations, providing sufficient liberation has been attained.

Monolayer ore sorting results for a blend of a nickel sulfide ore and gangue rock demonstrated that if a discrete heat signature is captured then the combination of microwave pre-treatment with sorting has considerable potential.

ACKNOWLEDGEMENTS

Sepro Mineral Systems is thanked for providing support during the pilot-scale microwave tests. Elizabeth Whiteman from XPS is recognised for overseeing the ICP and QEMSCAN analysis. The authors would like to thank Corem for their assistance with the XRT analysis. Izzat Redza, Spencer Gulbrandsen, Byron Liang, Christine Yu, James Ambrose, and Trevor Kok are thanked for their efforts in the laboratory. Thank you to all the mining companies who supplied the ore samples for this research. Natural Resources Canada is thanked for sponsoring team CanMicro during the Crush It! Challenge.

ABSTRACT

A better understanding of ore fragmentation and the textural features of ore is a key to the energy efficient extraction of targeted minerals from low-grade ore deposits. In this study, X-ray microcomputed tomography (micro-CT) is employed to study mineral liberation during the tensile failure and onset of fragmentation of a copper ore. Our results show that X-ray micro-CT could inform new studies of ore micromechanics and fragmentation at the laboratory scale and may offer new avenues to address current challenges in the design of efficient comminution processes.

We present the results of experiments based on a high-pressure apparatus enabling micro-mechanical studies to be carried out *in situ* (inside a micro-CT scanner). This platform produces high-quality 3D images of the evolution of a sample of porphyry copper ore during an *in situ* fragmentation test. A sequence of tomographic images enables mapping in 3D of both the deformation of mineral phases and the fragmentation process. The fragmentation occurs quasi-statically through multiple stages starting with an initial tensile fracture splitting the ore diametrically, followed by tensile-activated nucleation and growth of multiple fractures producing a complex fracture network.

Coupling breakage with microstructural information enables quantitative determination of the impact of ore texture heterogeneity on fracture patterns and mineral liberation. This microstructural information can be compared to key measurements of the ore mechanical behaviour such as the global deformation energy, strain deformation field and the stress relaxation response. The latter allows one to identify interesting precursor signals of the tensile failure. The copper liberation, fragment size distribution and breakage patterns are statistically characterised and related to comminution mechanisms which are clearly identified in the sequence of tomographic images. The two dominant mechanisms are rock-rock friction/compression induced by fracture closing and compression-driven fragmentation at rock-crusher contact points.

INTRODUCTION

The mining industry uses diverse crushing and grinding methods to reduce lumps of ore into smaller fragments. This process of breaking a coherent orebody into many pieces, called comminution, is used to expose valuable minerals from the rock groundmass and to produce ore-concentrate. Ore comminution represents a substantial part of a mine's energy consumption. Energy-efficient comminution and optimal mineral extraction are key to the economics and sustainable development of critical mineral mining. Current research efforts to better understand the key factors governing geomaterials comminution reflect the need to rationalise empirical practices. Moreover, the increasing demand for minerals pushes the mining industry to exploit low-grade ore deposits. This trend challenges the usual modelling of comminution efficiency in terms of optimal liberation (resource efficiency) at minimal overgrinding (energy efficiency).

Failure and fragmentation of an ore lump involves a range of complex mechanisms at multiple length scales from microscopic crack openings, to the behaviour of large fractures interacting and producing broad distribution of fragment sizes (Jaeger, Cook and Zimmerman, 2007; Gueguen and Bouteca, 2004). In the context of mining applications, several questions on comminution are the subject of current and intense research efforts (Tavares, 2021; Ord, Blenkinsop and Hobbs, 2022). Typical questions are: What are the mechanisms of fragmentation of an ore with a given texture? Is there a dominant mechanism for a given crushing process? How is the prevalence of a fragmentation mechanism reflected in the final fragment size distribution? How is the coupling of breakage mechanisms with the ore texture heterogeneity impacting the efficient liberation of critical minerals?

Recent advances in X-ray microcomputed tomography (micro-CT) may offer new avenues to address these difficult questions and to inform studies of ore micromechanics and fragmentation at the laboratory scale (Cnudde and Boone, 2013; Noiriel, 2015; Viggiani *et al*, 2015), while providing the basis for development of energy-efficient liberation process streams. Indeed, high resolution X-ray scanners and micro-CT reconstruction techniques enable non-destructive observations of the inner structure of rocks, giving access to three-dimensional information on the crack density, mineral texture and heterogeneous structure of rocks. The capability of micro-CT to provide this structural information from microscopic to centimetre scale also makes it a remarkable tool for studying failure mechanisms in geomaterials (Cnudde and Boone, 2013; Noiriel, 2015; Ghamgosar *et al*, 2016; Viggiani *et al*, 2015). Over recent years, CT-based research efforts have focused on the realisation of *in situ* mechanical tests (Lenoir *et al*, 2007; Hurley *et al*, 2016; Saadatfar *et al*, 2012; Ando *et al*, 2013), whereby a rock is tested inside the scanner. This approach provides direct observations of the evolution of a rock microstructure as it deforms and fails. However, to date, the *in situ* study of hard rock failure remains extremely difficult and to our knowledge *in situ* tomography has been rarely exploited to study a rock on its path to fragmentation (Parapari *et al*, 2020; Jiang *et al,* 2021).

Here, we present the results of a model *in situ* experiment on mineral liberation during the failure and onset of fragmentation of a low-grade porphyry copper ore. This experiment is concerned with tensile activated rock failure which triggers fragmentation. We analyse *in situ* multiple stages of the ongoing fragmentation process starting with an initial tensile fracture splitting the ore diametrically, followed by tensile-activated nucleation and growth of multiple fractures producing a complex fracture network. During the mechanical test, high-resolution 3D images are acquired and the quasi-static fragmentation process is mapped sequentially. These 3D images enable tracking of the influence of ore texture on the local fracture mechanism and observing the interaction of multiple growing fractures in this heterogeneous rock. Moreover, tomographic data enables quantification of the copper liberation, the fracture density and the fragment size distribution.

ORE SAMPLE AND EXPERIMENTAL SET-UP

The objective of this experimental study was to explore the mechanical behaviour and fragmentation process of an ore sample subjected to a dominant tensile stress. For this pilot study, a 12 mm diameter 8 mm length subcore was used. It was extracted from a 45 mm diameter NQ3 drill core from the late Ordovician-early Silurian (~455–435 Ma) Northparkes porphyry copper mine in New South Wales (Australia). The geology of the deposit has been described in (Lickfold *et al,* 2003; Pacey *et al,* 2019). The deposit is made up of a cluster of intrusion-related porphyry copper orebodies centred on quartz monzonite porphyry intrusions and each has a copper core within potassium silicate altered intrusive and surrounding rocks (Pacey *et al,* 2019). The core sample used

here is from an altered volcaniclastic breccia that contains clasts of porphyritic andesitic volcanic lava and volcanic sediments ranging from bedded mudstones-siltstones to coarse sandstones and clast rich volcanic breccias.

Central to this study is a unique experimental platform: the X-ray micro-CT high-pressure apparatus (XCT-HP apparatus) which is part of the CTLab based at the Research School of Physics of the Australian National University. The design of the instrument grew out of research performed at the Australian National University for the last 15 years (Saadatfar *et al*, 2012; Sheppard *et al,* 2014). In the context of geomechanics, this instrument produces very high-quality 3D images which are pivotal to identifying key microscopic displacements and 3D microstructural changes during rock failure and fragmentation.

The XCT-HP apparatus is fully integrated to a cone-beam X-ray micro-CT instrument that was designed and built in-house at the ANU (Francois *et al*, 2022). Figure 1a and 1b show the main components of this instrumental platform, namely, the high-pressure cell, an X-ray source, an X-ray photon detector and a high precision sample manipulator consisting of a rotation stage and a vertical translation stage. Figure 1c shows the different components of the high-pressure cell. The design of the cell is based on two opposed pistons positioned at the extremities of a cylindrical confining chamber. The top piston is locked in position while the lower piston moves axially and is driven hydraulically by a syringe pump. The syringe pump is connected to a PID controller that enables an accurate control of the axial pressure applied to the moving piston. The pressure in the hydraulic loading line is measured using pressure transducers and simultaneously the piston displacement is measured by a Linear Variable Differential Transformer which provides an additional input to the PID control loop. These various transducers enable a control of pressure and piston displacement in a $\pm 1 \times 10^{-3}$ MPa and ± 0.5 µm range respectively.

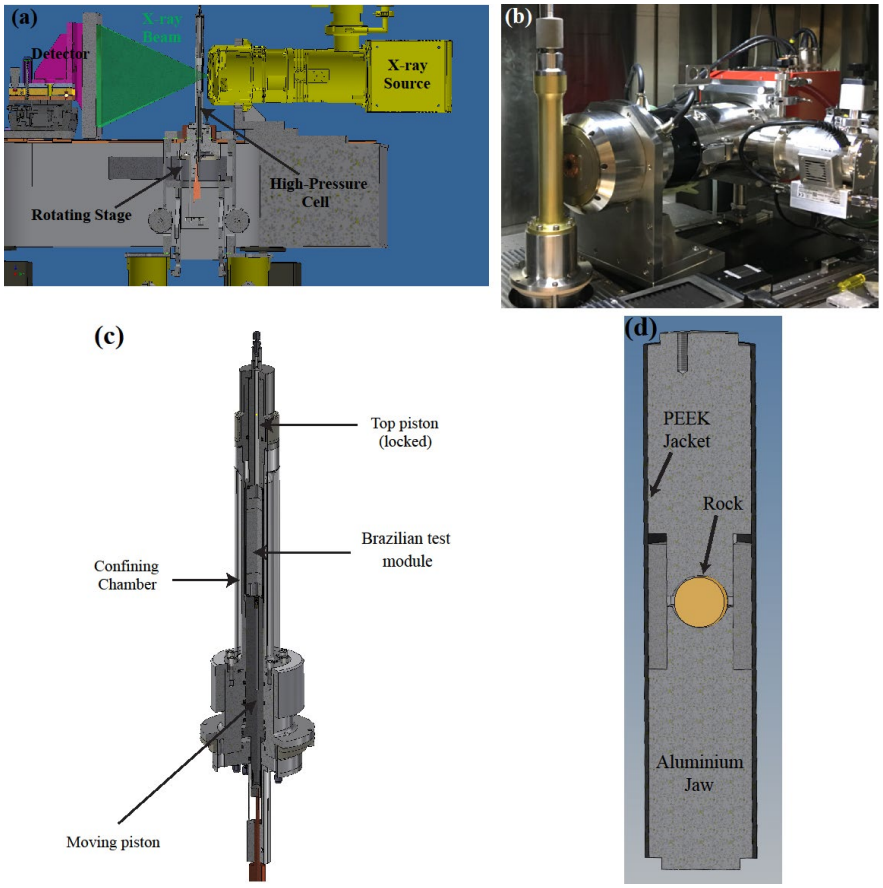

FIG 1 – (a) CAD drawings depicting the XCT-HP apparatus mounted on the high-resolution X-ray micro-tomography platform at the Australian National University. (b) Picture of the instrumental platform showing the confining chamber of the high-pressure cell and the X-ray source. (c) CAD drawing of the main components of the high-pressure cell. (d) Schematics of the crushing-test module. A disc-shaped rock sample is placed in the jaws of the rock-crusher device. The crushing device is placed in the confining chamber of the high-pressure cell.

To perform a tensile activated fragmentation test, we use an in-house designed crushing device. This crusher module is shown in Figure 1d, the loading configuration is based on that of Brazilian tensile tests (Li and Wong, 2013). It is composed of a pair of curved Aluminium jaws encapsulated in a cylindrical jacket made of PEEK. This module sits in the confining chamber of the high-pressure apparatus. A disc-shaped ore sample (diameter d = 12 mm, thickness t = 8 mm) is placed in the crusher. As the ore is compressed between the two jaws, a compressive stress is directed along the diameter of the rock while tensile stresses develop in the horizontal direction. The axial force F exerted by the hydraulic piston on the jaws may be converted to a tensile stress $\sigma_t = F/(d \times t)$ (Li and Wong, 2013). The strain ε_t is computed as $\varepsilon_t = \delta l/d$ where δl is the change in the gap distance between the jaws. Twelve high-resolution tomographic images were acquired at different stages of the mechanical test of the ore sample. The typical scanning time for an image is 17 hours. The image spatial resolution (ie the voxel size) is $9\ \mu$m. These images allow sequential quantitative tracking of the quasi-static failure and fragmentation of the ore. The loading protocol between each image consisted of a pressure ramp at a rate of 1.4×10^{-3} MPa/s followed by a 4-hour long relaxation period at fixed strain value before the image acquisition.

RESULTS

Figure 2a shows the stress-strain curve of the copper sulfide ore measured during a 15-day-long experiment. These mechanical measurements can be compared to tomographic sections of the rock obtained at increasing values of the tensile stress (see Figures 3a and 4a). These two figures clearly show how the rock undergoes successive tensile-activated failure and fragmentation. The images also reveal an interesting fact about the stress-strain curve shown in Figure 2a. An elastic deformation region seems to exist for a range of strain values extending up to $\varepsilon_t = 0.47$ per cent, however a large tensile-activated fracture (F1) occurred at a strain $\varepsilon_t = 0.26$ per cent, and a stress of 38 MPa. It was possible to load the ore beyond this failure point, and a linear relation between stress and strain was recovered until the rock sample could not sustain any further increase of the stress. This mechanical event is correlated to the emergence of a dense network of fractures, it occurred at a strain $\varepsilon_t = 0.47$ per cent, and a stress of 78 MPa. Figure 2b shows the fragmented rock after unloading from the high-pressure cell.

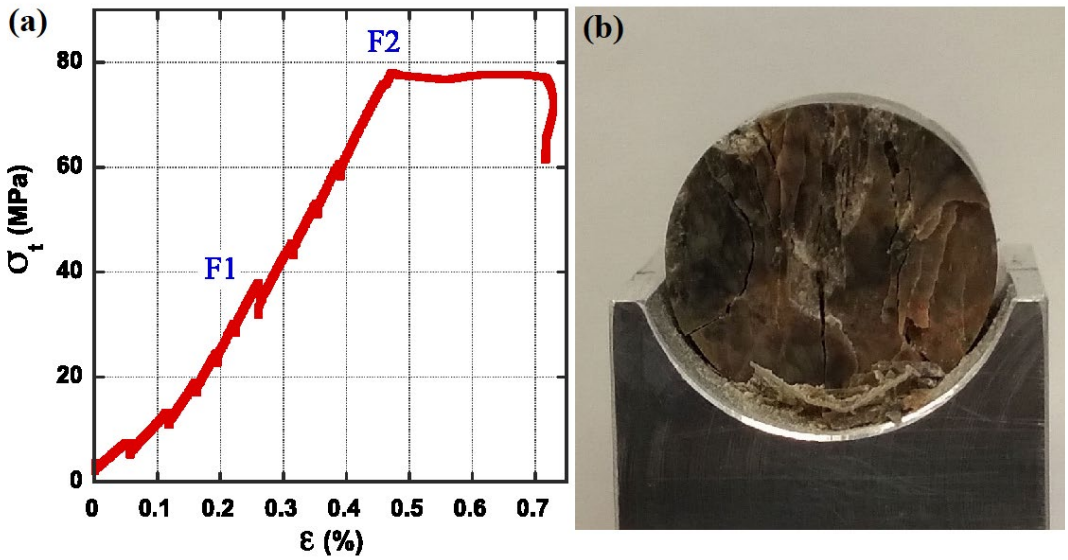

FIG 2 – (a) Stress-strain relation during the *in situ* tensile strength test performed on the copper sulfide ore. Indices F1 and F2 indicate the tensile failure and ultimate fragmentation. (b) Picture of the fragmented ore.

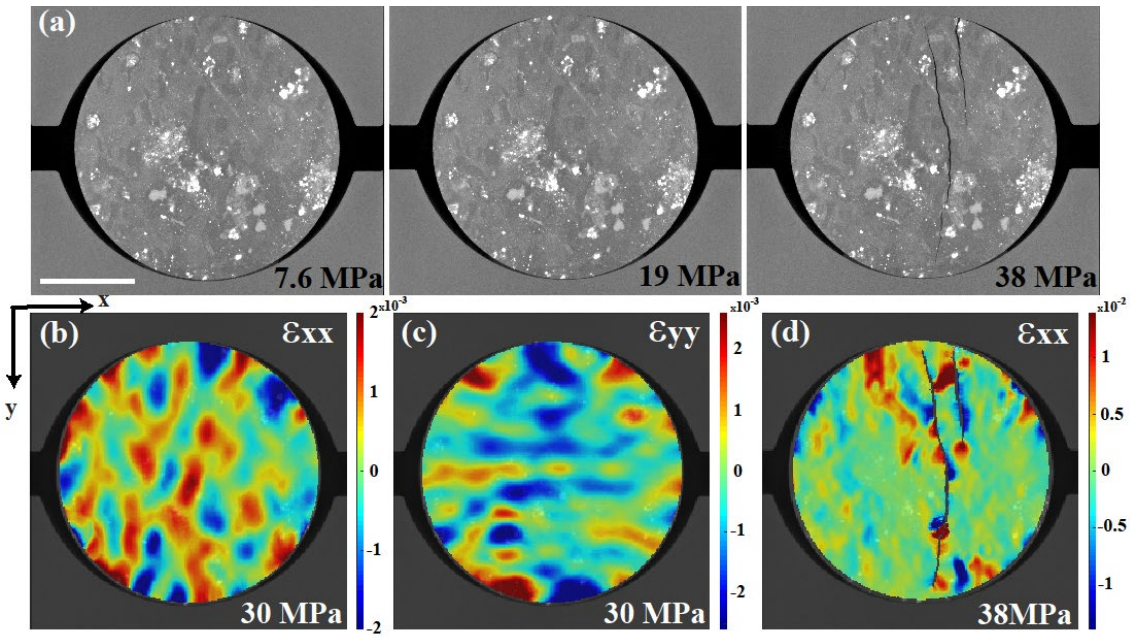

FIG 3 – (a) Midplane tomographic sections of the ore sample at increasing applied load until tensile failure occurs at $\sigma_t = 38$ MPa (Scale bar = 4.5 mm) (b–c) Maps of the strain components ε_{xx} and ε_{yy} measured for an increase of σ_t from 7.6 MPa to 30 MPa. (d) Strain map of ε_{xx} measured between the stressed state at $\sigma_t = 30$ MPa and the tensile failure at $\sigma_t = 38$ MPa.

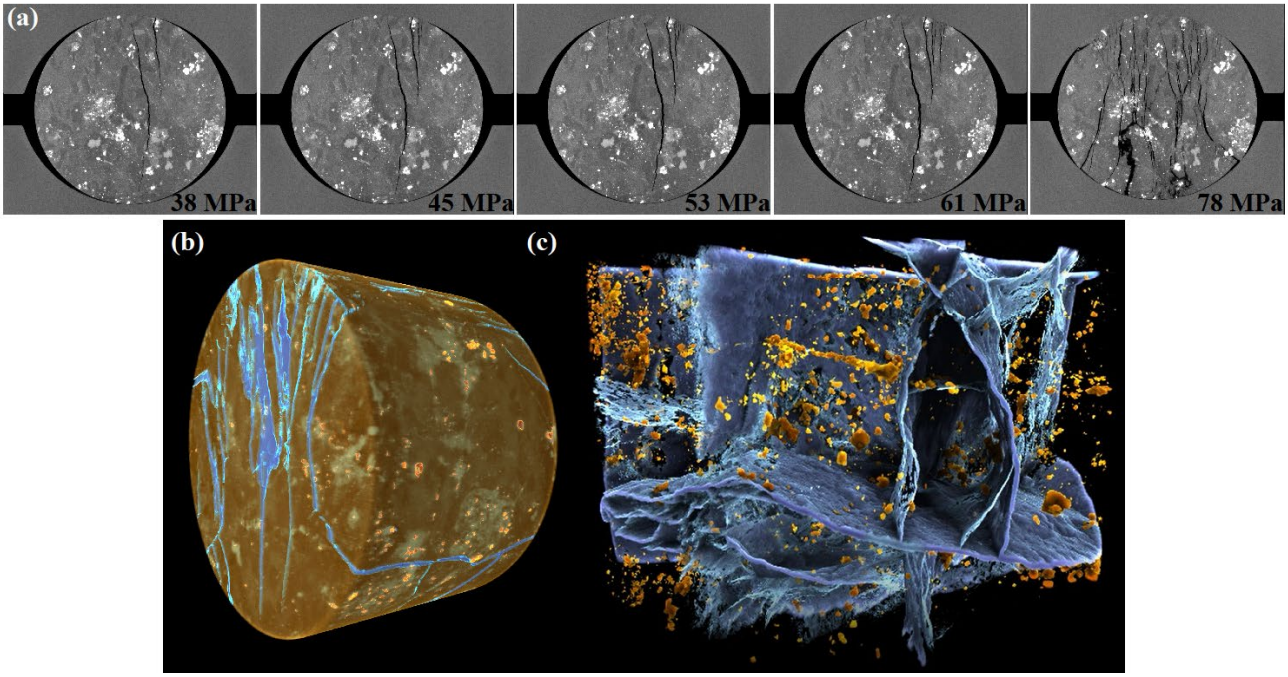

FIG 4 – (a) Midplane tomographic sections showing the ore undergoing successive failure ($\sigma_t = 38$ MPa) and fragmentation ($\sigma_t = 78$ MPa). (b) 3D reconstruction of the fragmented ore (at $\sigma_t = 78$ MPa): fractures (blue) and Cu-rich minerals (orange) are highlighted. (c) 3D visualisation of the fracture network and the Cu-rich grains.

The quantitative analysis of the tomographic images provides valuable information on many aspects of the breakage mechanism that leads to the rock fragmentation. For instance, the deformation field of the copper ore is mapped using digital image correlation technique in Figure 3 (Lenoir *et al*, 2007). Local strain amplitudes as low as 5×10^{-5} are measured using a 500-μm-diam interrogation window on a spatial grid with a mesh size of 50 μm. In Figure 3b and 3c, both tensile and compressive strains are observed on the maps of different components of the strain tensor. The spatial distribution of strain is quite different to that computed for homogeneous model rocks (Li and Wong, 2013); this

difference reflects the complex coupling between the ore heterogeneous structure and the deformation field. The maps in Figure 3b and 3c were computed by comparing a reference image with the image acquired at $\sigma_t = 30$ MPa just before the tensile failure. The axial strain component ε_{yy} shows an interesting structure with alternative compression and dilation bands along the vertical direction. The transverse strain component ε_{xx} shows the presence of tensile strain hot spots in particular in the central region and the region in contact with the top jaws. The locations of these hot spots are correlated with the opening of the three large fractures observed at $\sigma_t = 38$ MPa (shown in Figure 3a). Figure 3d shows a map of the strain component ε_{xx} measured at the tensile failure point when the first three fractures opened. As expected, there is a high tensile deformation at the tips of the different fractures. We also note the interesting interaction between the tips of the two central fractures which produces a region with both high tensile and compressive strains. The map also reveals the spatial distribution of compressive and tensile strain along the fracture contours.

The tomographic sections shown in Figure 4a illustrate the multiple stages that leads to the fragmentation of the ore. The initial large fracture splits the ore diametrically. As stress is further increased, we observe tensile-activated nucleation and growth of multiple fractures producing a complex fracture network. Remarkably the high-pressure apparatus and the PID controller enables us to stabilise the ore sample in a critical mechanical state, in a sense allowing to freeze the fragmentation process. Figure 4b shows a 3D *in situ* visualisation of the ore in its fragmented state. Taking advantage of this digital twin of the fragmented ore, segmentation techniques can be used to visualise the geometry of the fracture network while highlighting the locations of the copper clusters (see Figure 4c).

This microstructural information can be compared to different facets of the mechanical response of the ore to tensile stresses. Figure 5a shows the mechanical work done by the crushing jaws computed as $E_w = \int F\delta l$. A sharp change in the evolution of E_w occurs at $\delta l_t = 56\ \mu$m, marking two different regions. $\delta l = \delta l_t$ marks the onset of fragmentation. For $\delta l < \delta l_t$, E_w can be interpreted as a deformation energy of the ore sample which accounts for elastic and plastic deformations as well as fracture opening beyond the failure point F1. The ore fracturing occurs at $E_w = 0.12$ J and its fragmentation at $E_w = 0.42$ J. Beyond the threshold value δl_t, the ore is yielding and the mechanical response is dominated by the dynamics of the fractures. In this regime, the interpretation of the energy E_w becomes difficult because some large fractures are opening while some other are closing. The closing of a fracture is a highly dissipative process which impacts the ore comminution, this will be discussed below with reference to Figures 6 and 7.

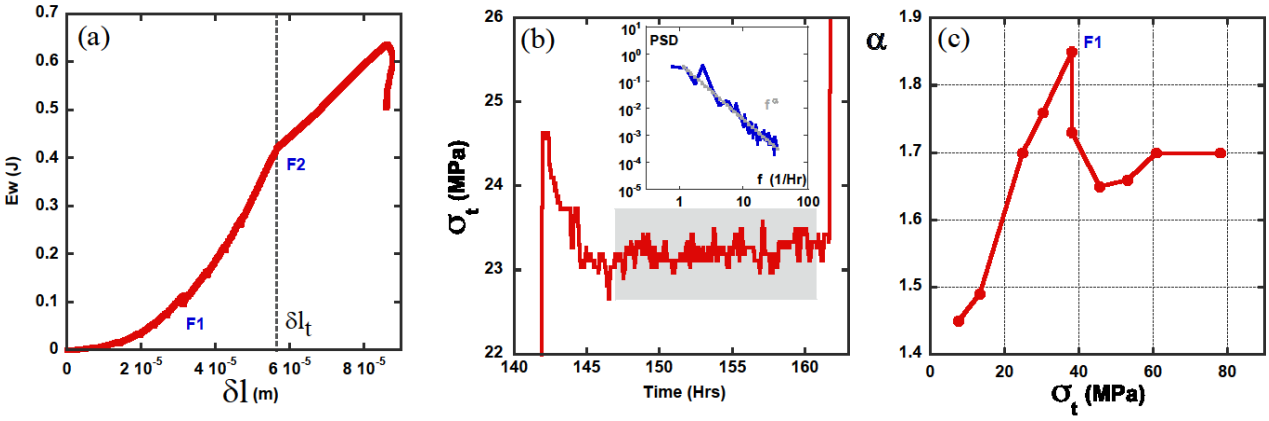

FIG 5 – (a) Mechanical work E_w done by the crushing jaws versus δl the reduction of the gap between the jaws. (b) Temporal fluctuations of the tensile stress measured at fixed strain during an image acquisition. The grey box indicates the time domain over which the spectral analysis is carried out. Inset: Typical frequency power spectrum of the stress fluctuations. The grey line shows the scaling law behaviour f^{α}. (c) Scaling law exponent α measured at various stages of the mechanical test.

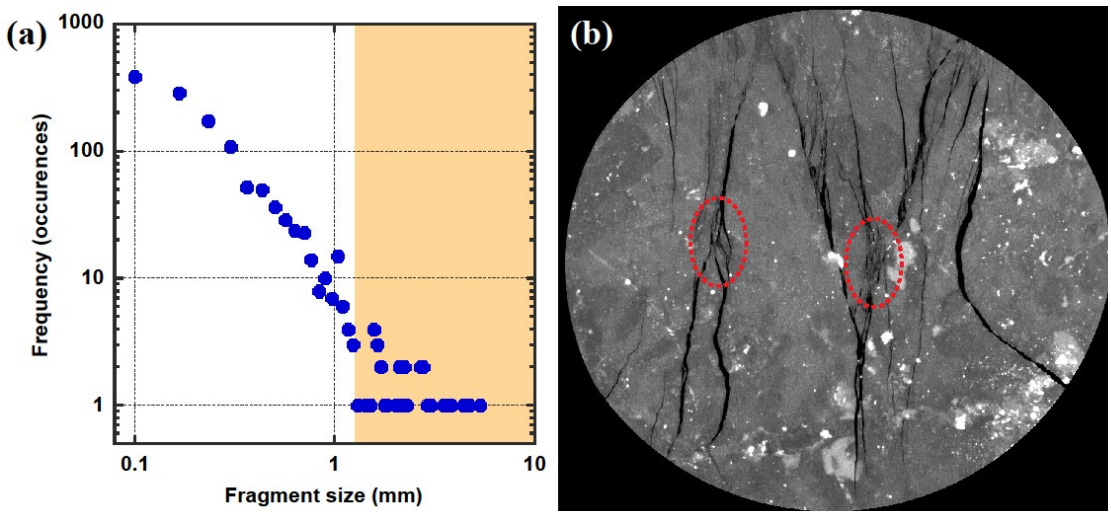

FIG 6 – (a) Fragment size distribution measured after the fragmentation point F2 at $\sigma_t = 78$ MPa. The fragment size l is computed as $l = \sqrt[3]{V}$ where V is the volume of the fragment. The orange area corresponds to the 50 largest fragments for which $l > 2\,m$m. (b) Tomographic section of the fragmented ore; regions of intense comminution are highlighted by red ellipses. In these regions, the closing of large fractures produces high compression and frictional stresses yielding small size fragments.

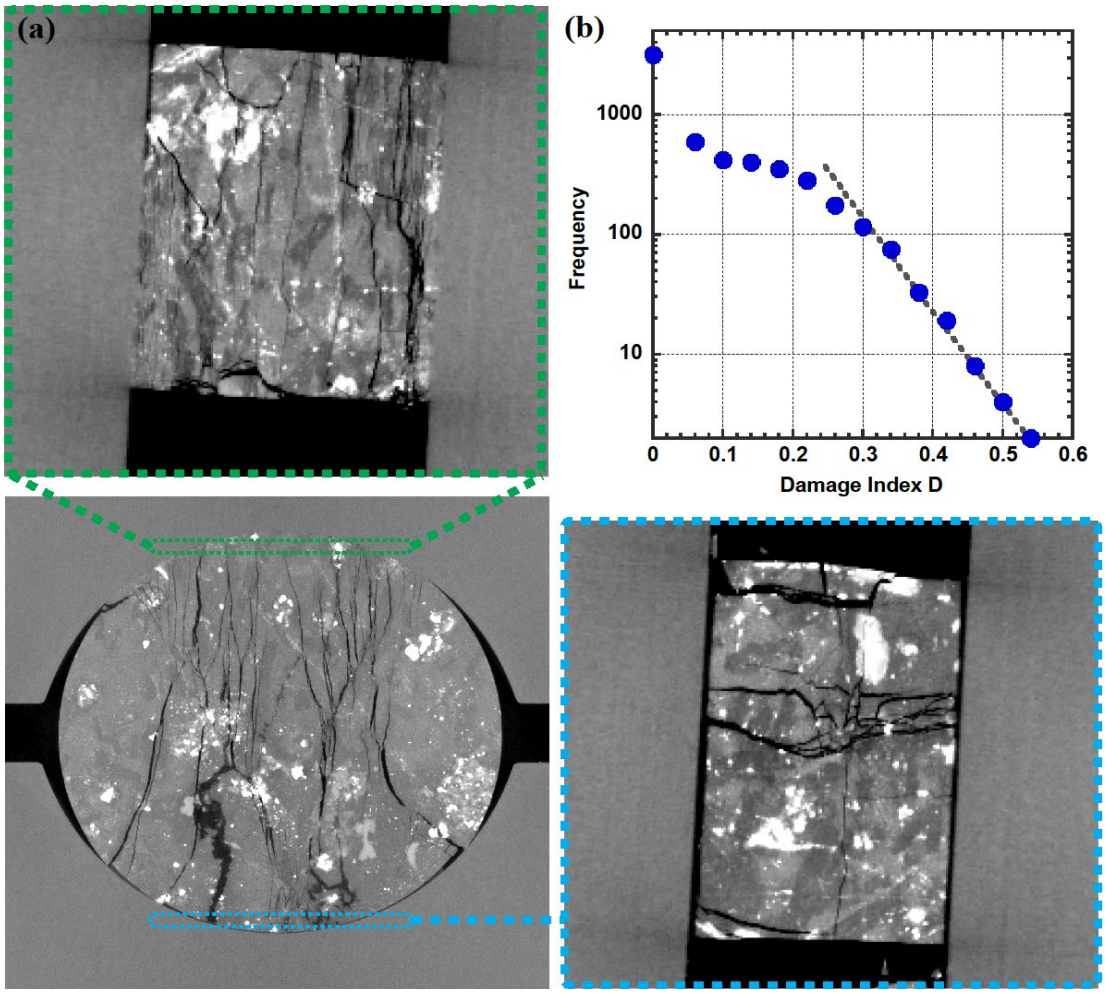

FIG 7 – (a) Vertical and horizontal tomographic sections showing regions of high comminution of the ore. Top and right panels show horizontal tomographic sections close to the contact regions between the rock and the aluminium jaws, where compressive stresses concentration produces a broad range of fragment size. (b) Damage index distribution computed on a 3D spatial grid with a mesh size of 0.5 mm.

The XCT-HP apparatus enables the study of the mechanical relaxation of the ore at different stages of the fragmentation process. The transient response to a change in mechanical deformation is an interesting phenomenon in geomaterials (Jaeger, Cook and Zimmerman, 2007). One typical transient experiment involves deforming a rock and observing the decay in stress over time under a constant strain level. In our experiment, the tensile stress is ramped up to a set value and after a conditioning stage, a tomographic image is acquired at fixed strain ε_t. During the day-long image acquisition, the relaxation of the tensile stress σ_t at fixed ε_t is continuously recorded. Figure 5b shows a typical time trace of σ_t measured over 17 hours. The fluctuations of σ_t are expected to be correlated to microstructural modifications occurring in the ore sample. To identify such correlations, we compute the frequency power spectrum of fluctuations of σ_t at different stages of the mechanical test.

These power spectra present a broad band with a scaling law behaviour where very low frequencies are excited (see inset Figure 5b). Figure 5c shows the measurement of the scaling law exponent α at increasing value of the tensile stress. Before fracture, the exponent α increases with the increase of σ_t, and peaks at the failure point, beyond which the exponent is saturating at a lower value $\alpha = 1.7$. These results suggest that the spectral analysis of the mechanical noise during stress relaxation could be used to predict the proximity to mechanical failure.

Tomographic data also enable precise measurement of two key descriptors of the ore comminution, namely, the fragment size distribution and the damage index. Figure 6a shows the distribution of fragment size as measured at the last stage of the mechanical test. The fragment size l is computed as $l = \sqrt[3]{V}$ where V is the volume of the fragment (note that the voxel size is $9\ \mu$m). Though the crushing of the ore is far from complete (the ore still withstands a tensile stress of $\sigma_t = 78$ MPa), the distribution of fragment size is already quite broad with a mean value at $\bar{l} = 250\ \mu$m. Quantitatively, the 50 largest fragments have a size $l > 2\ mm$ and represent 90 per cent of the ore volume, while the remaining 10 per cent of the ore volume is made of more than 1600 fragments. This large population of small fragments arise from two different breakage mechanisms:

1. As the ore yields beyond the fragmentation point F2, several large fractures are actually closing up and therefore producing high compressive and shear stresses (see regions highlighted by red ellipses in Figure 6b); the rock-rock friction and compression stresses when the two faces of a fracture come into contact produces small fragments with a broad range of sizes.
2. Other regions yielding many small fragments are located at the two rock-jaw contact points. Indeed, the geometry of the loading induces compressive stresses concentration at the contact point, this stress concentration is known to influence the failure process and to induce local damages (Li and Wong, 2013). In these locations, first damages appear after the initial fracture F1. As the loading increases, this process gives rise to a dense local fracture networks whose final state is shown in Figure 7a.

We should emphasise two challenges related to the measurements of the fragment size distribution. First, it relies on an accurate detection of the fracture location, such measurements are inherently dependent on the spatial resolution and the contrast level of the tomographic image. In this experiment, the voxel size was $9\ \mu$m, for future work we plan to use advanced image analysis method based on deep learning to improve the precision of our fracture measurements. Another difficulty is related to the segmentation of the ore image to identify its different fragments. We have used so-called grain partitioning methods which are very efficient in identifying the rounded grains of porous rocks. The application of these methods to fragmented ore is difficult because the ore fragments present a great diversity of size and shape.

To complement this quantitative description of the fragmented ore, we have also measured a damage index D. This descriptor is a popular measure of damage introduced by Kachanov (1958). It is based on a continuum mechanics approach to estimate the degree of damage from 2D sections of rocks. In 2D, the definition of the damage index D is given by $D = A_v/A$ where A is the surface area of the rock section and A_v is the area occupied by the cracks and fractures, also named the void area. In this study, we extend this definition to the 3D case, and compute the damage index as $D = V_v/V$ where V is the volume of the ore and V_v is the volume occupied by the fractures. In a sense, D quantifies the fracture density in the ore. When computed on the totality of the ore sample then $D_t = 0.072$. This descriptor can also be used to analyse the field of damage. To do so, local values

of D were computed on each unit of a 3D spatial grid with a mesh size of 0.5 mm. Figure 7b shows the distribution of the local value of D measured by using this approach. This distribution presents a strong peak at $D = 0$ corresponding to the undamaged parts of the ore. It also reveals a high probability of observing a damage index in the range $0.1 < D < 0.2$ that is associated with the fine cracks and the region of high comminution (such as those highlighted by red ellipses in Figure 6b). Finally, the distribution shows an exponential tail for large values of D that is related to the many fractures that are wide open.

A better characterisation of the coupling of the breakage statistics (fragments size distribution, local damage index D) with texture breakage and critical mineral liberation is key to improving current fragmentation models. In the recent study by Zhang and co-workers (Zhang *et al,* 2022), we have described a workflow integrating simultaneous 3D mapping of fracture locations and of the dominant mineral phases in an ore sample. Figure 8a shows such a texture map of the fragmented ore at $\sigma_t = 78$ MPa. This map has been computed by combining SEM_EDS data with the X-ray attenuation values of the tomogram. The ore texture is coarse-grained to present the dominant mineral phases only. Quantitatively the ore is made of: $67.2\ per\ cent$ of Alkali feldspar, $24.4\ per\ cent$ Plagioclase and $7.1\ per\ cent$ Epidote (expressed in volume fraction). Moreover, in our ore sample, there is $1.3\ per\ cent$ of copper sulfides (bornite and chalcopyrite). We emphasize that such estimations are not trivial, because it relies on the use of many experimental techniques, each bringing its own challenges as discussed in (Zhang *et al,* 2022). The fracturing of each phase can be clearly identified and quantified as the creation of new surface area compared to the unfractured state. In the fragmented state at $\sigma_t = 78$ MPa, $56\ per\ cent$ of the new surface area was produced in the feldspar phase, $39\ per\ cent$ in the plagioclase, $4.3\ per\ cent$ in the epidote and $0.7\ per\ cent$ in the copper.

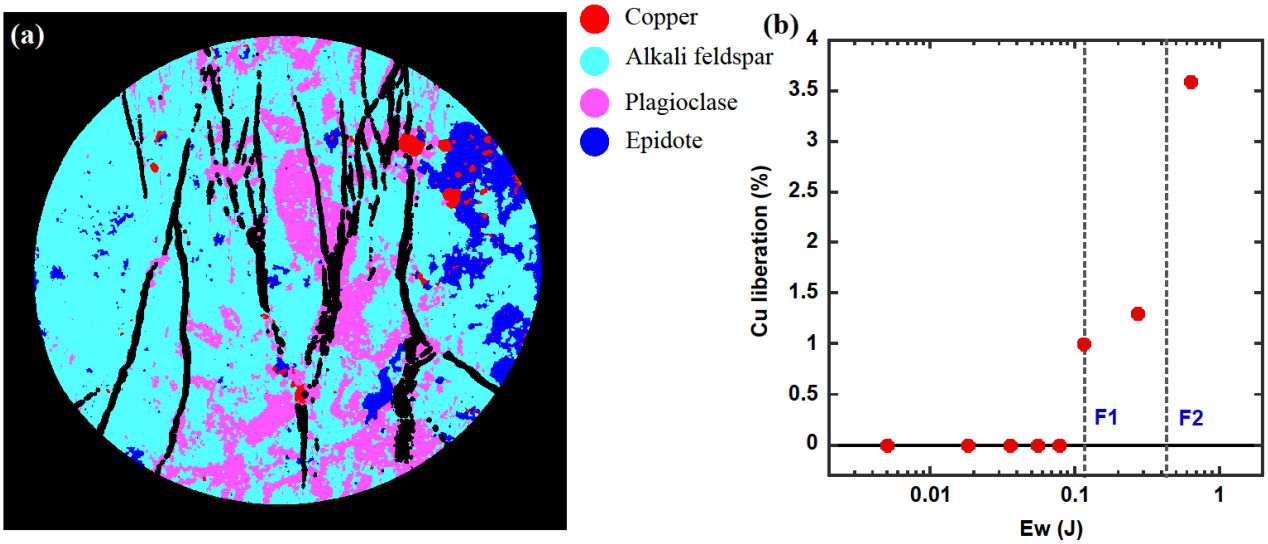

FIG 8 – (a) Texture map of the fragmented ore at $\sigma_t = 78$ MPa. The texture map has been computed by combining SEM_EDS data with X-ray attenuation values of the tomogram. In this section of the 3D map, the coarse-grained ore texture presents four main phases (Alkali feldspar, Plagioclase, Epidote and Copper sulfides), the fracture location is coloured in black. (b) Evolution of the Copper liberation versus the deformation energy.

The degree of liberation of copper (the proportion of copper exposed by fracturing) is shown in Figure 8b as a function of the deformation energy E_w. Two regimes of liberation are observed: after the rock fracturing (event F1), approximately $1\ per\ cent$ of the copper sulfides is freed from the gangue and this fraction increases weakly until the rock is fragmented (event F2). In the final fragmented state, the copper liberation increases substantially to $3.6\ per\ cent$. This evolution is consistent with three main features of the ore texture and breakage behaviour:

1. The copper sulfides grains are mainly embedded in the epidote and feldspar phases (with the highest contact preference with the epidote).
2. The plagioclase and feldspar are the most damaged phases during the fracturing and subsequent fragmentation.

3. The epidote is only substantially damaged beyond the onset of fragmentation.

The latter process explains the increase in the liberation of copper sulfides observed beyond the event F2. In this experiment, we only investigated the onset of ore fragmentation which explains the relatively low ($< 5\ per\ cent$) degree of liberation of the copper grains. Ongoing work focuses on measuring copper liberation at more advanced stages of the fragmentation process.

CONCLUSIONS

In summary, this experiment tackles a tensile-activated rock fracturing which triggers a substantial fragmentation of a porphyry copper ore. The results presented here show how high-resolution X-ray micro-CT has the potential to link breakage fundamentals and ore texture features such that this combined information may assist in the design of optimal processes for critical mineral liberation (Tavares, 2021; McKinnon and Ferguson, 2018; Ord, Blenkinsop and Hobbs, 2022).

This study shed light on the potential of *in situ* mechanical testing for empirical modelling of comminution processes as used in the mining industry. *In situ* data enable simultaneous quantification of mineral liberation, mechanical energy dissipation, fragment size distribution and of the coupling of local fracturing with the ore texture. Such data are needed to inform the modelling of optimal liberation (resource efficiency) at minimal overgrinding (energy efficiency).

In terms of rock mechanics, this example of an *in situ* fragmentation test, based on a simple loading configuration, opens up interesting opportunities to model in the laboratory complex breakage mechanisms. In this study, the focus was on comminution based on rock-rock friction induced by fracture closing and on fragment production at rock-metal compression contacts.

Ongoing work includes *in situ* investigation of more advanced stages of the fragmentation process with a focus on the relation between fragment size distribution and mineral liberation.

ABSTRACT

A 'Variable Blend and Rates' model is developed for SAG mills which extends upon the JKSimMet® Variable Rates Model. Similarly, a 'Variable Blend Residence Constrained Perfect Mixing' Ball Mill model is also introduced, also extending upon the existing JKSimMet® model. These models are used in conjunction with JKSimMet® while employing external technical programs. The technical model is then used to inform an economic model described elsewhere in Hanhiniemi and Powell (2022), which calculate operating and unit costs based on operating conditions, design, and ore characterisation.

The SAG and ball mill models include constraints beyond those in the JKSimMet® models. The SAG model constraints include Size Specific Energy (SSE) verification, charge weight limit, and assessment of the impact of media to ore composition in the charge using the SAG Charge SSE Model developed in this paper. The ball mill model includes residence time, volumetric capacity, and SSE verification constraints.

These models are applied to Cortez Gold Mine in the processing of two very different ore types and their blends; 'Horse Canyon' which is softer in coarser sizes and competent is fine sizes, and 'Wenban' which is competent at coarser sizes but softer in fine sizes than Horse Canyon. Horse Canyon also has a finer run-of-mine size distribution then Wenban. The application of the model at this site included undertaking five surveys at varying blends.

The behaviours of the blends and individual components is then studied in the SABC circuit. A non-linearity is observed with throughputs increasing with blending. The newly developed modelling approach captures these responses. Controlled blending based on ore competence-by-size and size distribution was implemented by the site, which then realised significant improvements in throughput without any capital cost (Ntiamoah *et al*, 2020).

The modelling developed in this paper is then compared to existing practice, and the new method was found to provide improved fidelity and utility. A three-dimensional surface is then developed using the model describing the SAG mill throughput capacity at varying conditions (speed-filling) versus varying blend. The change in throughput as a function of only the changing charge composition is presented. The result is nonlinear, and explanations are provided to describe this behaviour.

INTRODUCTION

Tumbling mills consume a significant portion of a concentrators operating expenditure, are capital intensive, and therefore often a bottleneck meriting careful attention. The performance of grinding circuits is also often impacted by processing differing blends of ore components with different physical properties and ROM size distributions, and this can result in throughput fluctuation, changing required transfer sizes between mills and variability in appropriate operating conditions (Mitchell and Holowachuk, 1996; Mkurazhizha, 2018; Bueno *et al*, 2011). Blending of components can thus have an important impact on financial performance. Controlled blending based on ore characteristics, competence-by-size, and feed size distribution in these cases offers the opportunity to increase overall throughput, reduce media and liner consumption, and balance utilisation across grinding stages (Powell *et al*, 2018; Ntiamoah *et al*, 2020). These blend effects are little understood and can be nonlinear with blend proportion. Existing technical modelling is not capable of simulating these effects.

A further issue with existing modelling is that of constraints and bottleneck identification. The JKSimMet® SAG and ball mill models are somewhat unconstrained with respect to comminution energy efficiency. The ball mill model is also unconstrained with respect to volumetric flow capacity and residence time and can produce results that are infeasible, as overfilling would have occurred in practice. Finally, the existing modelling does not include consumable models such as media and liner wear and life, and their response with operating, design, and ore characterisation.

This paper presents a multicomponent model of ore blending for Tumbling Mills and provides a Case Study detailing its application. The model first uses and expands upon the existing and well proven JKSimMet® models which are described in literature (Napier-Munn *et al*, 1996; Grimes and Keenan, 2015). It also incorporates energy, and volumetric/residence time constraints in the ball mill. Finally, it incorporates mechanistic consumable models and an overall operating and unit cost result. This grinding circuit model is one part of a wider comminution techno-economic model described in Hanhiniemi and Powell (2022).

OVERALL MODELLING STRUCTURE

The overall modelling structure is illustrated in Figure 1. Multiple JKSimMet® flow sheets, one per blend increment, form the basis of the model which employs the Variable Rates AG/SAG model and the Perfect Mixing Ball Mill models. Within each of these flow sheets the blends feed portion of each component is set using multiple feeders and splitters to achieve the combined feed particle size distribution of the blend, as each component has a different feed size distribution based on upstream conditions such as selective blasting, rock quality differences, etc.

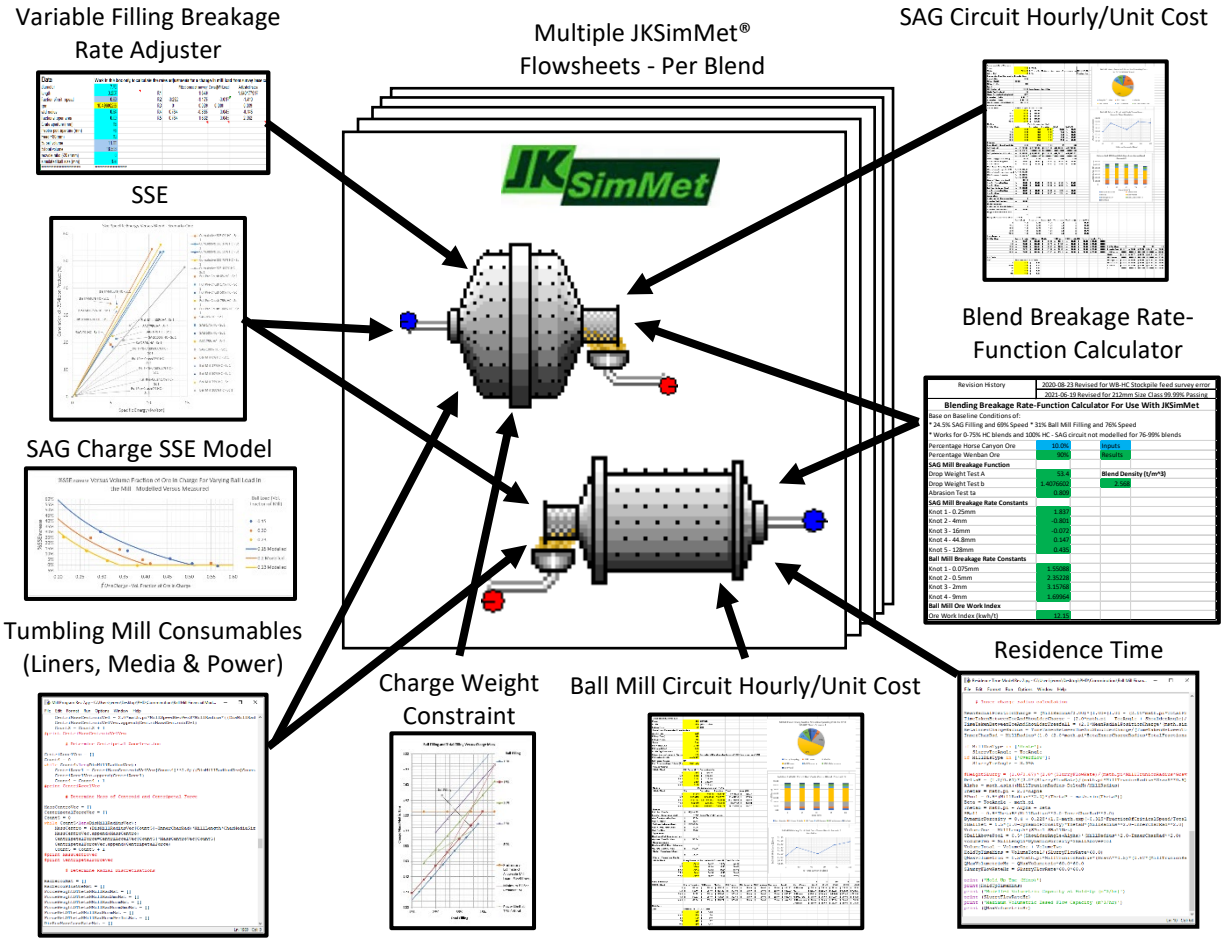

FIG 1 – Technical architecture.

Variable filling functionality for the SAG mill is achieved using Morrell (2001) by iteratively running JKSimMet® with the external 'Variable Filling Breakage Rate Adjuster' to determine adjusted breakage rates, until the filling in both closely agree. Only filling adjustments are made in this external calculation, and speed adjustments are made in JKSimMet®.

A 'Blend Breakage Rate-Function Calculator' model was developed and incorporated to provide the Breakage Rate response in the SAG and ball mills, including for blends of two components. It also provides a response to blend for the Breakage Function for the SAG mill, and the Bond Work Index in the ball mill, as well as providing the blends density, and is used in conjunction with JKSimMet®.

For ball milling, a constraint on the residence time is also applied based on the work of Shi (2016). This restricts unrealistic simulations where overfilling would be occurring. Further a basic volumetric flow constrain is also incorporated to ensure the volumetric capacity can be achieve in overflow ball mills. For the SAG mill, a charge weight constraint is applied based on total and media filling.

Size Specific Energy (SSE) calculations are performed across the circuit and Unit Processes to validate scenarios. This is done by measuring the percentage change in SSE from surveyed baseline for that blend, which is then interrogated against other measured changes in SSE in the literature. A SAG Charge SSE Model is also developed and applied to provide insight into the expected change in SSE with charge composition, as it is known that when media filling becomes the predominant volume fraction of the charge, there is a drop in SSE performance.

A Tumbling Mill model was also developed to capture consumable rates. In this media and lifter-liner life and consumption is modelled mechanistically, as described in Hanhiniemi and Powell (2019). Finally, integrated with all these technical models is an Operating and Unit Cost model for both SAG and ball mill circuit Unit Processes. The remainder of this paper will describe each of these elements in further detail (excluding consumables modelling, and operating and Unit Cost calculation for brevity) before describing their calibration and application in a Case Study.

BLEND BREAKAGE RATE-FUNCTION CALCULATOR

The various elements of the Breakage Rate-Function Calculator are now described.

Breakage function for blending

As described in Napier-Munn *et al* (1996) the breakage modelling for the SAG mill within JKSimMet® relies on the specific comminution energy (Ecs)-breakage index (t_{10}) relationship, which is fit to the following function from laboratory test data thus determining A and b constants for the ore type being treated:

$$t_{10} = A\left[1 - e^{(-b \times Ecs)}\right] \tag{1}$$

It is necessary to develop an approach to model the breakage characteristics *A* and *b* for any blend of the two ore types. The *A* value of this function is the asymptote, and this asymptote is typically fairly constant between most hard rock ores at approximately 50 (Napier-Munn *et al*, 1996) and pertains to high specific energy conditions which generally do not occur in horizontal tumbling mills. The *b* value is sensitive to ore competence differences and is sensitive in the range of specific comminution energies experienced in tumbling mills. Based on these observations above the *A* value can be set to the average of the any two ore types provided the measured values are not too dissimilar. A corrected *b* value, b_C, for each of the ore types was then determined by ensuring the as tested original *Axb* product of each ore type remained the same with the use of the averaged *A* value. The average *A* would be the mass weighted average of the ore blend:

$$A = \%w_{Ore\,1} \times A_{Ore\,1} + \%w_{Ore\,2} \times A_{Ore\,2} \tag{2}$$

$$b_{c_{Ore\,1}} = \frac{Axb_{Ore\,1}}{A} \tag{3}$$

$$b_{c_{Ore\,2}} = \frac{Axb_{Ore\,2}}{A} \tag{4}$$

Having established an averaged *A* for all blends, and two corresponding b_C values for pure blends of each ore, some means of adjusting the *b* value for varying blends was needed. As described by Bueno (2013) a weighted arithmetic average of these *Axb* values based on the respective mass portion in the blend is not believed to be representative of the breakage behaviour in mills for the blended mill contents. Instead, the inverse of the *Axb* for each ore was taken, *C*, and the weighted arithmetic average was taken on that based on the blend proportion. The resulting inversed *Axb* for

the blend was then inversed back to an *Axb* product. Finally, this allowed the determination of the *b* value for the blend by dividing the *Axb* product by the averaged *A* value. This is shown mathematically below.

$$C_{Ore\,1} = \frac{1}{Axb_{Ore\,1}};\ C_{Ore\,2} = \frac{1}{Axb_{Ore\,2}} \tag{5}$$

$$C_{Blend} = \%w_{Ore\,1} \times C_{Ore\,1} + \%w_{Ore\,2} \times C_{Ore\,2} \tag{6}$$

$$b_{Blend} = \frac{1}{AC_{Blend}} \tag{7}$$

Thus, the blends *Axb* has been established as a function of individual component Drop Weight Test results and the mass proportion of the blend and this was imbedded in the calculator. When the user enters the blend mass-proportion, the calculator returns the blends Breakage Function.

Blend breakage rates

To model the response in the SAG/AG and Ball Mills breakage rates with blend, multiple surveys of controlled blends were undertaken. The breakage rates were then model fitted for each blend at consistent knot sizes. As each of these surveys occur at different speeds and fillings in SAG/AG cases, adjustment had to be made to achieve a consistent filling and speed. Filling adjustment of the breakage rates was achieved using the Morrell (2001) model. Adjustments for speed were made using the Variable Rates model. The result was a model fitted set of breakage rates at consistent filling and speed, called the 'Adjusted Survey Simulation'.

A set of Bessel Spline functions were then fitted between the knot sizes versus blend fraction for this Adjusted Survey Simulation to predict their response between surveyed blends. This set of breakage rates versus blend data sets for both the SAG mill and Ball Mill were imbedded in the 'Blend Breakage Rates-Function Calculator' and used with the JKSimMet® modelling. When the user enters the blend mass-proportion, the calculator returns the breakage rates for SAG and Ball Mill knot sizes.

To remove the effect of the transport function in this breakage rate blend model, the SAG/AG discharge model was model fitted to consistent values across the blends surveyed and the simplifying assumption made that the discharge model did not vary with blend.

Other ore characterisation

The blended ore abrasion parameter is also needed. This was determined based on a weighted arithmetic mean value based on the proportion of ore mass in the blend. For Ball Milling the blended ore Bond Work index is needed. Similarly, this was estimated to also be the weighted arithmetic mean value based on the proportion by mass in the blend.

VARIABLE FILLING CALCULATOR

SAG mill breakage rates in the models above vary with mill filling. Once these rates are fitted to one filling condition, the change in these breakage rates with different fillings can be estimated using an external calculation to JKSimMet®. The modelling behind this external calculation has been developed and validated by Morrell (2001) and was employed in this work.

BALL MILL RESIDENCE TIME

The Ball Mill modelling in JKSimMet® is not constrained with respect to residence time or flow constraints (Shi, 2016). Shi states power modelling cannot offer an effective constraint as the power consumed is little effected by overfilling conditions in overflow Ball Mills. To address this a limit was determined on minimum residence time necessary to indicate effective Ball Mill operation. The method developed by Shi was adopted in this work. This calculates the residence time of slurry in the mill, and sets a minimum time of 2 minutes for mill with internal diameter below 5.9 m and 1 minute for mills larger than 5.9 m, based on industrial data sets. Below these residence times the risk of overfilling is deemed heightened. In this work this approach was coded in Python® and applied as a constraint over the modelling.

An absolute limit on volumetric flow out of the mill was also established based on the relation from (Morrell, 2016) derived from Bernoulli's equation, and is based on the allowable vertical height between the inlet invert and the discharge trunnion invert ($\Delta h_{Inverts}$), and the trunnion radius R_t, as follows:

$$Q_{Max_{Flow}} = 0.5\pi R_t g^{0.5}(0.67\Delta h_{Inverts})^{1.5} \quad (8)$$

SIZE SPECIFIC ENERGY

SAG milling

Figure 2 shows the result of laboratory scale testing of SSE and its relationship with volumetric fraction of media in the charge, and the mills volumetric filling of media after Powell *et al* (2015). Once a certain fraction is reached inefficiency begins to set in. This is thought to be due to the increase in media-on-media energy loss.

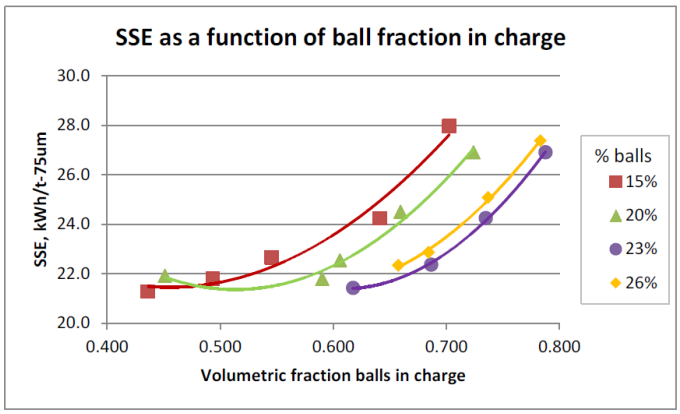

Figure 5 - SSE_{75} as a function of fraction of balls in the charge for different ball fillings

FIG 2 – Laboratory SSE versus volumetric fraction of media in the charge after Powell *et al* (2015).

A generalised function for this behaviour was sought so that any differences in SSE between simulations and measured results with different media and ore fillings could be compared for reasonableness. It was assumed that the results provided could be generalised across varying feed distributions, speeds and other conditions. The bounding case for this general function was that there would be zero increase in a baseline SSE due to high media composition in the case of AG milling, and conversely as the mill empties entirely of ore the inefficiency would rapidly rise to a vertical asymptote at no filling. The basic functional form that meets these bounds which was first employed is in Equation 9.

$$\%Increase_{SSE-75\mu m} = \frac{1}{f_{Ore_{Charge}}} - 1 \; for \; f_{Ore_{Charge}} < 1 \quad (9)$$

The *x* axis of Figure 2 was changed to present the fraction of ore in the charge $f_{Ore_{Charge}}$, and the vertical axis values were divided by the SSE at which all the cases appeared to asymptote at low media fraction in the charge, estimated to be 21.5 kWh/t -75 µm for this ore. This resulted in the vertical axis representing the percentage increase in SSE due to the media in the charge, $\%Increase_{SSE-75\mu m}$. It was assumed that having divided by this value, the resulting relative increase could be generally applied across other ores with varying competence.

The strength of the response in SSE increase versus the reduction in ore charge is varied by introducing a new calibration term, γ, which does not impact the $\%Increase_{SSE-75\mu m}$ intercept at 0 per cent with no media. It was further observed that the onset of this inefficiency does not appear immediately with media addition, but only when a certain threshold is reached. To account for this the relation above was modified to include an offset term, α, which is the fraction of ore in the charge when the inefficiency begins to manifest. This offset, α, appears to be a function of Ball Load in the mill. The data from Figure 2 was replotted using this new plane and equation and the data was fitted

to it. Each α was then estimated and plotted against each Ball Load expressed as a fraction of the total mill volume, $f_{Ball_{Mill}}$, and was found to fit the linear function below. Unfortunately, there is a coupling between the α and the γ terms, so γ was fitted individually. Once complete no relation of γ versus $f_{Ball_{Mill}}$ was obvious and fitted values ranged between 0.45–0.55 with an average of circa 0.5, therefore γ was set to 0.5. Therefore, the final relation is as follows:

$$\%Increase_{SSE-75\mu m} = \begin{cases} \frac{\alpha^{\gamma}}{f_{Ore_{Charge}}^{\gamma}} - 1, for\ f_{Ore_{Charge}} < \alpha \\ 0, f_{Ore_{Charge}} \geq \alpha \end{cases} \quad (10)$$

$$With: \alpha = -2.07 f_{Ball_{Mill}} + 0.82\ for\ 0.15 < f_{Ball_{Mill}} < 0.23\ and\ \gamma = 0.5 \quad (11)$$

The resulting generalised model and the measured results transposed from Figure 2 are illustrated in Figure 3. As the 26 per cent media filling was very high this was excluded. The model describes the behaviour of increasing inefficiency with low ore fraction in the charge, its onset, and its change with media filling, and fits 15 per cent and 23 per cent media well, with some inaccuracy at 20 per cent.

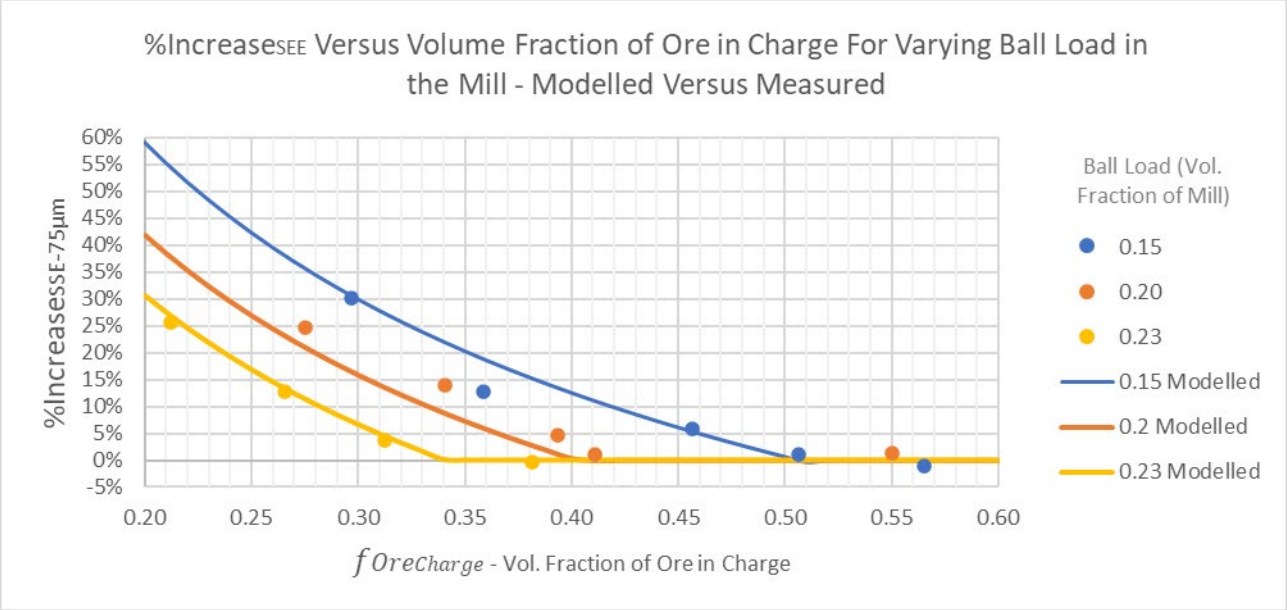

FIG 3 – Change in SAG SSE with charge composition.

In summary, the model developed above can be used as a guide to the differences in SSE between simulations and measured results with different media and ore fillings, and support evaluation of the reasonableness of simulated results. The data set employed is small and based on laboratory testing, however it is not used for predictive purposes, and supports the checking and validation of simulations.

CASE STUDY – CORTEZ MINE

Having described the modelling, it is now applied to a case study – Cortez Gold Mine. It is an open cut gold mine with an SABC circuit followed by CIP leaching. Two major ore components are mined together in the active pits – Horse Canyon and Wenban. Horse Canyon has an *Axb* 83.5 and a Bond Work Index (BWI) of 17.1 kW/t. Wenban has an *Axb* 74.3 and a BWI of 11.6 kW/t. Horse Canyon has a finer ROM distribution than Wenban, is softer in the larger size fractions, but harder in the finer fractions. This is illustrated by the lower *Axb* for Wenban indicating higher competence, with the Horse Canyon then having a markedly higher BWI. The site implemented controlled blending of these ores and increased overall throughput without any capital expenditure (Ntiamoah *et al*, 2020).

Two full surveys were taken of the circuit for Wenban and Horse Canyon including crash stop and grind out with surveyed streams shown in the top left figure by the stars. Three further snapshot surveys were taken of controlled blends of the two components. These five surveys were 0 per cent,

17 per cent, 50 per cent, 75 per cent and 100 per cent Horse Canyon. These were mass balanced, and model fitted and achieved convergence and were very successful.

SAG mill modelling

For SAG mill calibration breakage rates were fitted to the five blends. These surveyed were at different speeds and fillings however, and were thus converted back to a constant SAG filling and speed using the external Variable Filling Breakage Rate Adjuster and JKSimMet®. Similarly, the discharge function was fitted consistently across all blends. The blends breakage function was set by blend based on the approach previously described. The results were a set of breakage rates whose response is isolated from other considerations outside the blend composition. This condition is called the Adjusted Survey Simulation. The results are shown in Figure 4 at each knot versus blend and are relatively smooth.

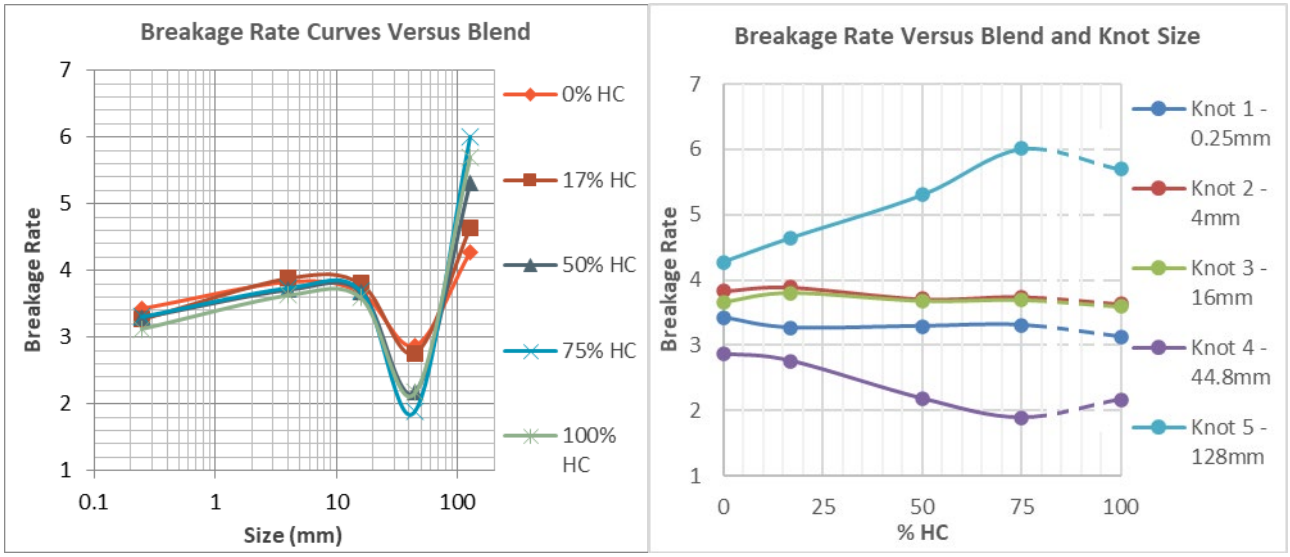

FIG 4 – SAG mill breakage rates versus size and blend – 24.5 per cent mill filling and 69 per cent speed.

To create the Blend Breakage Rate and Function Calculator, a spline was fitted to each of the corresponding rate constants for the baseline SAG filling and speed for any blend, as shown in Figure 5. A new regime (poor filling) was entered beyond 75 per cent HC – and transition from 75–100 per cent was not included in the spline as this transition may not be well modelled. The resulting spline function was added to the Blend Breakage Rate and Function Calculator.

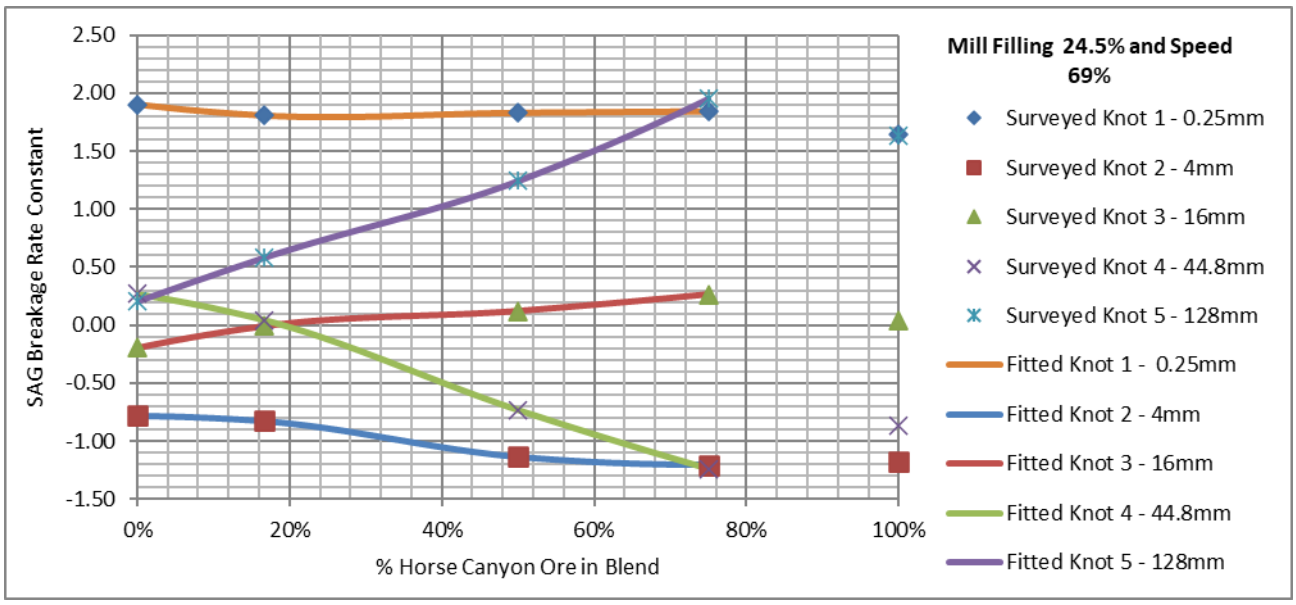

FIG 5 – SAG mill breakage rate constants versus knot size and blend.

The SSE was calculated for the SAG mill circuit for each blend and appears in Figure 14, baseline ('BL'). This was then used to evaluate the reasonableness of an example upgrade scenario below.

Ball mill modelling

A similar process as in the SAG was conducted for the Ball Mill. The five surveys were model fitted and the breakage rate curves versus blend are shown in Figure 6. The Ball Mill is simpler as surveyed filling and speed were consistent so no adjustment to consistent conditions was required. A spline was fitted to each of the corresponding breakage rate knot sizes versus blend, also shown in Figure 6, and this was employed in the Blend Breakage Rate and Function Calculator. BWI was also included and determined by the mass weighted average of the components. The resulting Blend Breakage Rate and Function Calculator interface is shown on the right in Figure 1.

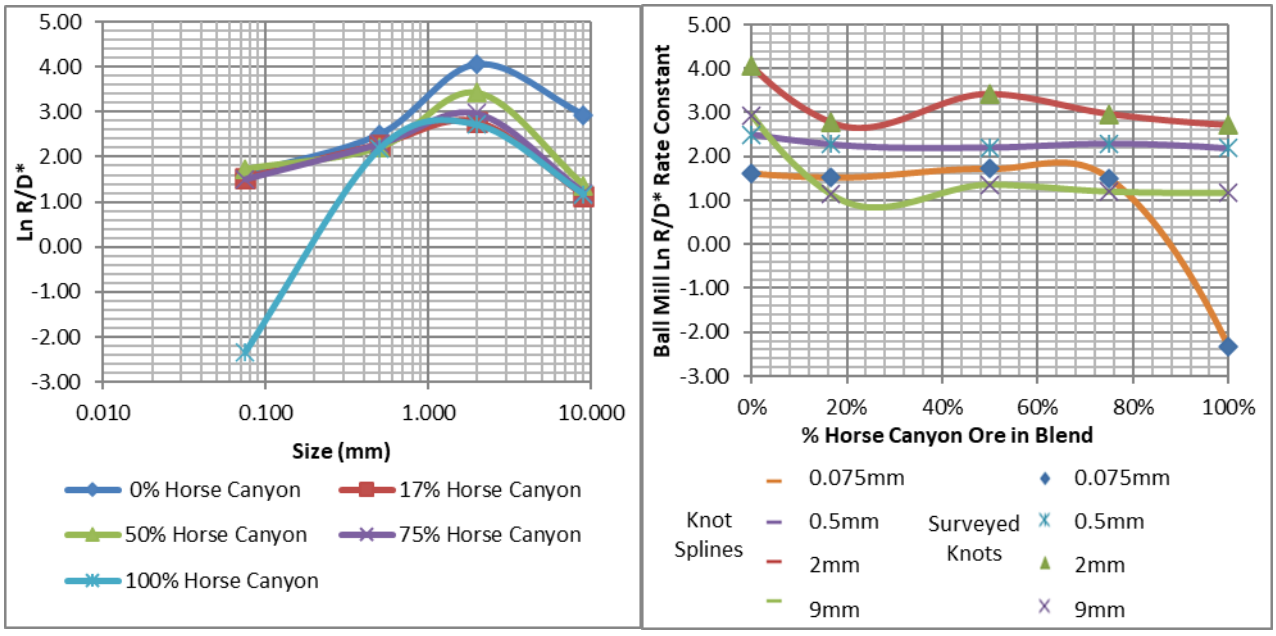

FIG 6 – Model fitted and spline ball mill breakage rates versus size and blend – 31 per cent filling and 76 per cent speed.

The maximum volumetric capacity of the ball mill was calculated. The ball mill is an overflow type, 8.66 m long, operates at 76 per cent speed, and has a filling of 31 per cent. Its trunnion diameter is 1.43 m and cone end length was estimated at 0.67 m. Its diameter is 4.67 m which is below 5.9 m,

therefore the minimum volumetric residence time is 2 minutes. The volumetric flow rate of this mill at this residence time was calculated at 1650 m^3/hr. All surveys were measured below this, and scenarios analysis was constrained below this limit.

Again, the SSE was calculated for the ball mill circuit also for each blend and appears in Figure 14, baseline ('BL'). This was again used to evaluate the reasonableness of an example upgrade scenario below.

DISCUSSION

Having introduces the modelling methodology, and then applied and calibrated it to the Cortez case study, we will now further explore the modelling capability. Comparisons to existing practice for modelling blending will be undertaken, and the modelling will be applied to evaluate an example upgrade scenario.

For the SAG mill the baseline model was then run for 11 blends and the resulting throughput is shown on the left in blue in Figure 9. Despite a constant SAG mill operating condition (filling and speed), and consistent discharge function, the throughput varies significantly based on the blend or ore. This figure is illustrating the effect of ore blend composition and characteristics in the mill in isolation. This result is thought to be explained by SAG composition as follows. In pure Horse Canyon there is a lack of adequate competent larger size material, and thus autogenous breakage is not promoted. With a small amount of Wenban ore added, a competent charge is established which promotes a higher frequency of autogenous breakage and attrition by having sufficiently large material available to act as media with sufficient energies to comminution the predominantly Horse Canyon charge which is soft in larger sizes. However, when this Wenban proportion increases to a higher proportion, the Wenban ore begins to dominate the charge content, and the effect of the higher frequency of larger particle comminuting smaller less competent ones is overtaken by more frequent more competent Wenban-on-Wenban ore breakage reducing overall breakage rate.

Conversely, in a charge that is all Wenban, more competent breakage events are occurring reducing throughput. Any addition of a small amount of soft-in-the-coarse Horse Canyon does not affect the charge content's ability to maintain load. Its finer distribution is ground by the Wenban pebbles in the charge, and its coarse sizes are broken at a high rate. This explains the improvement seen with small additions of HC ore to predominantly Wenban. Still however these explanations above fail to be reconciled with a dip in throughput at more even blends. This dip in middle blends is thought to be influenced by the selected speed-filling. Throughputs are known to peak at different speeds and fillings based on their ore properties, Grind-Curves refer (Van Der Westhuizen and Powell, 2006; Powell *et al*, 2009). This will now be further evaluated by extending the modelling to higher speed-filling conditions in the next section.

Extension to other SAG mill filling-speed conditions

The modelling was also extended further to a total of four speed-filling conditions. This modelling considered the SAG with screen and recycle crushing per the circuit in Figure 7, and it ignored recycle crushing and downstream constraints, to gain insight into the response of the SAG circuit in isolation at higher throughputs, speeds and fillings.

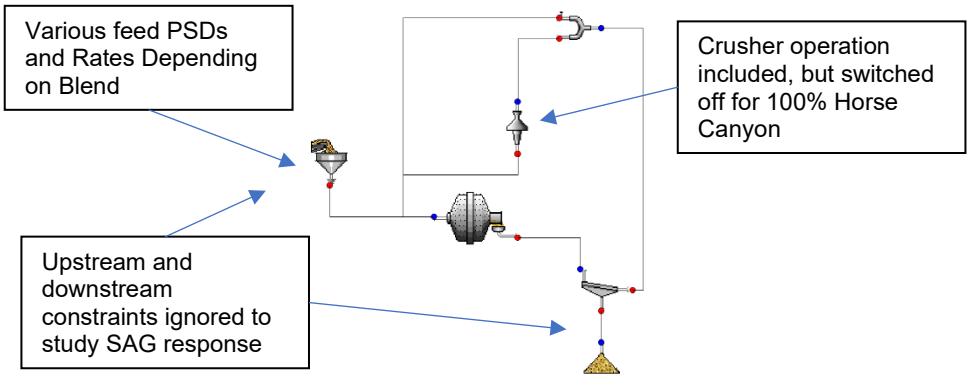

FIG 7 – Cortez SAG circuit isolated for model evaluation.

These SAG conditions were selected based on incrementally increasing speed. The filling for each speed was established by using MillTraj® and the existing liner design by determining what minimum filling was required to prevent ball-liner impact. The maximum speed-filling condition was set at the power limit of the mill. The resulting conditions were Case 1 as the baseline at 24.5 per cent mill filling and 69 per cent speed, then Case 2 at 27 per cent and 74 per cent, Case 3 at 30 per cent and 76 per cent, and Case 4 at 35 per cent and 78 per cent respectively.

The results are illustrated under 'New Methods' in Figure 8. As expected, each blend exhibits a varying Grind-Curve. Horse Canyon exhibits a peak and decline in throughput. Other blends appear to be still rising in throughput. A high throughput peak is observed at approximately 75 per cent Horse Canyon in Condition 4 that is higher than any other condition. The blends at which peak throughput performance is achieved varies at different speed-filling conditions. At the lower speed-filling conditions the peak occurs at between 20–30 per cent Horse Canyon.

Some comparison with measured results will now be made to support verification of the results. The same model results from the 'New Methods' surface of Figure 8 is also presented against measured throughput data in 'New Methods' in Figure 9 along with speed and filling. As seen in both the modelling and in measurements, blends produce throughputs larger than processing the ores separately. The peak at 75 per cent would have not been achieved in practice due to downstream constrains in ball milling with the high competent-in-the-fine-sizes Horse Canyon, and because these high fillings and speeds of condition 3 and 4 were not achieved in practice. Operation during measurements over the six month program being more like Condition 2, and here the modelling and measured results agree well for Wenban rich blends up to 67 per cent Horse Canyon. Beyond this the measured result drop below the model as expected from the known ball mill constraint treating Horse Canyon. The highest throughput blend measured in the survey, and also in a subsequent six month program of measurements, was at 33 per cent Horse Canyon. This is not too dissimilar to this peak shown by the model at between 20 per cent to 30 per cent.

The measured (but not fully surveyed) blend at 33 per cent shows close speed, filling and throughput agreement to the model. The 17 per cent, 50 per cent and 75 per cent surveyed throughput measurements agree with the model as indicated by their speed-filling condition lying between Condition 1 and 2, consistent with measurements. The model appears to somewhat underpredict the throughput for pure Wenban and Horse Canyon, despite being calibrated to include these. This is because the modelling reported was also part of a wider model which including blast modelling, so there were small differences in the baseline model feed distribution as compared to survey, due to model fitting differing to measurements.

Overall, the modelling was found to agree reasonably well with measured results. Where differences where identified, explanations have been identified. Therefore, the measured results have supported verification of the model. Next the existing methods of modelling blending will be undertaken and likewise compared against measured results.

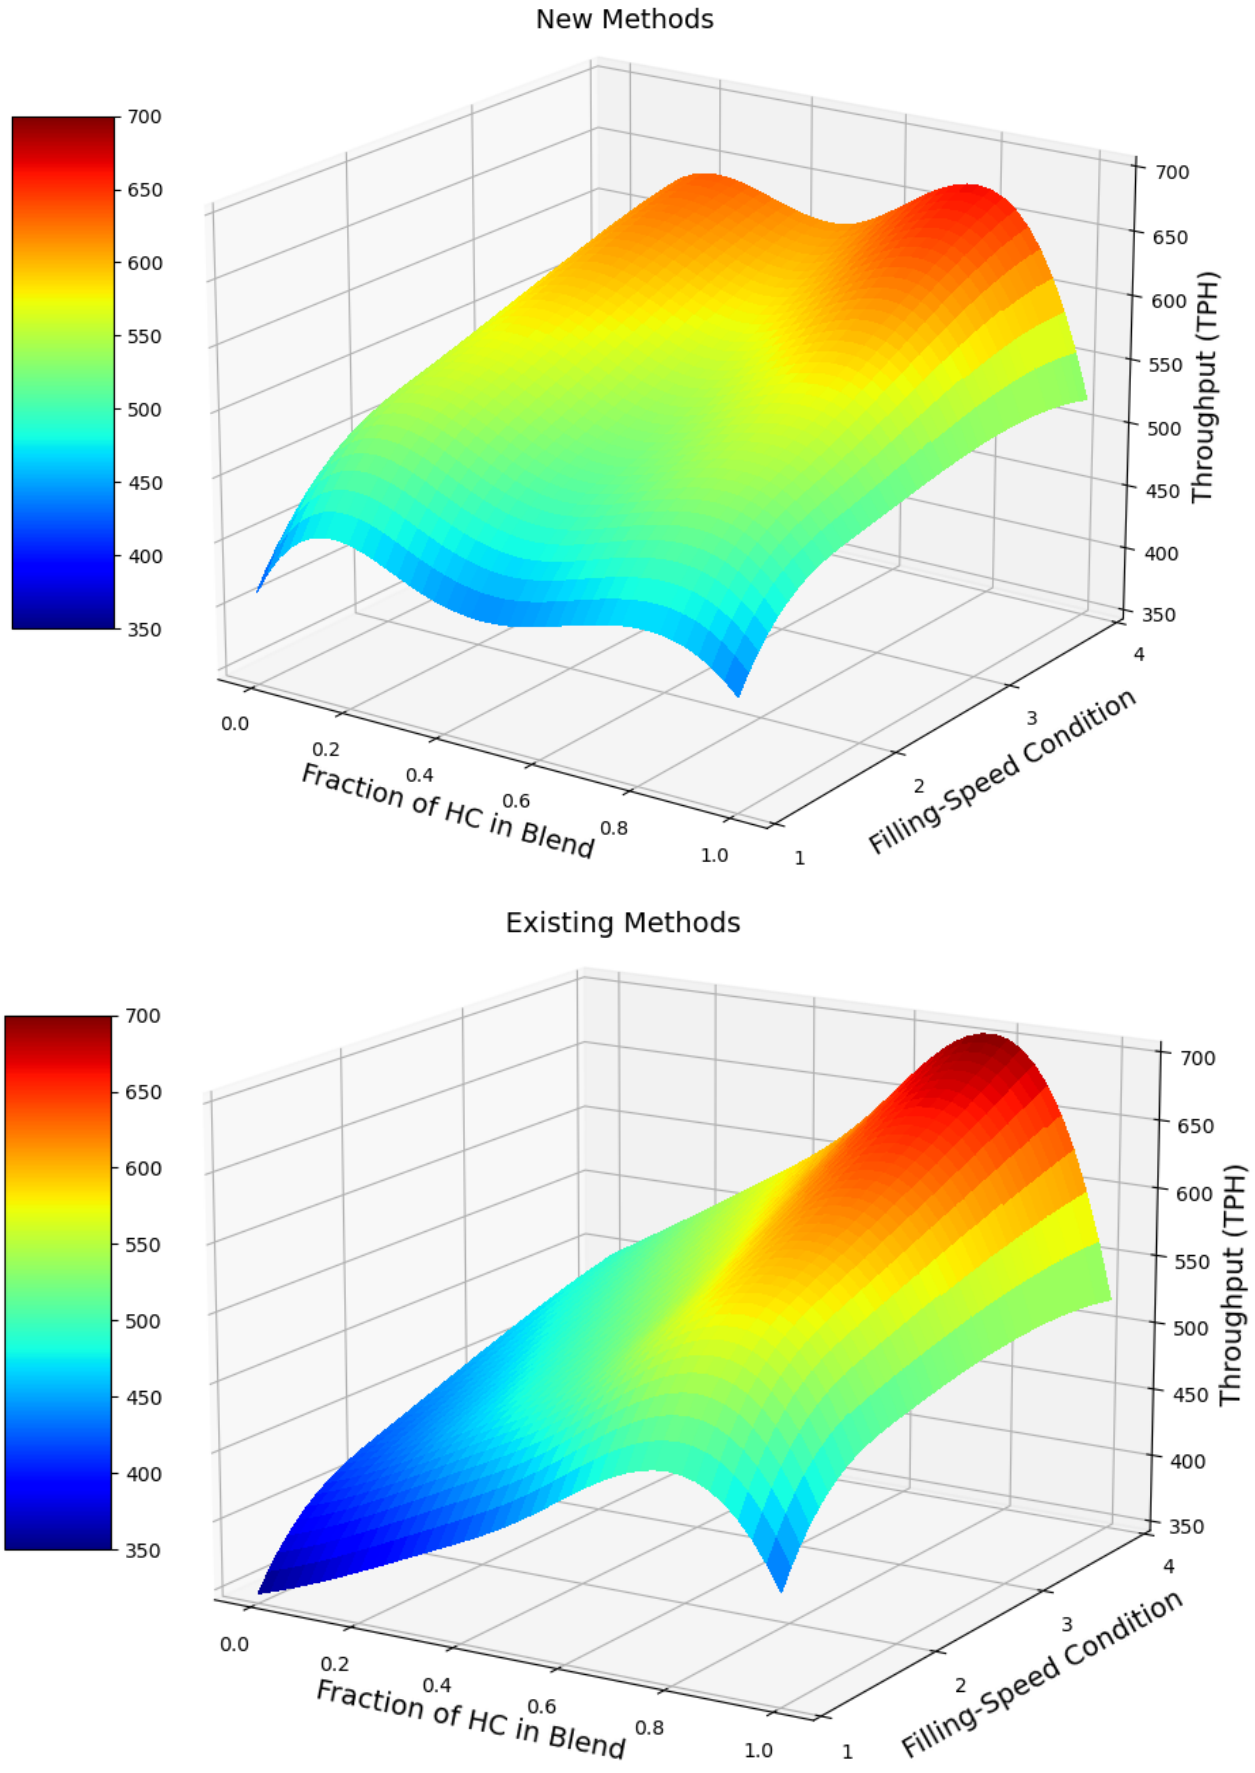

FIG 8 – Cortez baseline SAG mill throughput surface versus blend and filling-speed condition – new and existing methods.

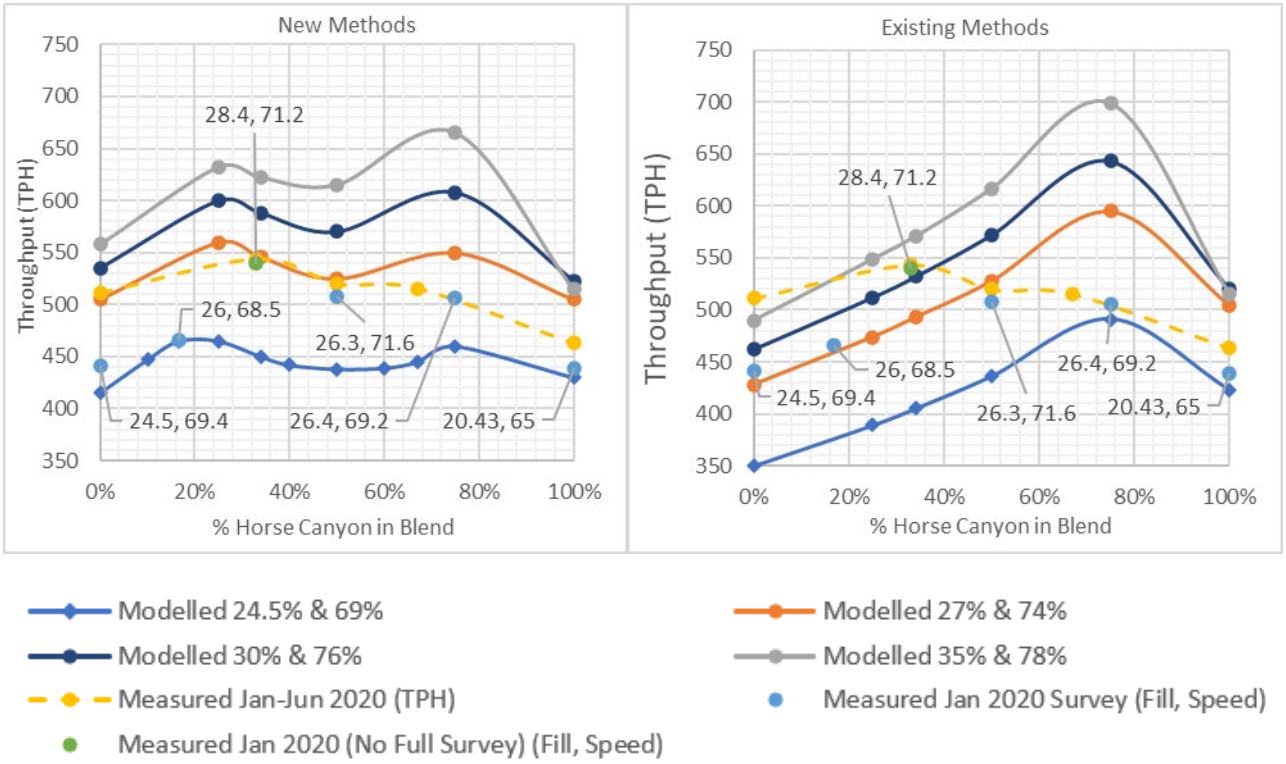

FIG 9 – Baseline SAG simulation throughput versus blend and speed-filling condition – new and existing methods.

Comparison with existing blend modelling practice in SAG mills

Existing practice for modelling SAG mill response is to survey at a single blend close to that most often processed in the mine plan, and to adjust to other blends based on mass weighted averages of the *Axb* and t_a. It is desirable to compare the new modelling approach described in this paper ('New Methods'), with this existing practice ('Existing Methods'), and to compare the fidelity of the two methods and any new utility achieved. The case study was used to do this using the same conditions to provide a direct comparison, and the single blend used for surveying and breakage rate fitting was selected at 50 per cent Horse Canyon.

The results are presented in Figure 8 ('Existing Methods'). The New and Existing Methods throughput versus blend and speed-filling surfaces are also overlayed in Figure 10 to provide a direct comparison. Comparing the two methods, the 100 per cent Horse Canyon blend is very similar between methods, as is 50 per cent as this was surveyed in both cases. The 75 per cent Horse Canyon blend has a higher result in Existing Methods, but interestingly the high throughput peak offered at this blend was identified by both models. This peak and subsequent drop at 100 per cent Horse Canyon may have been influenced by turning off the recycle crushing for this blend in both cases.

The other peak at 20–30 per cent Horse Canyon identified in the New Methods is not captured by the Existing Methods at all, and performance is underpredicted at these blends and for Wenban. This peak captured by the new method, and not by the existing methods, was demonstrated earlier as being real based on measured results.

As before, the same model results from the 'Existing Methods' surface of Figure 8 is also presented against measured throughput data in 'Existing Methods' on the right of Figure 9 along with speed and filling. As seen in both the modelling an in measurements, blends produce throughputs larger than processing the ores separately, as was also identified in New Methods.

The Existing Methods underpredict performance Horse Canyon to a worse degree than New Methods, and the performance of Wenban rich blends is grossly underpredicted with 0 per cent and 17 per cent blends having lower modelled throughputs at 27 per cent filling and 74 per cent speed compared to measured results at fillings of 24.5–26 per cent and 68.5–69.4 per cent speeds. The measured (but not fully surveyed) blend at 33 per cent shows that the model is predicting a

throughput commensurate with a filling and speed greater than 30 per cent and 76 per cent respectively, compared to the actual of 28.4 per cent and 71.2 per cent. This inaccuracy was not present in the New Methods, where modelled and measured speed, filling and throughput were in close agreement.

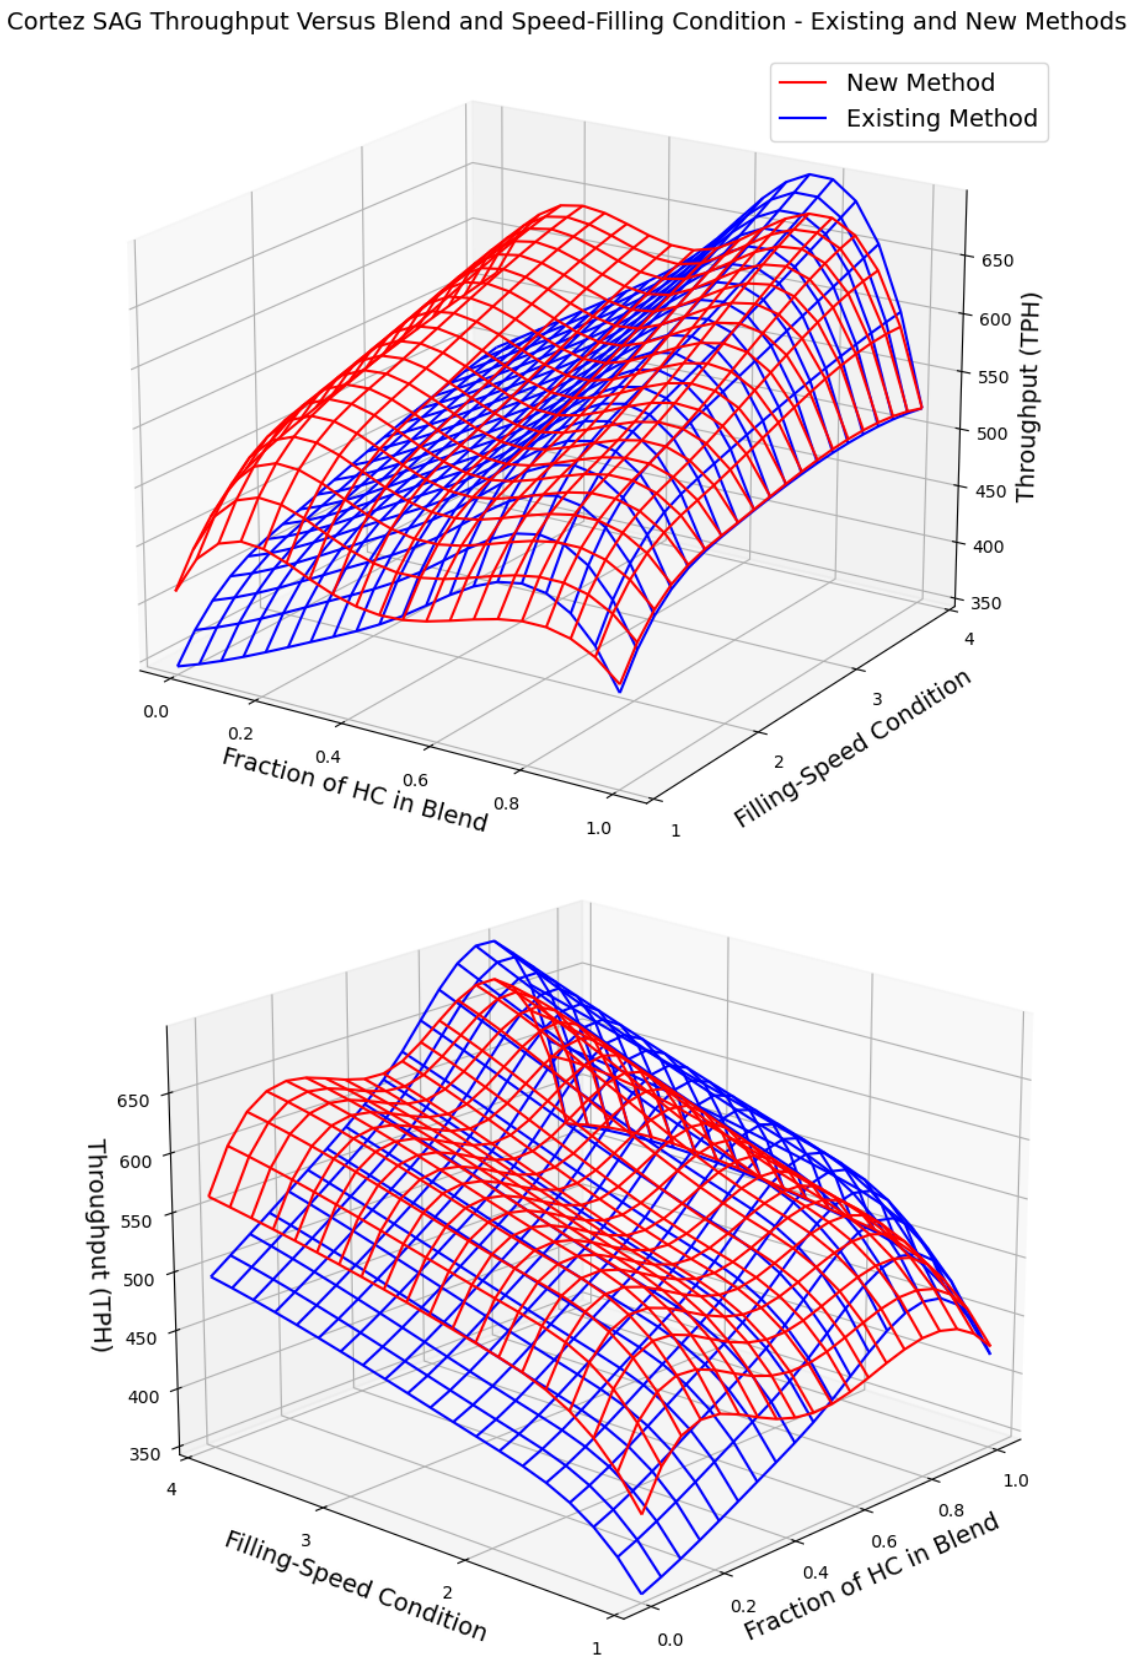

FIG 10 – Cortez SAG throughput versus blend and speed-filling condition – new and existing methods.

As described previously, operation during the measurements over the six month program would have been closest to Condition 2 of the 4 conditions, except for a drop off in predominantly Horse Canyon blends below the model resulting from the ball mill constraint treating highly competent-in-the-fine-sizes Horse Canyon. In the Existing Methods there is no close agreement between these measured results and the model. The highest throughput blend measured in the survey, and also in a subsequent six month program of measurements, was at 33 per cent Horse Canyon. This other peak is not captured at all, resulting in a completely different outcome when using Existing Methods, diverging from measured results.

The 17 per cent, 50 per cent and 75 per cent surveyed throughput measurements should, as indicated by their measured speed-filling condition, lie between Condition 1 and 2. The Existing Methods model fails this requirement at 17 per cent blend indicating performance above Condition 2 due the model's inability to identify the second throughput peak, but otherwise is consistent.

Overall, the Existing Methods modelling was found to agree reasonably well with measured results only close to where it was surveyed against. Its performance across blends was not as accurate as that achieved with the New Methods, and the non-linear behaviours arising with SAG composition were not captured, like the second peak in throughput at around 33 per cent blend. This has demonstrated improved fidelity and utility of the New Methods.

Scenario analysis and SSE

The modelling described in this paper was employed, along with wider modelling practice, to analyse an example potential upgrade option of Full Pre-Crushing ('Scenario 1'). Here the existing SABC circuit was upgraded with full pre-crushing, SAG discharge modifications, high media filling and reduced ball size, higher intensity Wenban blast design, and lower intensity Horse Canyon blast design, and increased number of operating cyclones with adjusted vortex and spigot sizes to promote coarser product. It is illustrated in Figure 11.

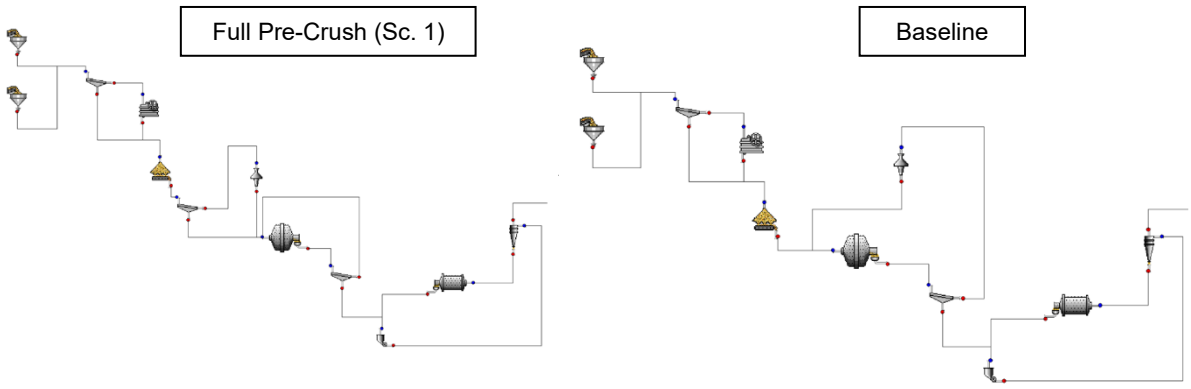

FIG 11 – Cortez upgrade scenario process flow diagrams.

The SAG Charge SSE model was used to support verification of the SAG circuit. The Baseline SAG circuit SSE was calculated and used along with total and media filling to back-calculate the SSE at no charge composition induced SSE increase ($\%Increase_{SSE-75\mu m} = 0$), thereby calibrating the SAG Charge SSE model at each blend. Then the calibrated model was used to calculate the expected $\%Increase_{SSE-75\mu m}$ per blend for Full Pre-Crush operation which generally had a higher media proportion in the charge. This was then compared to the JKSimMet® model produced SSE. The results are plotted in Figure 12.

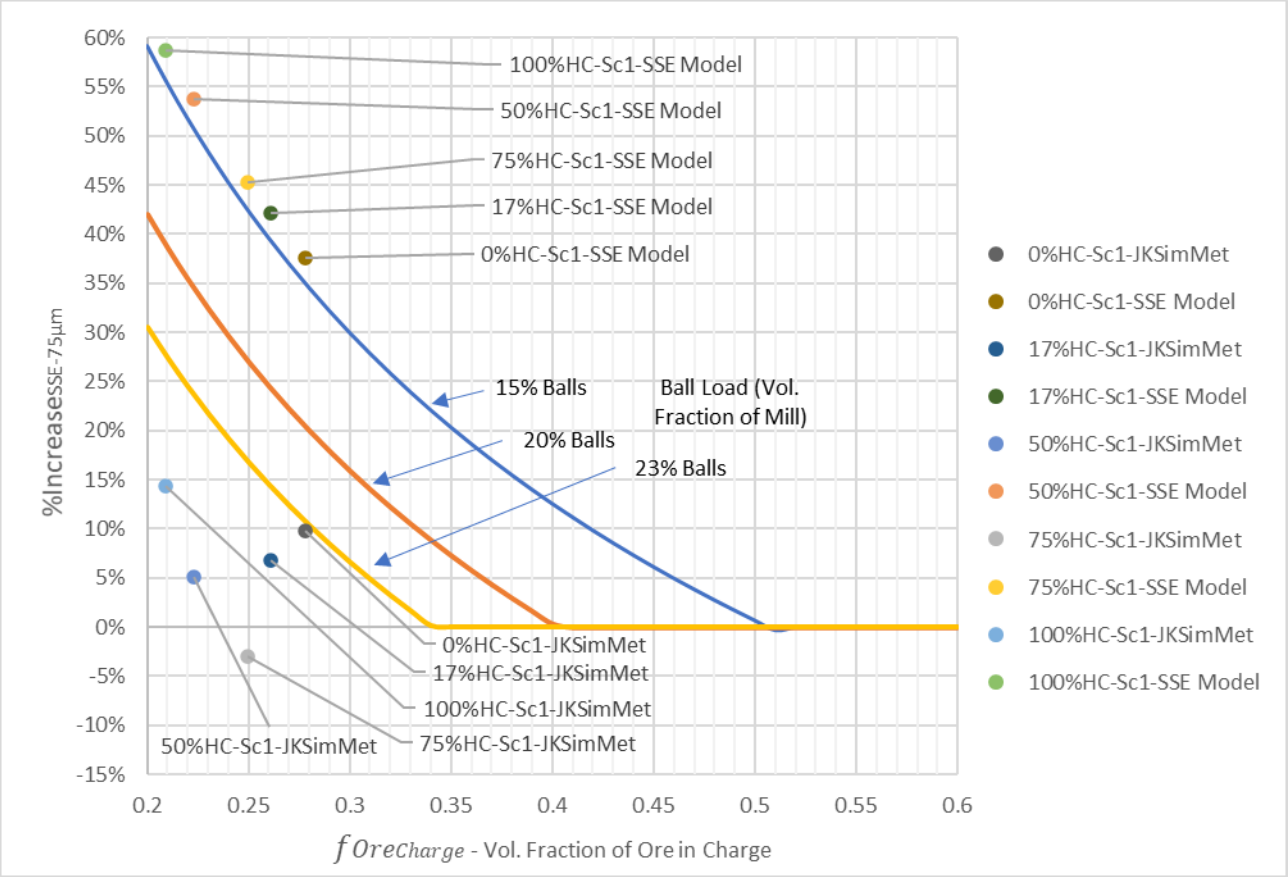

FIG 12 – Cortez SAG full pre-crush ('Sc 1')%Increase$_{SSE-75µm}$ versus volume fraction of ore in charge for varying ball fill – JKSimMet® modelled versus SAG charge SSE Model ('SSE Model').

The SAG Charge SSE model has been extended well beyond its very limited fitted data set, but it indicates JKSimMet® overpredicts performance of the full pre-crushing scenario by underestimating the SSE detriment from Barely Autogenous Grinding (BAG). JKSimMet® has little response to charge compositions by comparison. The data set from which the variable rates model was established has only up to 12 per cent ball load, and the form of the regressions used in its rate equations are provided in Grimes and Keenan (2015). These regressions do not include media to ore charge composition terms and given the low ball fraction limit in the fitted data set, it is not definitive JKSimMet® is providing any SSE increase response due to reducing ore charge fraction, as is clearly present in the SAG Charge SSE Model once a threshold composition fraction is reached.

The JKSimMet® derived SSE, SAG Charge SSE Model result, the relative difference between these, and also the as surveyed SSEs, are shown in Figure 13. A marked difference in SSE between the SAG Charge SSE Model and JKSimMet® models is shown. Little change occurs between the surveyed conditions and JKSimMet® results for the full pre-crush case due to its lack of response as described above.

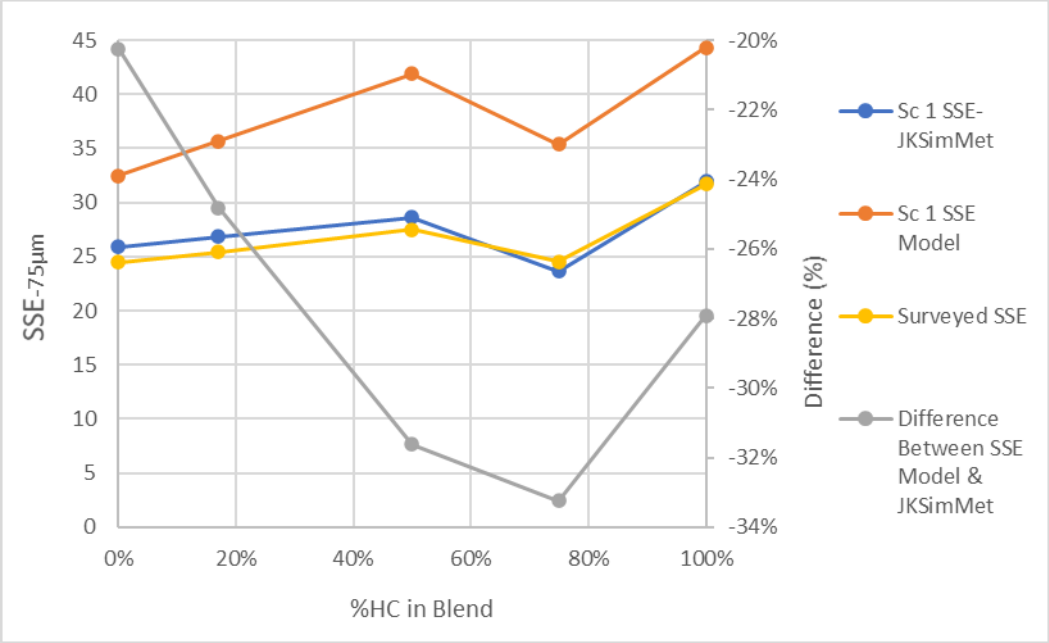

FIG 13 – Cortez full pre-crush (Sc 1) SAG SSE – surveyed, JKSimMet® and SAG charge SSE modelled results.

The SSE for the ball mill and whole comminution circuit was also calculated, to provide comparisons between the baseline and the full pre-crush case. Note the baseline is not quite the same as the as-surveyed because there was some variation from blasting through to cyclone overflow model fitting, and from employing consistent SAG speed-filling conditions across blends. The results show close agreement between the SAG SSE's as discussed above which is believed to be erroneous due to the different charge compositions.

The ball mill will now be evaluated. Ball mills can operate more efficiently with finer feeds which should be achieved with full pre-crushing, and so as expected the SSE has decreased for all blends with the finer feed. The degree of reduction is much larger than expected from prior experience however compared against typical changes in SSE measured at sites described in literature. Some of these cases will now be reviewed.

Ballantyne *et al* (2015) provides two data sets from two mines. In the first example SSE was found to be 32 per cent higher in one mill as compared to others. The cause was attributed to the recirculating load being higher than 450 per cent reducing classification efficiency, and possibly a bias in feed particle size between mills. In the second example poor classification is attributed to approximately 13 per cent increase in SSE. Powell *et al* (2018) provides a data set where a ball mill was underperforming with an approximate 8 per cent increase in SSE witnessed, determined by again employing the same methods. In this case the increase in SSE was attributed to the ball mill being overloaded and containing coarse rock. In summary potential differences in SSE have been reported in the literature of between 8–32 per cent due to a variety of factors including poor classification, overloading, and coarse feed.

Comparing this literature with the reduction in SSE of the ball mill from baseline to full pre-crush, it is suspected that the JKSimMet® model is overpredicting the performance of the ball mill circuit. This is likely exacerbated by the fact that the reduction in feed size to the ball mill might also be overpredicted by the SAG mill performance overprediction as previously described, resulting in a coarser than modelled feed size distribution.

The JKSimMet® overall circuit indicates reduced SSE for all blends in full pre-crush (Scenario 1) as compared to baseline SABC as shown in Figure 14, however this analysis has shown the opposite effect is expected, with pre-crushing and Barely Autogenous Grinding (BAG) expected to produce a less efficient result. The effect of this suspected inaccuracy in the modelling is that the product size is expected to be coarser than simulated, and the ball mill circuit may not be able to treat simulated throughput. In summary, the use of SSE for evaluating potential upgrade scenarios has been demonstrated. It should be noted that other scenarios were also run including partial pre-crushing of

critical size prior to SAG mill feed. This approach provided a more balanced ore-to-media charge composition reducing the expected inefficiency in the SAG mill, and the new SAG Charge SSE Model was able to indicate the benefits of this approach over full pre-crushing. These scenarios are further described in Hanhiniemi and Powell (2022).

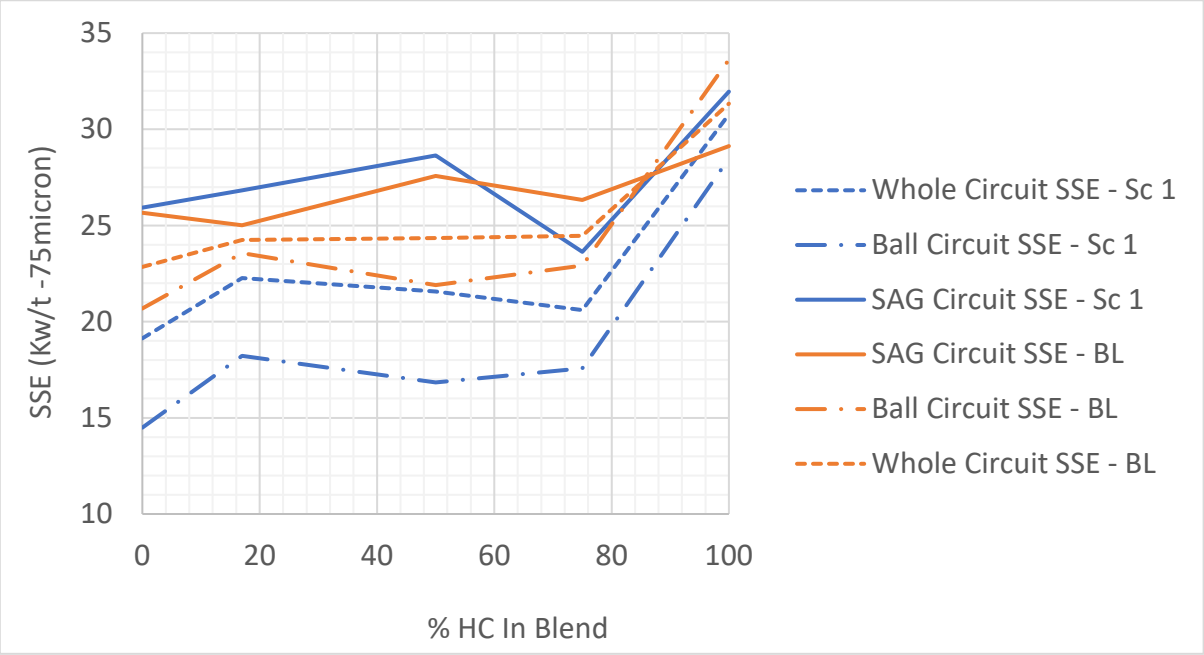

FIG 14 – JKSimMet® based SSE for full pre-crush (Sc 1) versus baseline (BL) – all blends.

CONCLUSIONS

A 'Variable Blend and Rates' model has been developed for SAG mills which extends upon the JKSimMet® Variable Rates Model primarily to capture blend response. Similarly, a 'Variable Blend Residence Constrained Perfect Mixing' ball mill model was introduced, also extending upon the existing JKSimMet® model, that captures blend response and residence time constraint. The generic approach of these models was applied to an example case study site to demonstrate their application. Comparisons with measured results showed improved fidelity of the new approach over current practice of blend modelling.

The use of SSE in validating simulation results was demonstrated. Further, a SAG Charge SSE Model which provides an indication on the impact on SSE with changing charge composition was developed, and then its application was demonstrated on a case study. This SAG Charge SSE model is based on a very small data set of pilot scale, and thus requires a larger data set. Several simplifying assumptions were made, such as assuming a consistent result irrespective of mill speed, mill size, and media size among others, and this requires validation or extension of the approach in future.

ACKNOWLEDGEMENTS

The authors would like to thank those involved in the survey including Marko Hilden, Vlad Jokovic, the Nevada Gold Mines Cortez team and the JKMRC. Nevada Gold Mines is also thanked for their permission to publish. This work was supported by the Australian Government Research Training Program (RTP).

ABSTRACT

Despite the importance of the primary crushing stage, performance optimisation is not well analysed with sufficient focus to give improvement opportunities.

At the Newcrest owned Telfer operation, liner life plays an important part in scheduling planned maintenance. Major consideration is given to monitoring crusher performance, as the highly abrasive nature of the feed significantly impacts the liner wear life.

A study was undertaken by the lead author which focused on establishing a strong baseline of accurate data pertaining to the performance of the crusher, in terms of, operating parameters, liner life and key machine design factors. As part of the study, mining feed materials were examined for a particular set of liners and this revealed that improved methods should be pursued.

Due to the competitive nature of the mining industry, the business solution to complex problems with long shutdown cycles should be streamlined to incorporate a non-operational modelling approach that is significantly more efficient than traditional online trial and error methods. In order to dramatically reduce the time and business risks, it was decided to engage services to model and simulate the liner life by varying main operational and mechanical factors.

The key to all simulation work is gathering high quality baseline data. Such data allowed deployment of the Kinematic Crusher Model and validation of the model against worn 2D wear liner profiles. The proven model was then successfully deployed to predict operational values that defined crusher performance.

To enhance the study, further investigation into a set of mechanical and operational simulations generated a sensitivity matrix measuring key performance parameters throughout the wear life of the liners. The study revealed throughput as a highly sensitive parameter and a change in eccentric throw provided the greatest improvement in extending liner wear life.

INTRODUCTION

Newcrest Telfer Operations uses a traditional front-end to the processing circuit (see Figure 1), which consists of two Metso 54–75 gyratory crushers operating in parallel. The crushers receive direct tip feed from the haul truck fleet, with the feed material varying in size and consistency. The characteristics of the ore lead to relatively high liner wear in the crushers, which impacts maintenance shutdown replacement strategies.

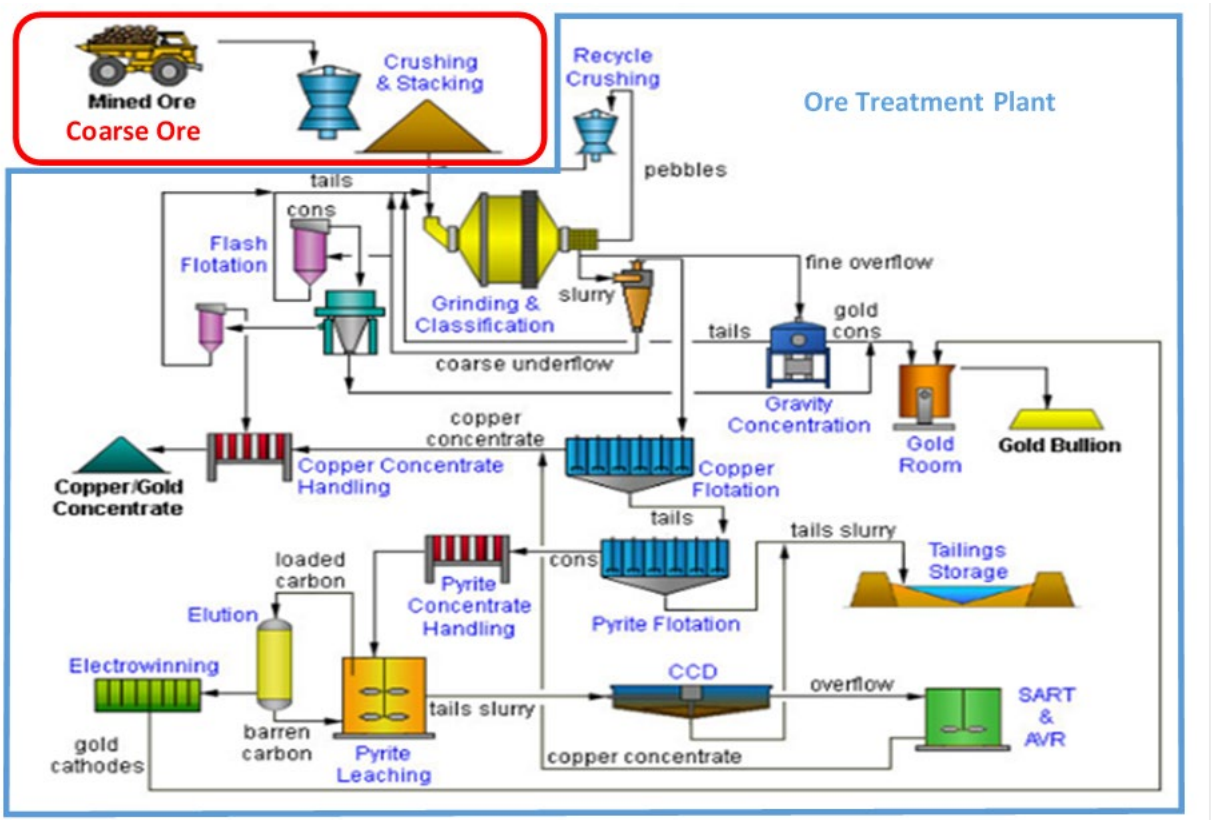

FIG 1 – Telfer: Single Train Processing Facility; simplified overview (Newcrest Mining Ltd, 2004).

In supporting the Newcrest vision to be 'Miner of Choice™', the Telfer Coarse Ore Maintenance team are constantly looking at innovative ways at reducing maintenance cost and improving plant reliability. The team identified that considerable value lies in extending liner life in the primary crushers. As an illustration of the fundamental issue, Table 1 shows the typical log of liner change-outs, with the repeating pattern of three mantles to one set of concave plates and the impact to the maintenance schedule from proposed liner life improvements.

Based on operational accounting data, if a 37.5 per cent increase in liner life cycle can be achieved, then an entire maintenance shutdown for a concave replacement can be removed from the schedule. The ability to remove one such shutdown equates to substantial savings through increased crusher availability and reduced maintenance costs. By utilising non-operational streamlined modelling, these savings can be realised over a shorter time frame, when compared with traditional trial and error approaches. The initial cost associated with modelling represents approximately 10 per cent of the estimated yearly savings and therefore represents a strong rate of return.

Currently the mantle and concave liners are replaced on cumulative throughput, due to liner wear influencing motor winding temperatures. Operating a maintenance strategy of three mantles per set of concaves, the Mainshaft Positioning System (MPS) showed that the average finished stroke height for each worn mantle in order is 58 per cent, 50 per cent and 40 per cent to achieve a cumulative throughput of 3 Mt of ore. By optimising mantle and concave liner wear profiles, this allows the opportunity to increase crusher runtime between scheduled shutdowns.

The study was designed to span two phases. Phase 1, which is the subject of this paper, was aimed at determining if simple and straightforward mechanical and operational changes resulted in positive improvement towards extending mantle liner life. Phase 2 is intended to examine, optimise and automate the design of crusher cavity profiles.

Approach to the study

From the outset of this project, the aim has been to deploy a method of investigation that allows key parameters to be tested in a non-operational setting. Basing the investigation in the virtual world removes the need for protracted trial periods and the possibility of introducing operational risk into a primary crushing installation.

The non-operational, streamlined modelling approach that has been used in this study has been underpinned by the generation of a high resolution data set, application of a structured investigation method and the use of detailed, mechanistic crusher modelling.

The following section provides details of the approach developed and deployed during this study, which leverages and combines methods from both maintenance and process engineering.

UNDERLYING PHILOSOPHY AND PROJECT STRUCTURE

Like all wearing components, the gyratory crusher operation requires a great deal of applied maintenance to ensure crushed ore is delivered on a regular and reliable basis. Setting and achieving targets to reduce the frequency of planned maintenance events leads to the maximisation of equipment utilisation and the extension of the life of wear components.

As previously noted, liner change-out at Telfer is based on a three mantle to one concave set strategy, ie for a single set of concave liners to reach a wear limit, three mantles – Standard, First Oversize and Second Oversize are required.

The three to one mantle to concave strategy is not optimal for all sites. Typically this ratio can vary from 2:1 to 5:1.

The ability to extend liner life, whilst maintaining process performance offers a value proposition that is compelling.

Given the mechanical nature of the study, the maintenance team at Telfer has led the efforts to understand what controls liner life and how it may be extended. In order to investigate the situation a Liner Management Strategy (LMS) has been developed.

LMS is based on standard approaches from asset management.

To methodically develop an LMS, the lead author looked to standard approaches commonly found in the maintenance community, namely:

- Dynamics Maintenance Strategy.
- Maintenance Business Process.
- Reliability Centred Maintenance.

Australian Standards (2004a), acknowledges a dynamic maintenance strategy as a non-scheduled task that utilises other maintenance tasks to assist in monitoring data collection and analysis to determine liner wear life. It is crucial in the case of the primary crusher, that an essential non-scheduled task involves monitoring liner wear profiles against feed type and rate (Bearman and Briggs, 1998). Such data can provide an overall picture of how the gyratory crusher is performing within its design limits (Posario, Hall and Maijer, 2004).

In combination, the Maintenance Business Process (MBP – see Figure 2) and Reliability Centred Maintenance (RCM – see Figure 3) have been the guiding principles for the investigation and the life cycle of events. The approaches recognise how system changes within organisations can allow the development of new ideas (Maintworld, 2013), while following a reliability process as per Australian Standards (2004b), that outlines the process to detect ‘failure modes’, which in this instance, is the point at which liners can no longer meet performance metrics.

The methodical gathering of data, in association with a structured investigation of the impact of crusher parameters, has been at the heart of the LMS development and the efforts to lower maintenance cost and increase productivity by minimising unscheduled downtime (Posario, Hall and Maijer, 2004; Metso, 2012; Major, 2002).

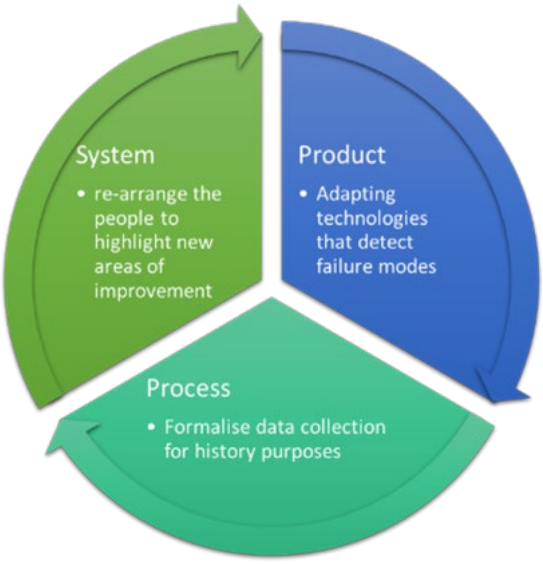

FIG 2 – MBP life cycle (Harding, 2018 after MaintWorld, 2013).

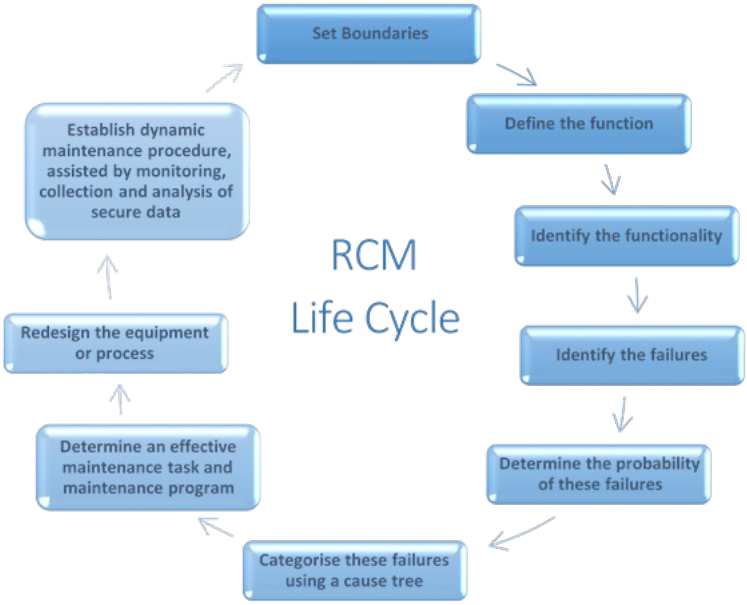

FIG 3 – RCM life cycle (Australian Standards, 2004b).

Embedded in the overall study approach are a series of sensitivity studies to determine the impact of mechanical crusher parameters. Within the study, this exercise was dubbed, a 'Matrix Evaluation'. In this part of the study key mechanical factors were varied to determine the impact on performance indicators.

The concept for the Matrix Evaluation comes from the One-Factor At a Time (OFAT) approach, which defines how to conduct a sensitivity analysis between input variables and directed output targets.

The approach is widely used, but as with many familiar concepts, some of the underlying principles can sometimes be overlooked. A sensitivity ('what-if') analysis is the most effective method to monitor and define the impact of behavioural change. The idea of sensitivity analysis is to monitor behavioural change of an input variable/s in respect to a single or multiple outputs within a set of boundary conditions (Saltelli, Chan and Scott, 2008). Monitoring large or small variations enables the sensitivity analysis to provide solutions, in terms of (Pannell, 2017):

- Understanding or quantifying, the relationship between each input factor and directed output targets.

- Model development, through testing of accuracy or validation, simplifying and calibrating, prioritising information and dealing with poor or missing data.
- Improved decision-making or recommendations, by knowing when and how to optimise the solution for changing circumstances.
- Communication of results, in logical format.

The OFAT approach investigates a single input in relation to multiple outputs, (Saltelli, Chan and Scott, 2008). The remainder of the input values stay the same allowing the analysis to evaluate each output factor in terms of its baseline value as a percentage.

Structure applied in the study

The overall philosophy of non-operational, streamlined modelling is to allow efficient testing of machine performance in a virtual environment, whereby production interruptions are removed from the investigative process.

In a typical case, the various phases involved in a physical process can lead to long and arduous projects. Figure 4 shows a typical, physical (online) process.

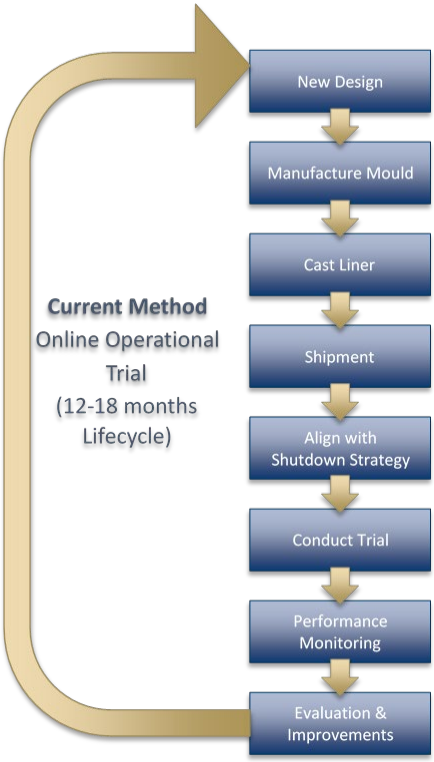

FIG 4 – Traditional, physical (online) liner evaluation process (Harding, 2018).

On top of the process of design, manufacture, operation and evaluation, there are other key factors to consider. The main areas are the data gathering requirements and associated personnel time, downtime of the crusher for performance testing and critically, the risk of an underperforming liner set.

The project that is the subject of this paper proposes to streamline the online physical process, by combining design, modelling and simulation to significantly short-cut the traditional process.

Figure 5 shows the offline streamlined process applied by Telfer Operations.

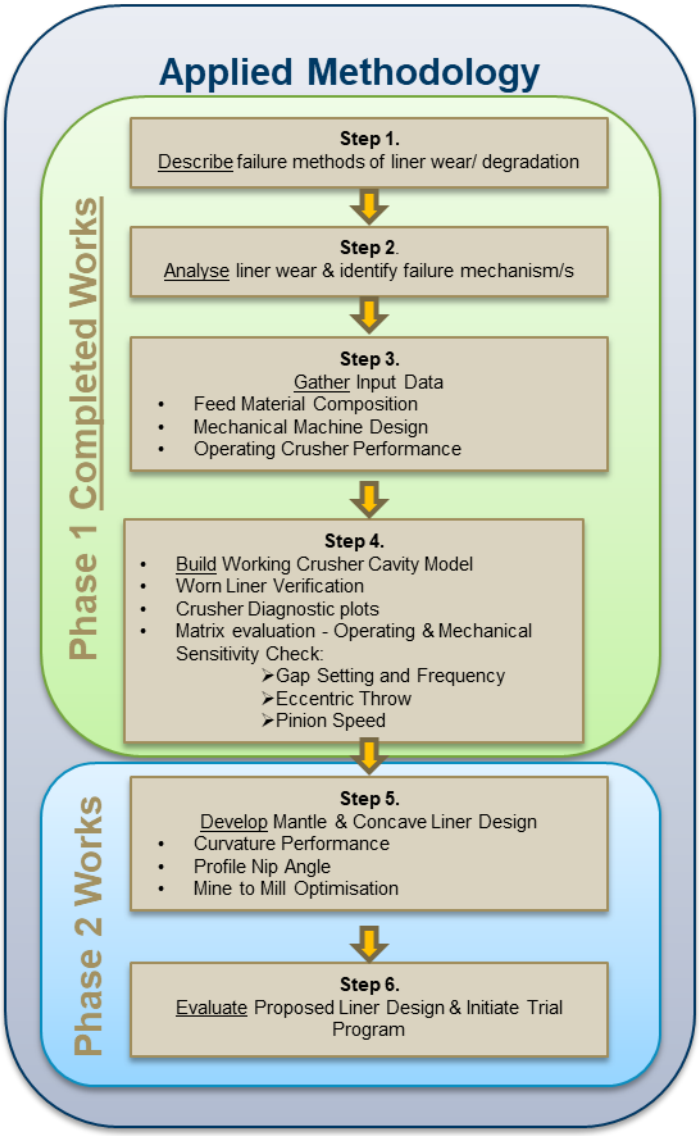

FIG 5 – Applied methodology for the non-operational streamlined modelling approach, with Phases 1 and 2 identified (Harding, 2018).

CRUSHER PERFORMANCE, DATA AND MODELLING

In terms of the project objectives, the target for Telfer Operations is illustrated in Figure 6.

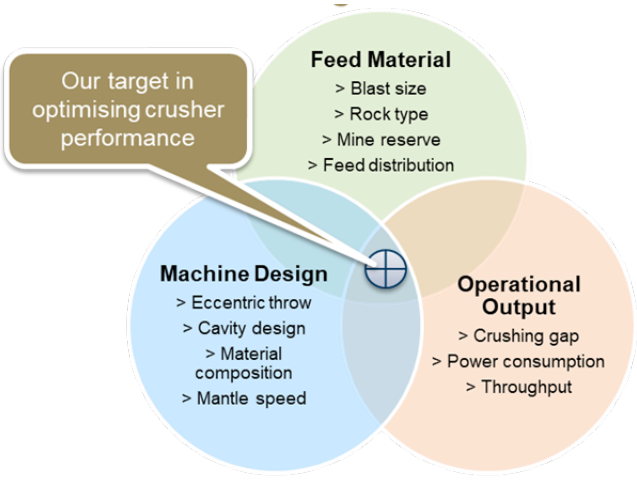

FIG 6 – Goal for primary crusher optimisation.

Factors impacting crusher performance

Various feed, operating and mechanical variables influence crusher performance and liner wear (see Figure 7), making it challenging to effectively optimise the crushing process and to develop a liner optimisation strategy.

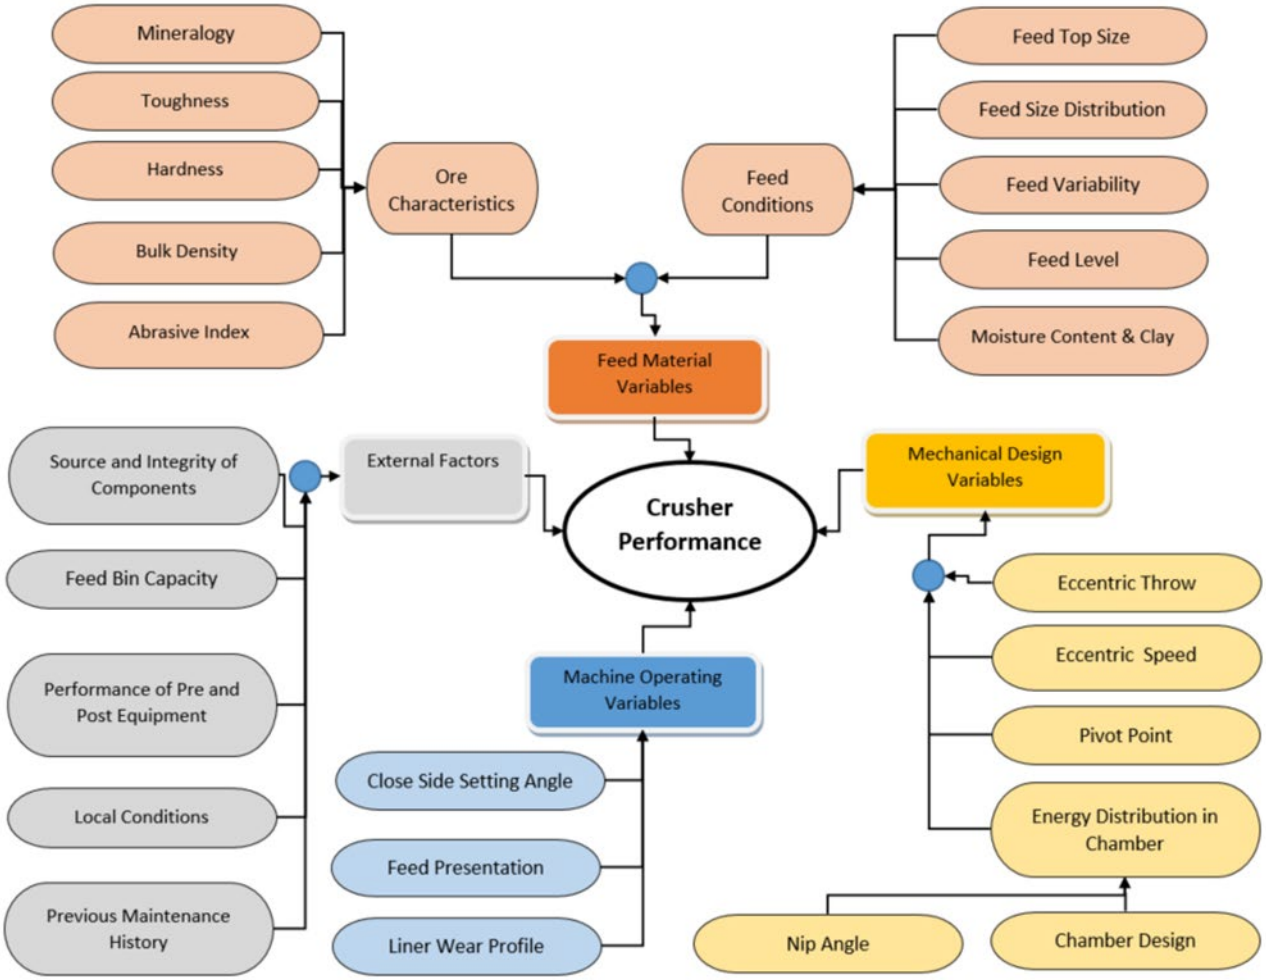

FIG 7 – Factors impacting crusher performance and liner wear (after Harding, 2018).

Any study requires a strong foundation and this relies on extensive and comprehensive data gathering and compilation. The factors shown on Figure 7 are split into:

- feed material variables;
- mechanical design variables;
- machine operating variables;
- external factors.

The categorisation is a deliberate decision by the lead author and it is based on work by Bearman (1994, 2019). The purpose of the delineation is to show that the crushing process is a combination of factors that relate to mechanical, maintenance, processing and feed and that all these need to be considered if a full study is to be undertaken.

Data gathering

A majority of the factors were gathered using available data from operational sources, vendor specifications and design documentation.

Where data was either unavailable or not current, efforts were made to gather new data using advanced technology. Two key exercises involved the lead author undertaking feed size distribution

measurement using a photogrammetry method and accurately measuring liner profiles using laser scanning technology.

To define the feed size distribution to the primary crushers, the PortaMetrics™ system from Motion Metrics was used (Motion Metrics, 2019a, 2019b). The system uses an optically based photogrammetry method, which uses 3D imaging and contributions from AI techniques to provide a size distribution, without the need for traditional screening methods. As with many electronic data collecting systems, results are based on quantity over quality leaving the finer particles to be manually sized. In this instance, Telfer was fortunate to have a database of historical feed size data and therefore the ore feed size distribution graphs incorporated both advanced and historical data to obtain the best result.

Accurate operational liner data relies on overlaying liner wear profiles of both new and worn liners across the full set of concaves, (ie three mantles to a single concave set).

Liner measurement in an operational environment, is often undertaken, but to match the level of modelling required, Telfer personnel embarked on a significant effort. The work was able to accurately generate worn profiles through all stages of mantle use and to also provide a full picture of wear around the circumference of the crushing chamber. The data for the mantles and concave plates was analysed and compiled, so that it could be presented in a number of ways. Figure 8 shows a screenshot from a master spreadsheet where it is possible to select from the full data set of liner profiles, spanning the entire life of the concave plates.

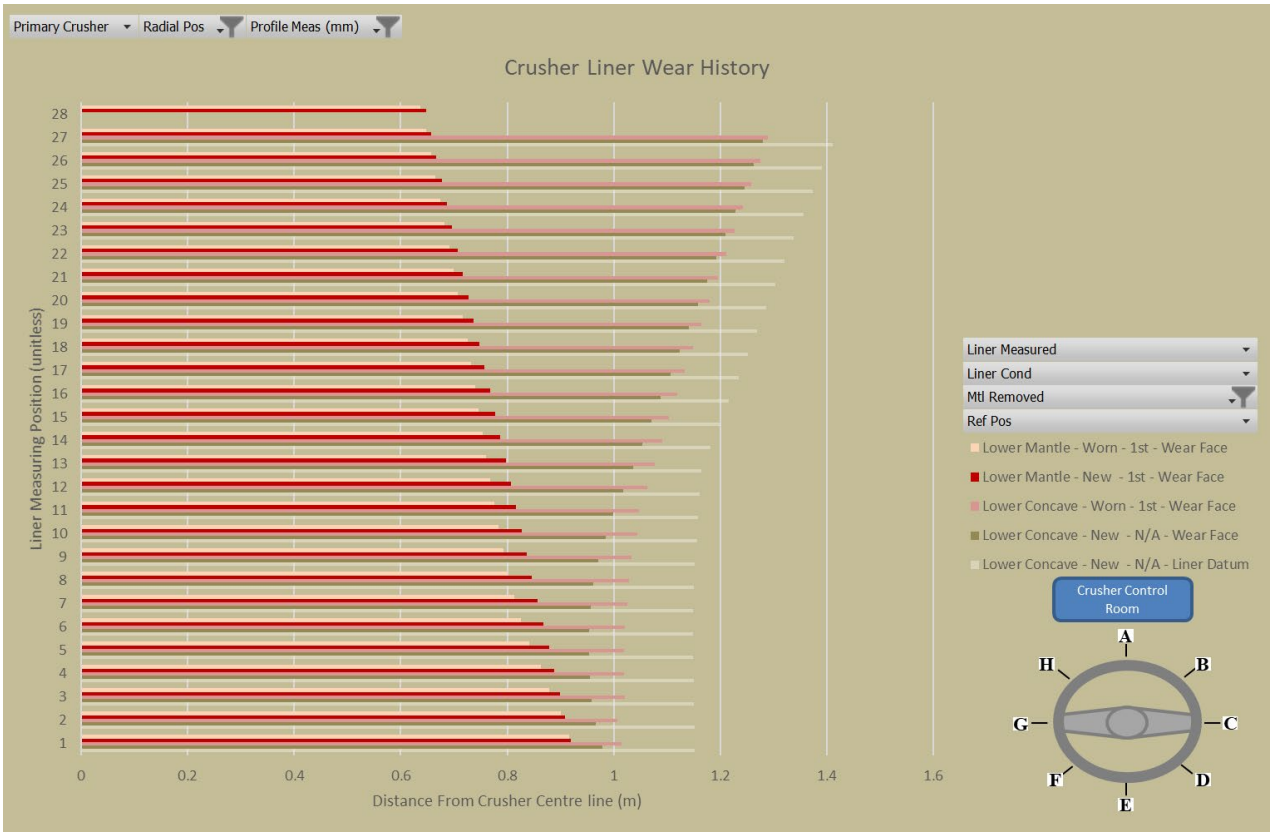

FIG 8 – Screenshot of the master graphic for the reporting of liner profile data.

Mechanistic crusher modelling

The ability to apply the virtual design and testing approach described in this study, relies on a model that is appropriate and comprehensive and can be shown to properly mimic physical processes.

The ability to virtually test potential modifications to liner profile, geometry and even material types, is particularly important in primary crushers.

On the basis of these functional and practical requirements for this project, Telfer decided to engage Bear Rock Solutions Pty. Ltd. (BRS) to provide independent advice and to deploy what is termed the Kinematic Crusher Model (KCM).

KCM was developed 10 years' ago as a joint project between BRS and Met Dynamics Pty. Ltd. The origin of the approach dates back to work by Bearman in the late 1980s (Bearman, 1991), whereby the need to combine breakage characteristics, processing parameters and mechanical crusher variables, was identified. In the prior, and intervening years, various workers (Karra, 1983; Whiten, 1984; Flavel *et al*, 1988; Evertsson and Bearman, 1997; Bearman and Briggs, 1998; Evertsson, 2000; Lindqvist, 2003) have advanced numerous methods and concepts, which have informed some of the approaches taken in KCM.

The KCM method is best described as a multi-component mechanistic model. It uses standard representations of geometry (see Figure 9) and feed characteristics, but then applies advanced techniques to generate material flow diagrams to determine both operating performance and mechanical wear of the crusher. KCM is tried and tested at many mine sites on a variety of both gyratory and cone crushers and has the ability to:

- Verify the machine specification against the required process duty (in both greenfields deployment and brownfields replacement scenarios).
- Align maintenance operating strategies by forecasting liner wear.
- Confirm mechanical and process changes, reducing business risk of long duration trials.

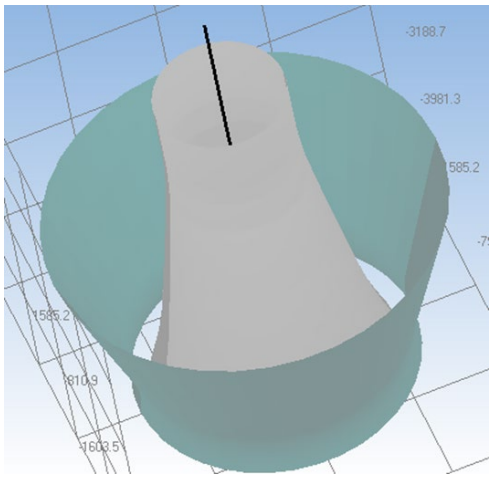

FIG 9 – Standard CAD coordinate plot in KCM showing liner geometry for a primary gyratory crusher.

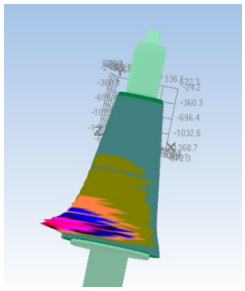
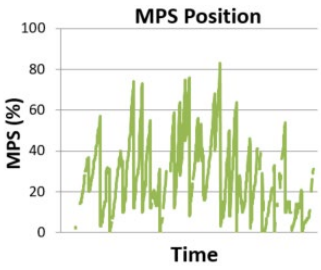
Some of the plots generated (see Figure 10a, 10b) show obvious behaviour, which can easily be interpreted. Other plots are designed to supply information that can be used by experts in the diagnosis of crushing issues or in the re-design of liners. Some of the outputs that are specifically of use in more in-depth analysis, include:

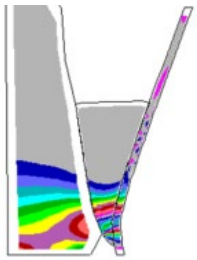
- *Energy Distribution* enables us to illustrate the number of crushed rocks in a given area and directly link it to crushing throughput – Figure 10a.
- Impact of wear profile on the Mainshaft Positioning System (MPS) to determine the remaining life of a set of liners and the optimal change point for a move to an oversized replacement mantle – Figure 10b.
- Evaluating Compaction Behaviour forces to support Root Cause Analysis (RCA) investigations into bush failures, oil flow and temperature issues – Figure 10c.
- Fatigue management on Concave Plate Stresses used to prevent premature failures of liners and liner castings – Figure 10d.



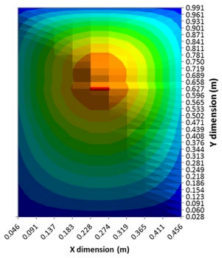
(a)



(b)



(c)



(d)

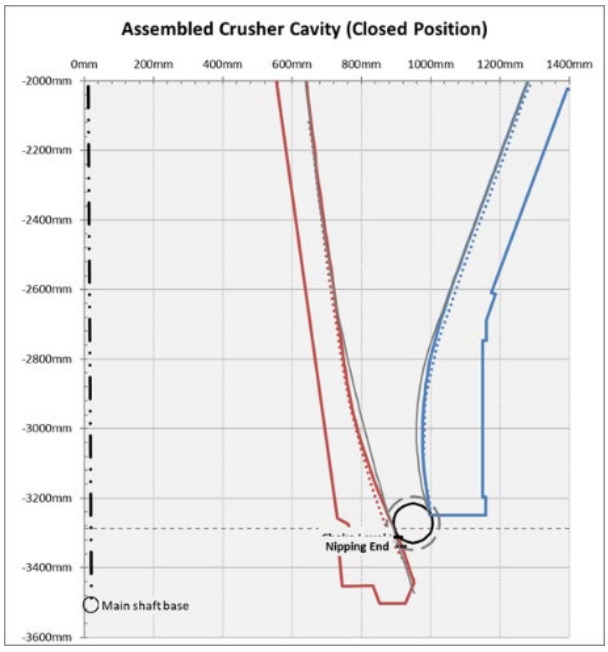
FIG 10 – Example plots from KCM and examples of subsequent analysis. (a) Energy distribution; (b) Mantle Positioning System; (c) Compaction behaviour; (d) Concave plate stress pattern.

Although there are several unique features of KCM, one of the most interesting, as it relates to primary crushers, deals with liner wear.

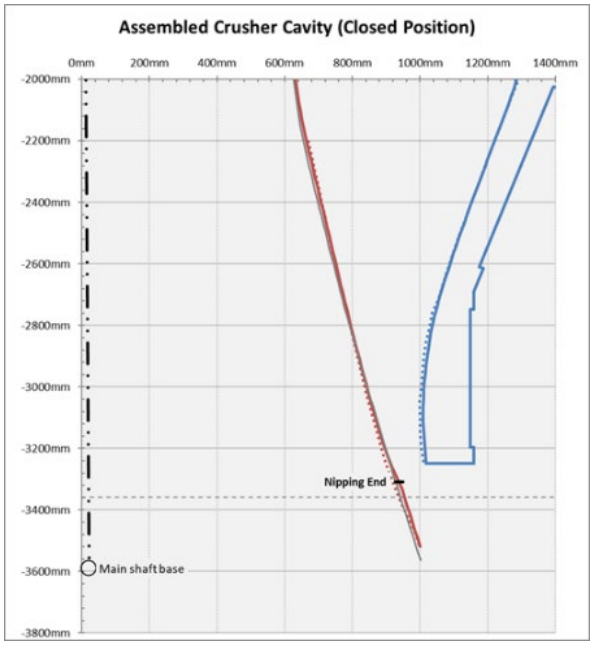
In the case of liner wear, the impact on throughput and power consumption, is seen every day in operations. For the Telfer operation and the requirements of this study, the ability to accurately predict wear was critical to success.

As detailed earlier, Telfer personnel took great care over data gathering and this included the measurement of liner wear.

As part of the evaluation of the utility of KCM, an early piece of work was to compare KCM wear predictions to measured mantle and concave profiles. Figure 11 shows the new profiles, with measured and KCM predicted profiles superimposed, at the end of the life of the Standard mantle and the second oversize mantle.



(a)



(b)

FIG 11 – Telfer wear analysis using KCM [Note: New liners (grey lines), measured profiles (solid red and blue) and KCM predictions (dotted red and blue)]. (a) Standard mantle – end of life; (b) Second oversize mantle – end of life.

The accuracy of the KCM predictions were acknowledged and determined to be a good basis for the crusher optimisation initiative at Telfer.

Study findings

The Telfer primary crusher study was aimed at defining if simple and straightforward mechanical and operational changes were likely to yield improvements in crusher performance. The crusher performance being mainly defined by the ability to extend liner life, but not at the expense of throughput, product size distribution or increased power draw.

In order to do this, the KCM system was set-up so that it was able to accept a range of inputs and run through the wear life of a mantle liner and vary the Open Side Setting (OSS), eccentric speed, and eccentric throw.

For every combination of input parameter, the model calculated outputs in the form of power consumption, mainshaft position (vertical) and product size distribution (P80).

The approach was internally referenced as a matrix evaluation.

Matrix evaluation

As previously noted, the matrix evaluation was designed on the basis of the OFAT approach. The work undertaken examined the crusher performance using original and new condition mantles and concave profiles, with these kept the same in the case of all changes to input parameters.

In this paper, the focus in Phase 1 was to look for simple improvements and validate the KCM model by examining variation in crusher parameters, before moving into Phase 2 to develop matched liner profiles.

The range of parameters used in this study are:

- OSS: 150, 175 and 200 mm;
- Eccentric Speed: Standard, +20 per cent and -20 per cent;
- Eccentric Throw: 36, 40 and 44 mm.

Figures 12, 13 and 14 refer to the second oversize mantle (end-of-life) and shows plots of the key output values with variation in input for OSS, eccentric speed and eccentric throw, respectively.

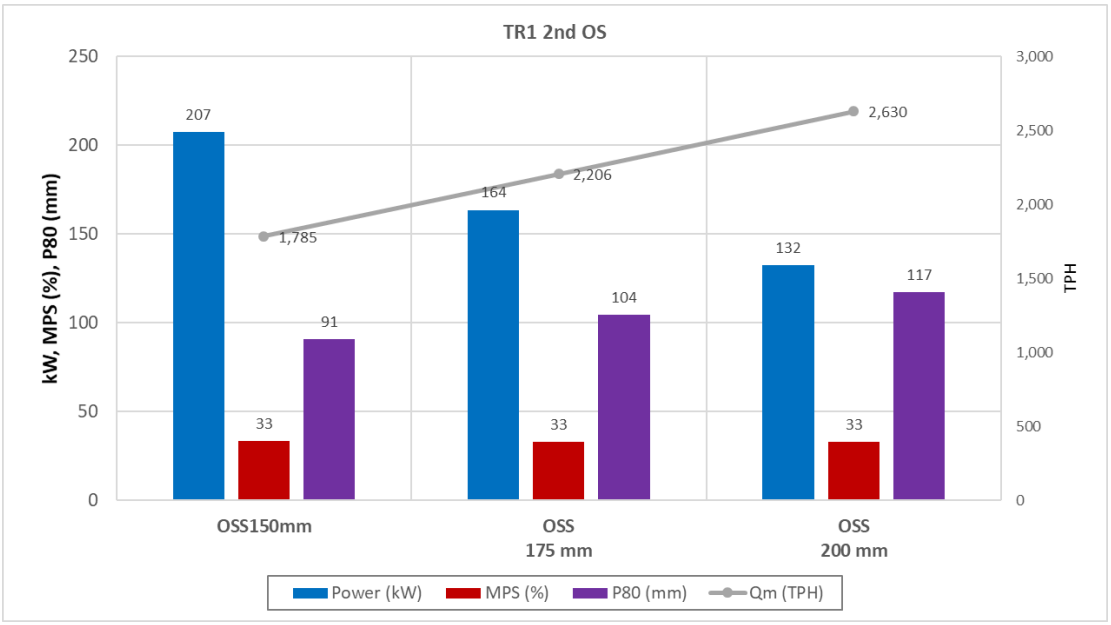


FIG 12 – Impact of changes in OSS.

In Figure 12 where the OSS is being varied, the plot shows the expected trends of increasing throughput and increasing product size, with increases in OSS. There is no change in the MPS value which shows that the same amount of liner use is required, compared to baseline.

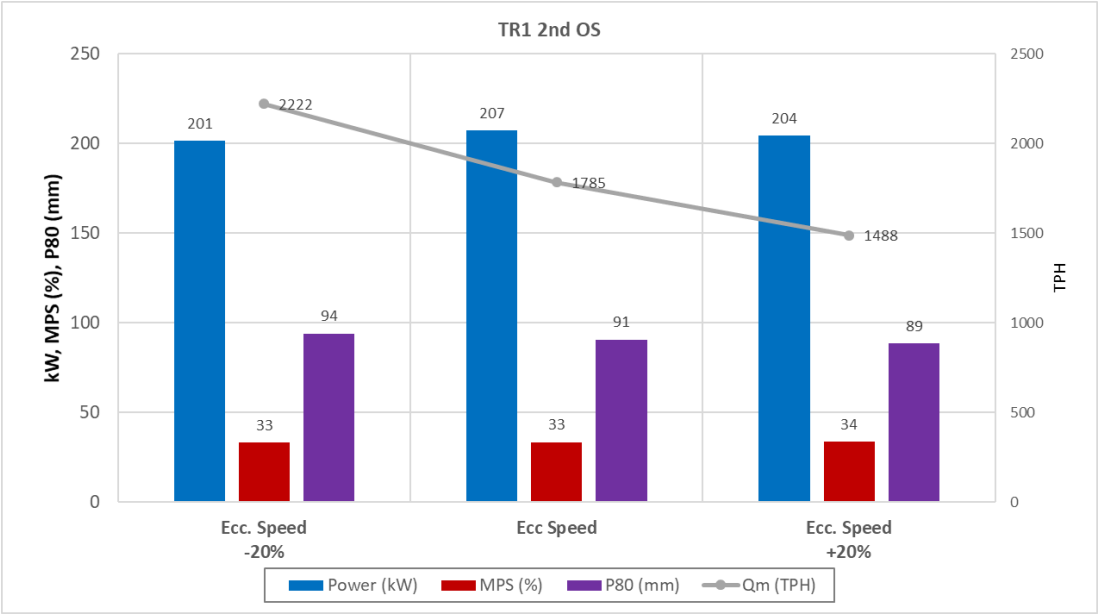

FIG 13 – Impact of changes to the eccentric speed.

In Figure 13, the impact of the eccentric speed is examined and the plot indicates that throughput decreases with increase in speed, which is commonly seen in primary gyratory crushers. Power consumption and MPS remains relatively consistent over the range of speed change.

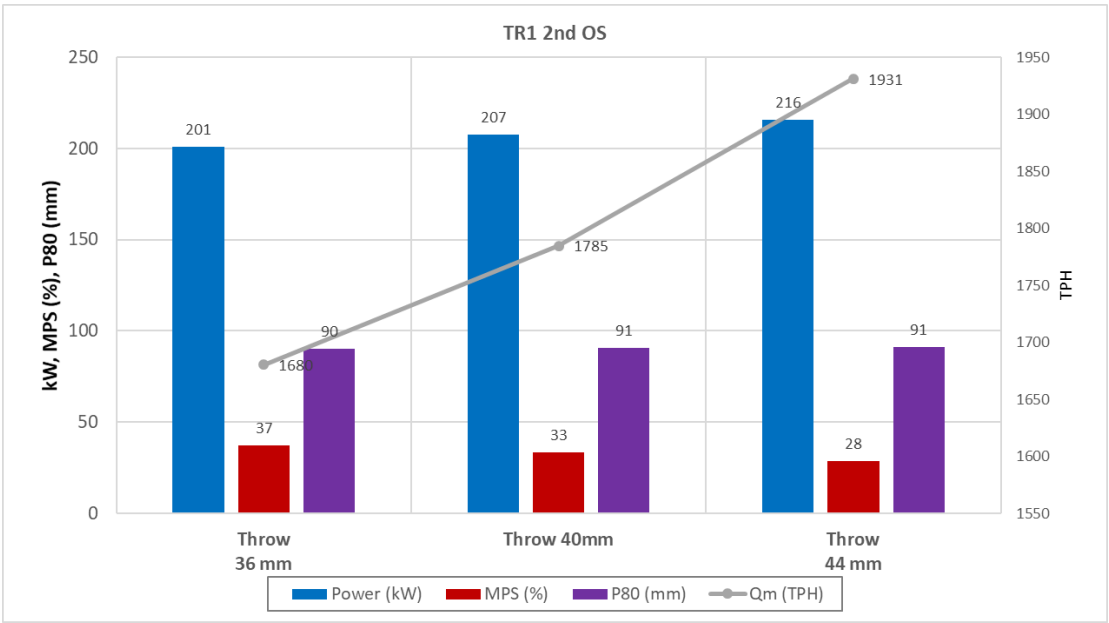

FIG 14 – Impact of changes to the eccentric throw.

For the same CSS, increasing the eccentric throw will provide more space at the discharge point of the crushing chamber, as the OSS is larger due to the increase in throw. Such a change, inevitably causes throughput to increase with throw, as seen in Figure 14. Similarly, power consumption rises as throw increases, primarily due to the increase in the flow of material. There is also a contribution from the fact that the throw increases the movement of the mantle and therefore the amount of compression applied to particles will be higher through the length of the chamber.

The most significant change that should be noted in Figure 14, is that the MPS value decreases with increasing throw. Essentially this shows that at the end of the nominal wear life of the liner set, the MPS movement required to achieve the desired setting is less than with the usual throw for this crusher, ie there is still mantle adjustment left that could be used and therefore the liner set could be operated for a longer period.

On the basis of the matrix evaluation, the move to a 44 mm eccentric throw was considered to offer the only significant benefit in the extension of liner life. Figure 15 shows the simulated changes in the key performance markers for crusher performance.

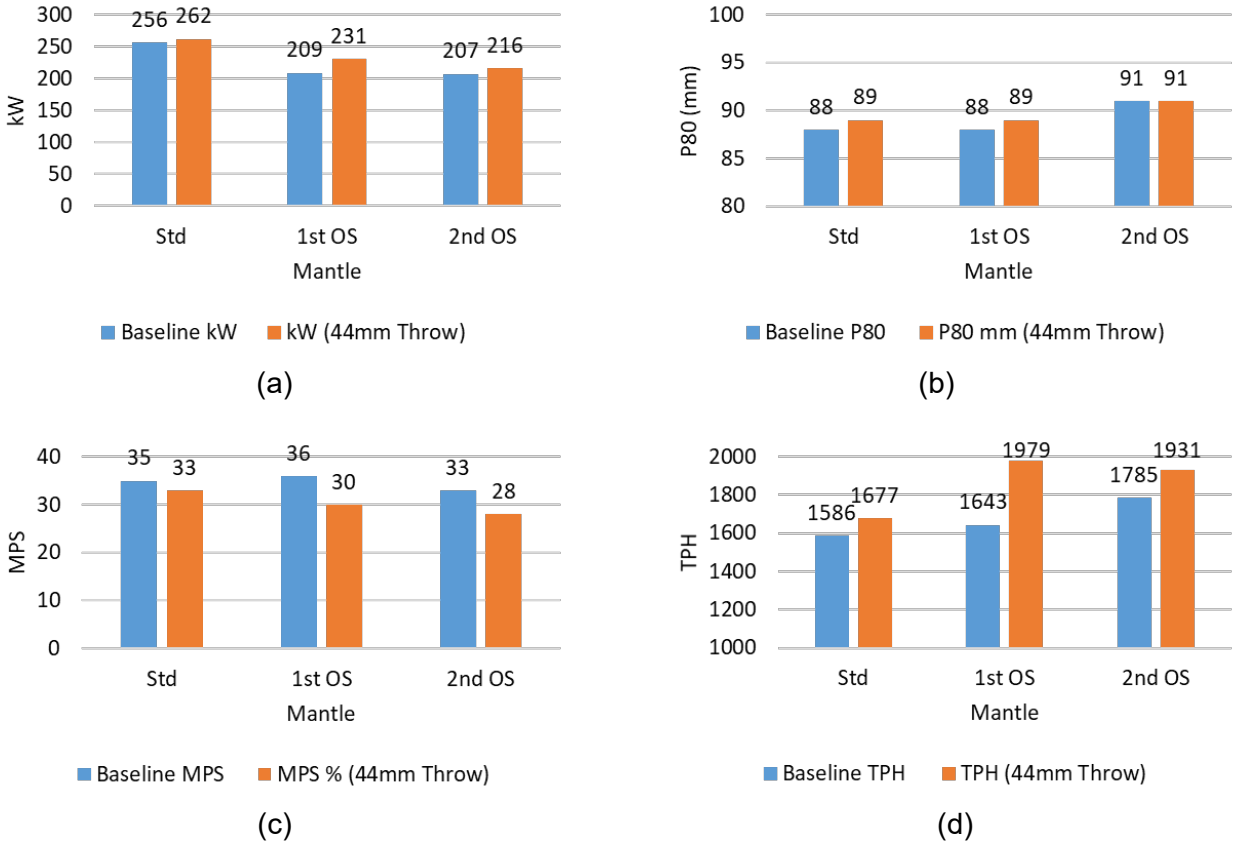

FIG 15 – Comparison of baseline crusher performance and simulated performance when a 44 mm eccentric is used. (a) Power Consumption; (b) Product P80; (c) Mainshaft Positioning System (%); (d) Throughput.

Figure 15 shows that in association with the positive change in MPS value (ie longer liner life), there were other changes that should be noted. The main points are that there is an increase in throughput and power is higher for all liner configurations. There is also a slight increase in the P80 size.

CONCLUSIONS AND FUTURE OPPORTUNITIES

The Phase 1 study reported in this paper, has shown that the non-operational, streamlined modelling approach can rapidly identify the areas influencing primary crusher performance. As such, the modelling is a system that builds trust between theory and reality, it can be used alongside physical adjustments to determine crusher parameters in order to manage business risk and develop life-long learnings.

The main technical finding points to increased eccentric throw as a way of lowering the MPS position and increasing throughput over the life of a set of liners. The associated slight increase in power consumption raises a concern for Telfer Mine site, as it currently experiences high motor winding temperatures. In addition, the impact of coarser product on downstream processing equipment needs to be carefully evaluated through modelling and simulation.

Given the success of the overall method applied in this study, the Phase 2 component (automated liner profile optimisation) is being evaluated in relation to operational considerations. As part of Phase 1, some initial work into semi-automated profile design was undertaken to build on the understanding of matched liner profiles.

Tables 2 and 3 show the results of semi-automated liner design between the existing profile and an alternate designed using the new method.

TABLE 2

New condition liners (first mantle and concave) – simulation of alternate liner set compared to current liners.

Liner set (no wear)	Power (kW)	Throughput	MPS (%)	P80 (mm)
Alternate (percentage change)	-3.6%	0%	0%	0%

TABLE 3

Worn condition liners (first mantle at end of life) – simulation of alternate liner set compared to current liners.

Liner set (worn)	Power (kW)	Throughput	MPS (%)	P80 (mm)
Alternate	-5.4%	+12.5%	-17%	0%

The results reported above are highly encouraging and they suggest that automated liner design may deliver significant performance benefits, in terms of liner life, power, throughput and control of product size.

In terms of the current status, the Liner Management Study has shown that rigour in gathering and consolidating baseline data has allowed development of an in-depth understanding that greatly assists in analysing crusher operating conditions and machine issues.

Phase 2 is now under consideration and the data, resourcing and funding requirements are being defined in readiness for management consideration.

ABSTRACT

HPGRs (high pressure grinding rolls) have been developed within the last decades for energy efficient processing of a wide variety of ores. Special interest has been raised by projects increasing the capacities of processing plants by installing HPGRs prior to ball mills. Bond ball mill tests have been used for decades as a base for ball mill dimensioning in mineral circuits. For final CAPEX-OPEX considerations of the processing circuit, one key question is about the level of grinding energy split between HPGR and downstream grinding stages. This is especially interesting if the downstream process comprises multiple grinding stages combined with separation steps.

The paper presents investigations on grinding energy consumption, size distribution and microfracturing of HPGR products, which affect the efficiency of the whole comminution and sorting process.

INTRODUCTION

The comminution process of High Pressure Grinding Rolls (HPGR) was discovered in the 1980s by the research work of the German Professor Schönert. Its main advantage is the high energy efficiency in comparison to ball mill grinding which has been the benchmark process in the cement industry by then (Schönert, 1988). Since then, a worldwide trend towards HPGR application has been established (Klymowsky *et al*, 2002), first in the cement industry but soon after also in ore processing.

Nevertheless, it has to be noted that the technology has its roots much earlier. Köppern, as one supplier of HPGR, has been working for more than 120 years on roller presses, starting with the formation of coal briquettes between two rollers. Subsequently, other fields of application, eg for fertilizer compaction, emerged (Schönert, 1966).

Even based on this history, it was a large step to transfer this process principle to minerals applications due to the much higher wear caused by the higher abrasivity of those materials. The first applications started in iron ore concentrate grinding. Meanwhile, with the optimisation of the roller surfaces using studs (Morely, 1995), the service life of the rollers substantially increased and the technology has been well established for ores and hard rock applications.

Figure 1 refers to a common installation of a HPGR for iron ore. Other set-ups with primary ball mills in circuit with cyclones which are prevalent in non-ferrous industries shall not be addresses in this paper. The material is pre-crushed to a feed size of 25 mm and then processed by HPGR within a pregrinding application in front of a primary ball mill (Morely, 1995). The HPGR is designed to work in open circuit in this case, with the transfer size to the ball mill being in the range of 80 per cent passing 7 mm. The primary ball mill is operated in a closed circuit with a screw classifier, followed by a magnetic separation stage. Tailings of this stage are reground in a ball mill hydrocyclone circuit for further processing.

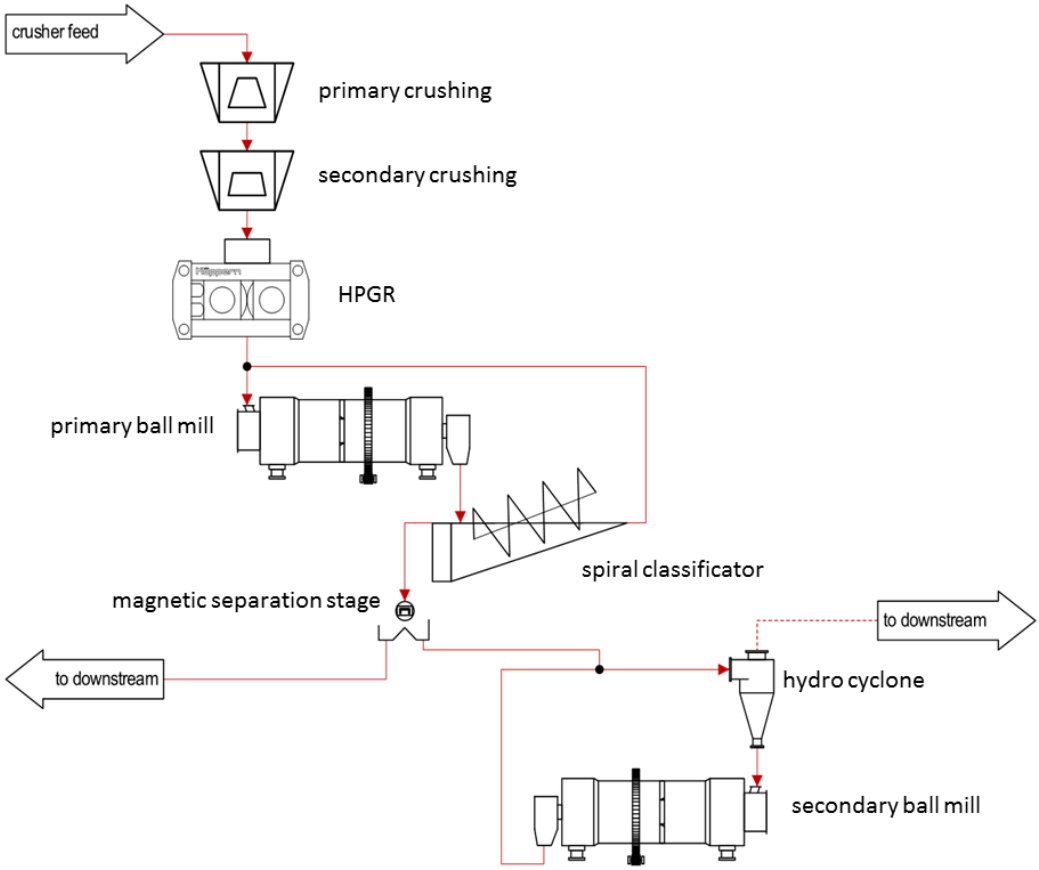

FIG 1 – Typical Flow sheet of HPGR processing in front of ball mill.

To achieve the best grinding efficiency, HPGR are available in a wide size range. Figure 2 shows a state-of-the art Köppern type HPGR. The key questions for sizing of such a machine are:

1. What throughput is to be processed by the machine?
2. What is the desired transfer size to the downstream process?
3. Which energy input shall be achieved?
4. How does the downstream flow sheet look like?
5. Which downstream effects shall be fostered, especially with regard to the subsequent ball mill grinding stage?

All those questions need to be answered in the process design phase, prior to selecting and sizing the key equipment.

FIG 2 – Typical example of a state-of-the-art HPGR.

SIZING KEY EQUIPMENT

The performance of HPGR primarily depends on the ore and its characteristics (Morley, 2006). Grinding tests are still indispensable to determine those characteristics and to predict the operational behaviour of the machine comminuting a certain material. The most important parameters are the specific throughput and specific energy consumption which allows selection of the appropriate HPGR for the required material and process parameters (Heinicke *et al*, 2016a; Gruendken *et al*, 2008). The specific energy consumption is a mass rate normalised value to describe the amount of energy transferred to the material in one single grinding pass.

$$W_{Sp,HPGR} = \frac{(P_{t,HPGR} - P_{i,HPGR})}{\dot{M}_{HPGR}} \quad (1)$$

where:

$W_{Sp,HPGR}$	mass specific energy consumption of HPGR
P_t	total power draw under load
P_i	idle power draw
$\dot{M}_{HPGR}$	total HPGR throughput equals fresh feed rate in open circuit operation

The Bond ball mill test (Bond, 1952) is a proven method to predict the performance of a ball mill. The power draw can be calculated respectively, using the following formula:

$$W_{Sp,BM} = W_i * k * \left(\frac{10}{\sqrt{P_{80}}} - \frac{10}{\sqrt{F_{80}}}\right) \quad (2)$$

where:

$W_{Sp,BM}$	power draw of ball mill
W_i	Bond work index as material specific parameter
k	product of correction factors according to Bond
P_{80}	80 per cent product size passing of ball mill
F_{80}	80 per cent feed size passing of ball mill

If the formula is analysed in an analytical way there are three influences to reduce the energy consumption which have different level of effect:

- reduce F_{80} at low impact
- reduce P_{80} at medium impact
- reduce work index at highest impact.

Figure 3 shows those effects on the throughput of a ball mill (varied parameters as per Table 1):

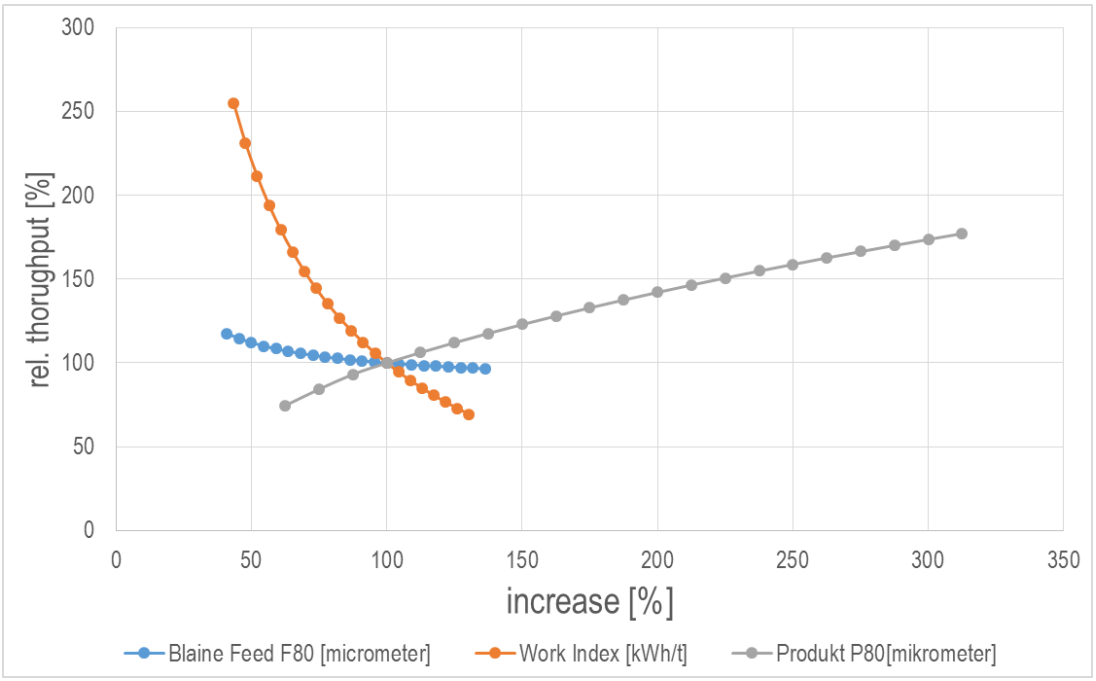

FIG 3 – Effect on throughput of Bond parameters.

TABLE 1

Input parameters for Bond variation graph of a brownfield plant (see also Povey *et al*, 2017).

Feed rate	466 t/h
Feed size F_{80}	11 mm
Product size P_{80}	0.181 mm
Mill power effective	3575 kW
Estimated Bond Wi	11.5 kWh/t

The total grinding energy according to the flow sheet shown in Figure 1 can be calculated as follows:

$$P_{TOTAL} = P_{HPGR} + P_{BM,1} + P_{BM,2} \quad (3)$$

where:

P_{Total} total grinding power consumption

P_{HPGR} power consumption of HPGR

$P_{BM,1/2}$ power consumption of primary (1) and secondary (2) ball mill

The combination of (1) and (3) results in (4):

$$P_{TOTAL} = W_{Sp,HPGR} * \dot{M}_{HPGR} + W_{Sp,BM,1} * \dot{M}_{BM,1} + W_{Sp,BM,2} * \dot{M}_{BM,2} \quad (4)$$

where:

$\dot{M}_{BM,1/2}$ total primary (1) and secondary (2) ball mill throughput

$W_{Sp,BM,1/2}$ primary (1) and secondary (2) ball mill work index

If a mass split of 50 per cent is assumed in the magnetic separation stage, the masses are related as follows:

$$\dot{M} = \dot{M}_{HPGR} = \dot{M}_{BM,1} = \dot{M}_{BM,2} * 2 \quad (5)$$

where:

$\dot{M}$ fresh feed rate

Thus, the combination of (2), (4) and (5) results in (6):

$$P_{TOTAL} = \dot{M} \left\{ \begin{array}{c} \left(P_{t,HPGR} - P_{i,HPGR}\right) + W_{i,1} * k * \left(\frac{10}{\sqrt{P_{80,\mathrm{BM1}}}} - \frac{10}{\sqrt{P_{80,\mathrm{HPGR}}}}\right) \\ +W_{i,2} * k * \left(\frac{10}{\sqrt{P_{80,\mathrm{BM2}}}} - \frac{10}{\sqrt{P_{80,\mathrm{BM1}}}}\right) * 0{,}5 \end{array} \right\} \quad (6)$$

where:

$W_{i,1/2}$ Bond ball mill work index as material specific parameter of primary (1) and secondary (2) ball mill

k product of correction factors

In a given brownfield application, the installed power of the ball mills is fixed which means that the product of specific energy and maximum attainable throughput has to be the same for each mill at all times. Also, the transfer size to the downstream process after second ball mill is defined by the material characteristics and respective specifications of the downstream process such as liberation size and throughput. The product size of the HPGR, however, can be adjusted by increasing the hydraulic piston pressure in the machine. Thus, also the feed size to the primary ball mill can be controlled. An increase of the hydraulic pressure in the HPGR leads to an increased power draw of the HPGR roll drives as well (see Figure 4).

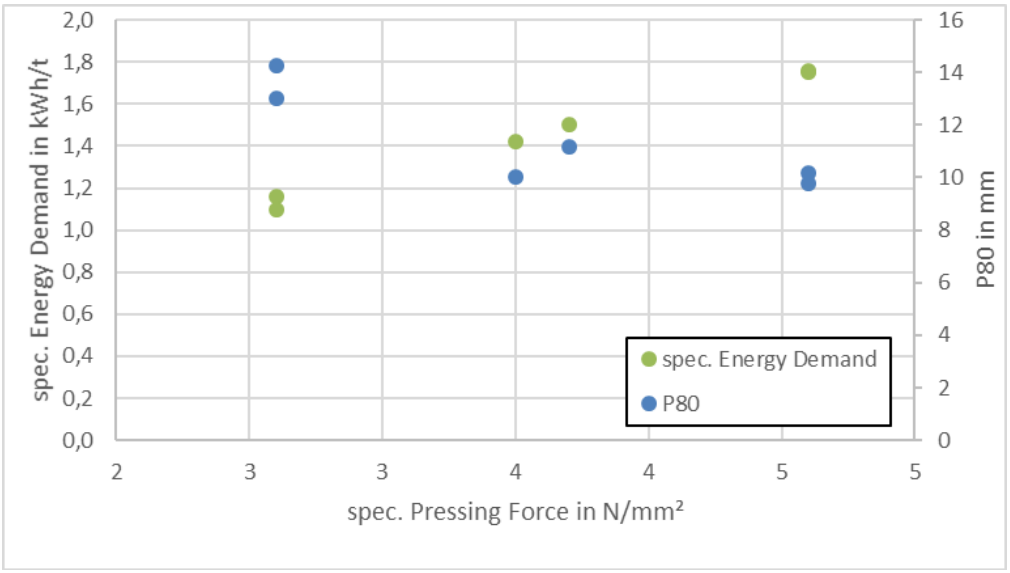

FIG 4 – Correlation of specific hydraulic pressure and specific energy demand from a test series with iron ore.

Moreover, the high pressure grinding regime leads to micro-fractures within the product as shown in Figure 5. Those micro-fractures reduce the strength of the ore fed to subsequent comminution machines. In the presented flow chart, they reduce the Bond ball mill work index of the material transferred from the HPGR to the primary ball mill. Thus, the throughput or the size reduction degree of the primary ball mill can be increased to fully exploit the installed power of the ball mill. It became clear that there is an optimisation potential between energy efficient grinding in the HPGR and downstream ball mill grinding.

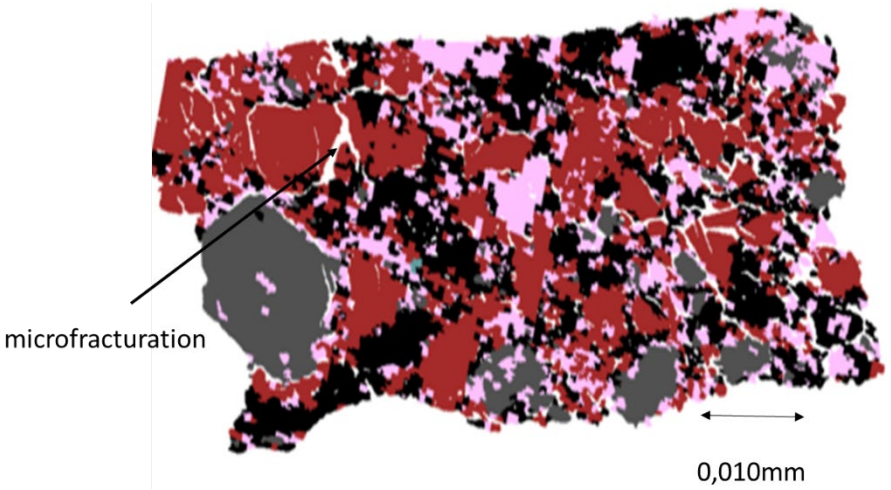

FIG 5 – Example of a micro-fractured particle of a HPGR.

Such an optimisation has to include the whole downstream process. An simple increase of the throughput in the primary ball mill would mean that the second ball mill would receive a higher feed rate as well. It can be assumed that the mircro-fracturing initiated by the HPGR will be exploited in the primary ball mill. Therefore, the secondary ball mill has to be designed considering a higher Bond ball mill work index than the primary one. The best way to avoid a potential overload of the secondary ball mill is to reduce the transfer size from primary ball mill. This affects the sorting behaviour and impacts the optimum process as well. The micro-fracturation of the particle is known to increase the liberation degree and therefore can influence the magnetic separation (Michaelis, 1995). Again the design of mass flows is influenced and need to be optimised. For this optimisation, it is essential to understand of the differences between ball mill grinding and HPGR grinding in view to the downstream energy efficiency effects.

INFLUENCES ON BOND WORK INDEX USING HPGR

To assess the energy efficiency effect of HPGR, various Bond ball mill test series were performed (see also Brüggemann, 2019), all of them following the stipulations of Bond. The feed material for the Bond tests was a medium grained granodiorite from Kindisch (Germany) with a compression strength of σ_D = 176 MPa, produced by a hammer mill with grate (HAZEMAG Unirotor 490/380), a single toggle jaw crusher (Retsch BB 250 XL) and an HPGR (Köppern HPGR 60/10–230 and HPGR 22/3), see Figure 6. In those three machines, the material is stressed in different ways, merely by compression in the jaw crusher and the HPGR or by blow and shear in the hammer mill.

Despite the upper limit of the feed size of the material for the tests was always the same (-3150 µm), the particle size distributions PSD vary significantly. The first mayor difference is the slope of the particle size distribution curve (see Figure 7). While the particle size curves distribution curves of the jaw crusher and hammer mill product in the respective size range show only minor differences, the slope of the HPGR product size distribution is shallower, which is a common observation for HPGR grinding (Heinicke, 2012).

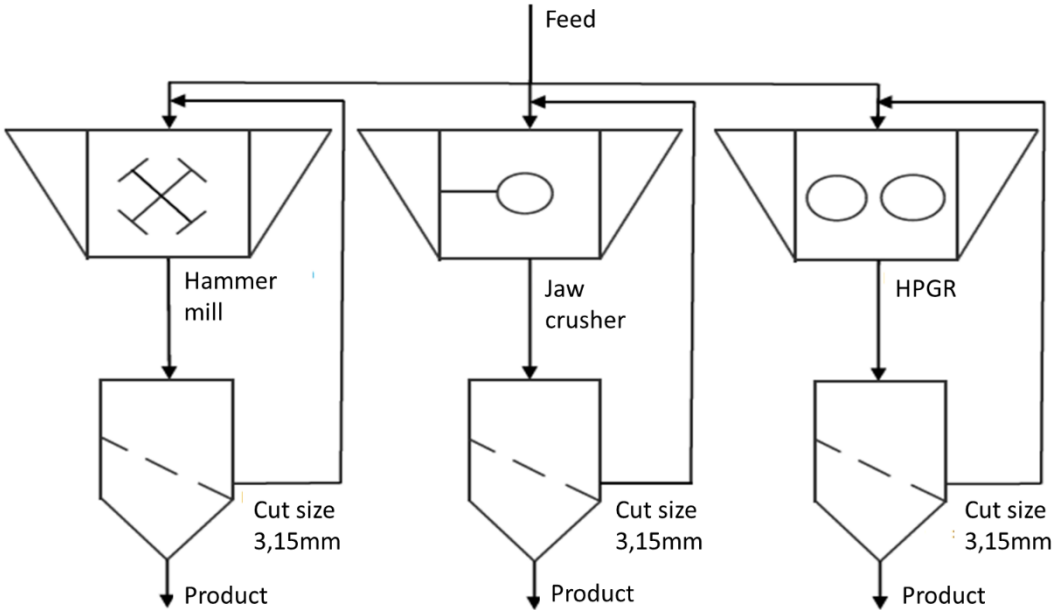

FIG 6 – Test work set-up for preparation of sample.

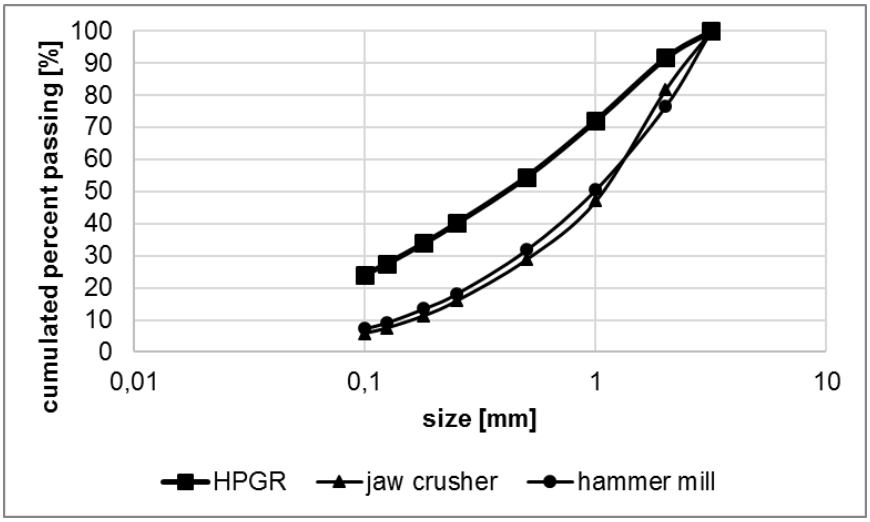

FIG 7 – Particle sizes for different preparations.

It has been well established, that among others the preparation of the feed material influences the results of the Bond test (Gonzáles, 2021; Weier and Chenje, 2018; Vizcarra and Wong, 2019) but the experimental error is usually small (Ballantyne and Giblett, 2019). The small experimental error was also confirmed in our own tests with the scatter of three repeated tests being around 0.4 per cent (±0.07 kWh/t of a medium 18.08 kWh/t). Therefore, the Bond test is used also in this paper to assess the influence of micro-fractures generated by HPGR onto the grindability. Initially the W_i values were assessed for the PSD of the materials as obtained by just screening at a cut size of 3150 µm, see Figure 7. The resulting values of the Bond test are given in Table 2. They showed a reduction of the Bond work index of up to 8 per cent for the material ground by the HPGR.

TABLE 2

Overview of Bond work index for different feed preparations.

Preparation aggregate	W_i [kWh/t]
Hammer mill	17.89
Jaw crusher	18.09
HPGR	16.79

This reduction included potential effects of micro-fractures caused by HPGR as well the difference of the three feed materials. To reduce the influence of the differing PSD distributions, the product materials of jaw crusher and hammer mill were screened and classified into eight size fractions between 0 and 3150 µm. For comparison, the same procedure was also conducted for the original fresh secondary crushed material from the quarry (fraction -3150 µm directly separated from original feed size -32 000 µm without further comminution). Afterwards, the mass per each fraction was adjusted to the shear of the respective fraction in the HPGR product. The modified fractions of each feed material were combined again and thoroughly blended and homogenised, finally well matching the particle size distribution of the HPGR product.

With the three modified feed materials, the Bond tests were repeated. The results are presented in Table 3. The reduction of the Bond work index increased even further to 15 per cent which indicates a remarkable effect for the power draw of a ball mill installed after the HPGR.

TABLE 3

Overview of Bond index for different feed preparations at same feed PSD.

Preparation aggregate	W_i [kWh/t]
Hammer mill screened to match HPGR	19.34
Jaw crusher screened to match HPGR	18.34
Fresh feed screened to match HPGR	18.32
HPGR	16.79

A further effect of an HPGR installation prior to ball milling in ore processing can be seen in the high comminution selectivity, as shown in Figure 8 (Kühnel, 2021). During size reduction in the sample preparation for the Bond tests deploying different machine types, the coarser particles report to the finer classes depending on their mineral content and the type of stressing introduced by the comminution machines. While selectivity in comminution is generally limited with machines such as jaw or cone crushers, machines deploying the confined bed comminution principle such as HPGRs may support such selectivity as shown in Figure 8. Here, the fine fractions (-1 mm) exhibit a remarkable reduced quartz content while the iron is enriched.

A sample collected from such material for the Bond test by just classifying the -3150 µm fraction would simply reflect the increased content of the softer iron containing minerals. Assessing such a sample in a Bond test may again result in overdesigning mills for a production process which do not account for the special comminution characteristics with an HPGR. This effect has not been quantified so far as the preparation method of material for the Bond tests is not further specified and typically does not reproduce the real production conditions appropriately for HPGR.

Those effects have to be carefully analysed for HPGR test work design. Typical vendors of HPGR have this ability and knowledge and will consult the individual clients accordingly for the individual ore type of the project (Heinicke *et al*, 2016b).

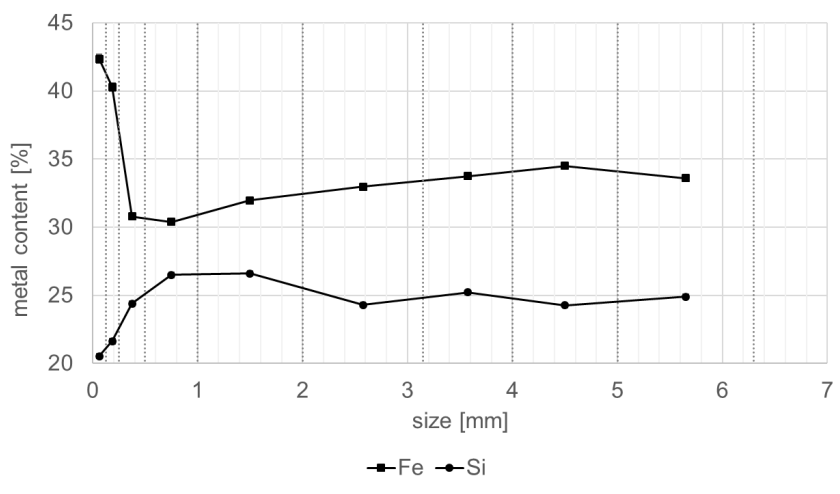

FIG 8 – Selective comminution effects in feed material processed by HPGR for an ore with high quartz and low iron contents.

CONCLUSIONS

The grinding with HPGR showed remarkable effects on the downstream energy efficiency in ore processing. To quantify those effects, common test routines according Bond may be oversate the actual specific energy consumption as they are influenced by size distribution, particle weakening and selective grinding effects of HPGR. A careful planning of HPGR test series has to be done to balance the effect to downstream processes correctly. As the ores will differ from project to project this procedure shall be addressed by client and vender for each individual project.

ACKNOWLEDGEMENTS

This work was funded by Köppern within a research cooperation with Technical University of Freiberg. The authors would like to thank Köppern for the right to publish this paper and Jonas Brüggemann for the excellent test work performed within his thesis.

ABSTRACT

Soft sensors offer several practical advantages for the process control of comminution circuits by combining multiple conventional sensors and other data sources with real-time analysis using mechanistic, phenomenological or machine learning models. While there has been a growth in the use of machine learning techniques for developing soft sensors in minerals processing applications, this paper describes advantages and challenges of using soft sensor models developed on the basis of process knowledge.

Recent experience with three new soft sensor technologies developed by the authors are discussed. The *Mill Filling Inference Tool* which has been implemented at several mine sites, compares SAG mill load cell and power draw measurements with outputs of a semi-mechanistic power model to estimate the mill ball and total filling in real time. The progressive wear of the mill liners is modelled, allowing the model to correct the load mass due to the mass loss automatically and to estimate the charge trajectory. This information enables the mill to be operated more confidently near its limits. A coarse-ore stockpile soft sensor as been recently developed using a 3D cellular automata-based model to track ore size throughout the pile, and estimating the live capacity and size at each stockpile feeder to the primary mills. Finally, a hydrocyclone soft sensor is being developed to monitor performance using available hydrocyclone models to estimate the size and flow balance around the cyclone in real time.

The model-based soft-sensor approach aims to synthesise and analyse existing data and provide operators and engineers with process- and model-relevant information that can facilitate making better process decisions. Maintenance data has proven useful for model development as it allows soft sensors to automatically adjust and compensate for the effect of progressive wear, for example for mill liners, thus helping the models to maintain calibration throughout the equipment life.

INTRODUCTION

Minerals processing plants rely on measured data from large numbers of physical sensors to monitor, control and operate the process. In many production environments, soft sensors (also known as software sensors, inferential sensors, virtual online analysers, adaptive estimators, state observers, or virtual sensors) are used to augment these process measurements. Soft sensors are mathematical models using data from physical sensors and other sources as inputs to calculate process parameters that may be impractical to measure directly or a redundant estimate to confirm physical measurements (Hodouin *et al,* 2001). Soft sensors can be capable of sensor fusion: synergistically combining multiple measurements with algorithms and models to provide the operator with deeper insights into the operating state of the process. Thus, soft sensors can range from relatively simple regression models to complex machine learning models potentially consisting of multiple submodels or even real-time simulations akin to a digital twin (Galan *et al,* 2021).

With the rise of the industrial internet of things and edge computing or smart sensor capabilities, physical sensors and virtual sensors can be combined using programmable microcontrollers

embedded into field devices, although soft sensor computation is more commonly performed on the DCS or a dedicated server. Performing some of the computation work locally can reduce latency and communication bandwidth requirements. Soft sensors have been used extensively, for example, in the chemical process industries (Kadlec, Gabrys and Strandt, 2009; Fortuna, Graziani and Rizzo, 2006), bioprocessing (Brunner *et al,* 2021), and minerals processing (Sbarbaro and del Villar, 2010; Hodouin *et al,* 2001) for a range of purposes. These include:

- Increasing the estimation frequency or reducing cost for parameters that can otherwise only be measured offline, which can then be used for process control.
- In parallel with hardware sensors for fault detection and to reconstruct sensor output in case of a fault (as a backup of the physical sensor).
- Monitoring and diagnosing process performance to detect process state and deviation from normal operation.
- Model-predictive process control.

Soft sensors may be primarily data-driven (black box) or model-driven (white-box), or a hybrid (grey box) (Kadlec, Gabrys and Strandt, 2009). These modelling approaches have pros and cons. The data-driven approach is based on a statistical analysis of historical performance specific to the process being modelled. This paradigm has become increasingly popular and is considered easier to implement as the degree of process knowledge required is much less. Various machine learning tools are employed, including deep learning, regression modelling (support vector regression, ARMAX, stepwise, principal component), artificial neural networks, fuzzy logic, case-based reasoning and clustering.

Model-driven solutions, on the other hand, incorporate process knowledge, for example, in the form of traditional engineering models. These can be more robust but are generally more costly to develop. An important advantage of the model-driven approach is the ability to embed existing knowledge of the process within the model. The complexity of real processes can be a barrier to model-based soft-sensors working reliably in practice, however. The industrial application of process models as soft sensors has long been an important focus of researchers. In fact, one of the earliest models developed at the Julius Krutchnitt Mineral Research Centre (JKMRC) by Rao (1966) was a site-specific soft sensor for hydrocyclone control. Since then, several soft sensor types have been reported for estimating hydrocyclone overflow size (eg P80 or minus 200#) (Casali *et al,* 1998b; Zhou, Lu and Chai, 2014; Karimi *et al,* 2010; Dai *et al,* 2016) and overflow solids concentration (Casali *et al,* 1998a).

Other examples of soft sensors in minerals processing include a dynamic weightometer soft-sensor for both fault detection and estimating conveyor weight from power draw and other measurements (Pan *et al,* 2003), estimation of ball mill overload (Forbes *et al,* 2021), monitoring of SAG mill filling (Gonzalez *et al,* 2008), and fault detection in hydrocyclones (Bazin *et al,* 2009). The reader is referred to Hodouin (2011) for a more comprehensive list of applications.

The soft sensor models in this paper adopt the model-based paradigm, and therefore the case for model-based soft sensors based on fundamentals and process knowledge is set out. Three soft sensor models are discussed as examples: a soft sensor for estimating the total and ball filling in SAG mills, a soft sensor for tracking ore flow in a coarse-ore stockpile, and a soft sensor for modelling the ball mill cyclones. Each of these soft-sensor models are designed to operate in real time to present additional information to the process control operator and production engineers. The advantages of the model-driven approach in minerals processing applications are discussed.

MILL FILLING INFERENCE TOOL

One of the most important factors affecting SAG mill performance is the filling level of the mill contents. Typically, mill control uses the mill weight (using a load cell) or the bearing pressure measurement (a proxy for mill weight) to maintain the desired filling. However, a complicating aspect for control is that the weight of the mill changes over the life of the mill liners due to wear. Furthermore, the mill contains both rock and steel balls as grinding media, and it is important to estimate the proportions of each.

The steel or composite rubber/steel liners in SAG mills are designed to lift the contents as the mill rotates as well as to protect the structural integrity of the mill. Liners are replaced every several months and, in many cases, on differing schedules due to wear rates varying in different parts of the mill. The 40' SAG mill at Cadia, for example, lost over 300 tons over the course of the 5-month liner life (Powell *et al,* 2012) relative to a typical load weight of around 750 tons. Hence the weight recorded by the load cells needs to be corrected for this change in mill weight. Given that laser scans are routinely performed for condition monitoring purposes at many sites, it is possible to use this data to create wear models, which can then be applied to automate the adjustment of the mill weight control set point.

A soft sensor developed by the authors combines multiple sensors and mathematical models to aid SAG and ball mill control. The system has been tested and is successfully operating at approximately 10 mine sites worldwide. The model, shown in Figure 1, incorporates:

- An estimate of the load mass, corrected for the change in liner weight, updated daily using a model of liner wear which is calibrated to historical data. Whether load cell or bearing pressure is used to estimate the mill weight, data are calibrated to measured filling levels obtained using crash-stop measurements.
- A version of Morrell's (1996) power model to back-calculate both the ball and total filling. Both power draw and load mass are required to estimate filling because a given load weight can be made of different combinations of ball and rock filling.
- Modelling of historical liner wear data to describe the shell lifter height and face angle, which is used with Powell's (1991) trajectory calculation to estimate the point of impact for the measured mill speed. This allows the mill speed to be controlled throughout the liner life in a way that avoids damaging shell impacts.
- A model of grinding media wear that provides an initial estimate of the ball filling. This is linked to the ball addition, whether added continuously or in batches.

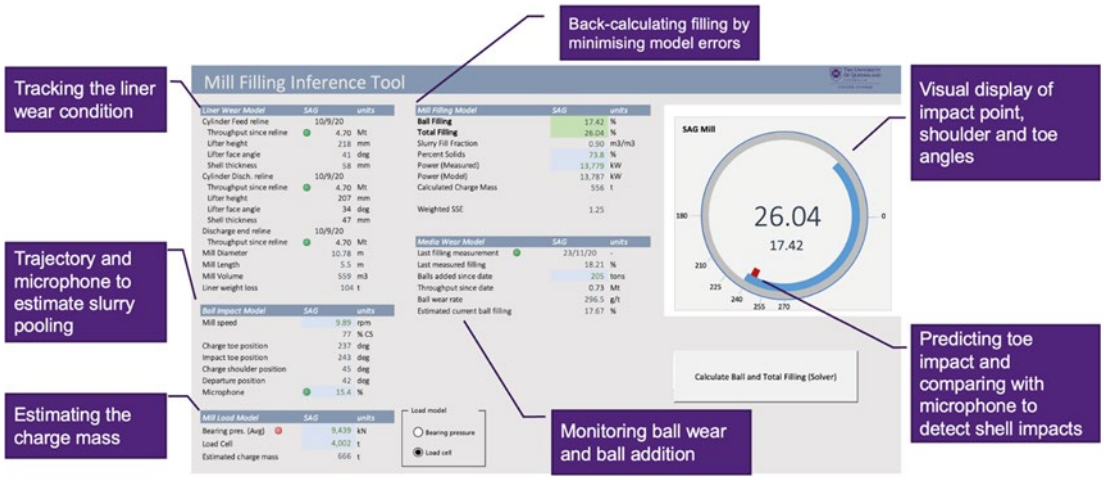

FIG 1 – A typical interface for the MillFIT SAG mill load analysis tool.

The objective of the sensor is to provide useful process information to the process control operator. Initially, this was via an Excel interface reading data from the plant historian system. More recent installations are being embedded directly in the DCS as the Excel-based solution is limited by a one or two minutes time lag before data appears in the historian system. The information provided by the soft sensor has several benefits for the operation and management of the SAG mill. The system provides an intuitive display of mill total and ball filling, making it easier to control the mill and prevent over or under-loading the mill. Likewise, the visual indicator of charge trajectory is useful for maintaining the optimal safe mill speed. Frequency of grind-outs can be reduced by estimating the ball load and tracking ball wear.

STOCKPILE SOFT SENSOR

Most milling circuits are fed from large coarse ore stockpiles that form a buffer between the mine and the plant. These piles typically contain several hours or perhaps up to a few days' worth of primary-crushed ore, which is drawn down to feed one or more SAG mills. The ore feeding the pile can vary in size and grade, and one of the functions of the stockpile is to blend the ore to reduce some of these variations. However, countering the blending function, granular materials with a broad particle size range can segregate by size within the pile resulting in product size variability. Various mechanisms contribute to segregation, although a dominant process is surface percolation which causes fines to settle between the gaps of larger particles while the particles are in motion.

Because stockpiles contain varying amounts of ore in the pile during operation, accurately quantifying storage volume is important for managing overall mine production. If the mine or primary crusher experience production delays, the mill can keep operating until the pile is emptied. Similarly, if the plant experiences downtime, the mine can continue production for some time, and the stockpile will continue to fill. Stockpile storage is measured using level sensors or photogrammetry. A soft sensor capable of estimating stockpile level was reported by Pan (2015) as a backup for existing ultrasonic or radar level sensors.

A mathematical model of the coarse ore stockpile has been developed at the JKMRC based on the continuous cellular automata approach. Details of the model are described elsewhere (Ye, 2022). The model (Figure 2) discretises the pile into a relatively coarse 3D grid of cells where the cells are in the order of 9 m^3 in size (cells are, however, permitted fractional filling), and therefore each cell represents many particles. This is necessary because particle-based methods such as DEM simulation would be too slow to permit real-time simulation with available computers.

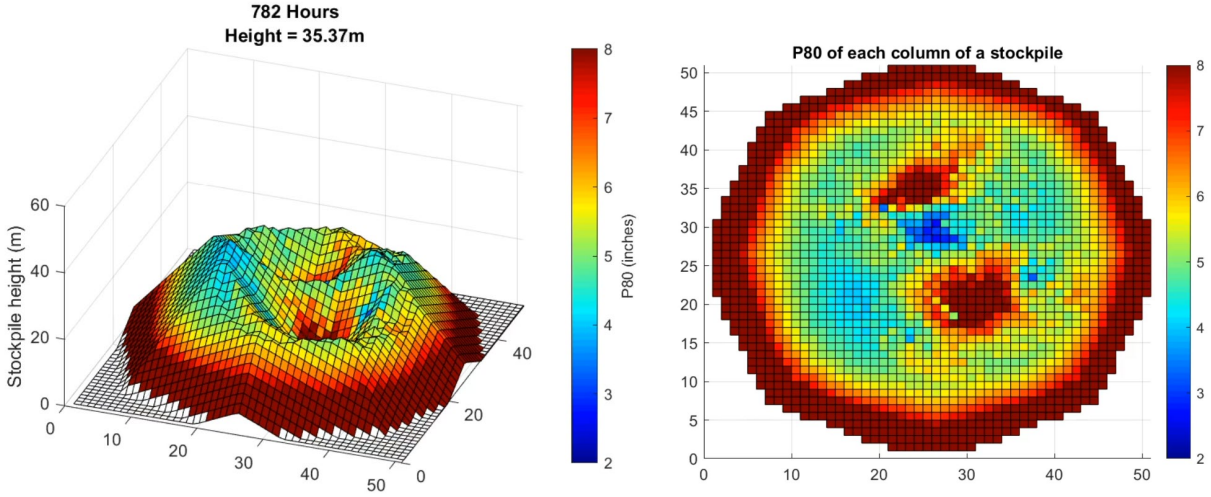

FIG 2 – Simulated coarse-ore stockpile showing significant size segregation of coarse particles to the edges of the pile (top view on right). Ore is extracted from up to eight drawpoints onto two product conveyors.

Each simulation timestep consists of four discrete processes:

1. New ore can be added to the grid at a position or positions corresponding to where a conveyor would throw the feed. This can be calculated using a conveyor trajectory model. The trajectory segregation mechanism can also be simulated in this step, separating the feed into a coarser portion to land on the pile slightly further from the conveyor position than the finer portion of the feed. Instrumentation from belt weighers, conveyor speed sensors and particle size cameras estimating the feed size can be used as soft sensor inputs to describe the properties of the ore being added to the pile.
2. Ore at the base of the pile can be removed at positions corresponding to the location of apron feeders. Multiple drawpoints can be assigned feeding one or more product conveyors. During the simulation, these feeders can start and stop or vary in feed rate. Data from the product conveyor belt weighers and, with the flow being characteirsed by the feeder speed and product.

3. Voids created at the base of the pile can propagate to the surface of the pile, allowing ore in the pile to migrate towards the drawpoints. The voids propagate vertically and laterally, eventually forming an inverted cone of flow towards the feeders (see Figure 2 near position (30,20,0)).
4. Material flows at the surface of the pile from higher columns to the lower neighbouring columns where the local slope exceeds the ore's angle of repose. The surface profile is continually perturbed by the feeding of new ore and the movement of the particles towards the discharge, causing new flow events. Size segregation takes place during flow events. This is modelled by dividing the volume of material located at the higher column into a coarser portion that flows to the lower column and a finer portion that remains at the higher column.

The soft sensor model incorporates many of the important mechanisms and behaviours observed in a coarse ore stockpile, albeit a simplification of the physics of granular process, which are still incompletely understood. The soft sensor model can report useful information about the operation of the pile in real time, including (Ye, Yahyaei and Hilden, 2021):

- Approximate surface profile and height of the stockpile that can be compared with measurements from photogrammetry and height sensors.
- Live volume of the pile that can be used for estimating remaining capacity for use in production planning, ore reconciliation and metal accounting.
- Particle size, grade and volume above each feeder that can be used for controlling the apron feeder speeds to control the feed size to the SAG mills.

CYCLONE SOFT SENSOR

Hydrocyclone soft sensors have been reported by numerous authors making use of existing empirical or semi-mechanistic hydrocyclone models designed for steady-state simulation (eg, Plitt, 1976 or Nageswararao, Wiseman and Napier-Munn, 2004), as noted earlier. Although in principle, empirical models can be used in soft sensor applications, naïve implementations of empirical hydrocyclone models in a real-time modelling application without also using a data-driven approach are typically not successful. For steady-state use, these empirical models contain parameters that have to be calibrated to experimental data collected during plant surveys. However, these parameters cannot be assumed to be constant for all operating conditions. Hydrocyclone performance is strongly affected by the feed particle size distribution, solids concentration and flow rate which are difficult to measure accurately in real time. Moreover, process dynamics also have to be considered.

Key process control variables that should be estimated by soft sensors are particle size distributions (especially the overflow P80) and solids concentrations. Plants typically have instrumentation to measure the cyclone feed flow rate and solids concentration, however these measures are rare for the cyclone underflow or overflow streams. Many plants have introduced particle size sensors on the overflow stream (for example, Metso Outotec PSI or Cidra PST), however these are not ubiquitous. A soft-sensor solution to measure these missing information would be an appropriate alternative. Additionally, it can be useful to develop fault detection algorithms or backup soft sensors for the physical instrumentation if they exist (Sepulveda *et al,* 2019).

A new hybrid hydrocyclone soft sensor (Figure 3) is under development at the JKMRC to model important operating parameters around the ball milling circuit. The developed system estimates the overflow P80, overflow solids concentration and circulating load.

Important features of the model are that it will:

- Estimate the cut size and flow rate for each cyclone in the cluster.
- Track the wear of key cyclone wear components, principally the spigot diameter and operating hours for each cyclone, as a means of automatically correcting the model for wear over time.
- Simulate hydrocyclone performance in the event of opening or closing one of the cyclones in the cluster to help with timing these control decisions.

- Warn of potential ball mill overloading when slurry accumulation in the ball mill circuit is detected.
- Estimate the operating work index and size-specific energy for detecting changes in ore properties.

FIG 3 – Dashboard of the JKMRC hydrocyclone performance soft sensor prototype. Online inference (yellow cells) of the feed properties, as well as the water and solids split, are provided using existing instrumentation (green cells).

DISCUSSION

As shown in the examples described in this paper, there are numerous challenges to developing soft sensors in minerals processing applications. However, the use of model-based or hybrid models can have advantages over pure data-driven or machine-learning models in soft-sensor applications.

Data quality

Data from sensors in minerals processing tend to be noisier than in many other industrial processes, sensors can be unreliable, missing values are common, and instrumentation faults can be frequent. Typically, subtle errors can take longer to detect compared with those that are grossly inaccurate (Pothina and Ganguli, 2020). However, soft sensors usually depend on having accurate data inputs. It is often necessary to apply signal conditioning (filters) and data reconciliation algorithms to validate the data before applying the models, whether they are data- or model-driven. Performing this processing work can require considerable manual effort and process knowledge to set-up.

The soft sensors described in this paper have been developed using offline data to fully develop the data preprocessing tools, and then transitioned to an online environment. Many of the data quality issues for a given process are identified during the offline processing stage.

Effect of Wear

An important factor affecting the performance of processes in minerals processing can be the wear of components over time. The aggressive wear environment due to handling large volumes of abrasive materials cause a progressive change in important equipment dimensions. Fortunately, the wear of many components follows a relatively predictable trend, and historical condition monitoring data can often be used to develop wear models. For example, the crusher gap can change appreciably on an hourly basis and typically needs daily adjustment. SAG mill liner and grate aperture wear is slower, with changes in performance occurring over weeks (Toor *et al*, 2013), causing grinding rates to change over the course of the liner life of several months. Cyclones, screen panels and pumps are other examples of components in a milling circuit that wear over time, affecting plant performance and efficiency.

Whether a soft sensor is data or model-driven, it should incorporate the effect of wear if it causes performance to change systematically over time. An advantage of the model-driven approach is that the effect of wear can be modelled separately and explicitly from the rest of the model. For example,

a wear model that tracks the change in apex diameter over the cyclone component life can be replaced with a different wear model if a component is changed, such as replacing rubber apex components with ceramic ones. An entirely new model may need to be developed in this scenario for a data-driven model.

Process knowledge

Data-driven soft sensors may sometimes be favoured because they do not rely on expert process knowledge for their development, however, in many cases, considerable process understanding is readily available. Existing mathematical models developed for simulating unit operations in minerals processing often have limitations including typically being designed to be used with process survey data rather than online data and ignore process dynamics. Many of the published steady-state models have inputs that require physical sampling, such as ore hardness, solids concentration and particle size distribution, which are usually difficult to measure in real time. There remains a lack of mechanistic or phenomenological models that are suited to use in soft sensors, and considerable research effort can be required for their development.

However, once developed, an advantage mechanistic models is that they can provide a physical interpretation that can help operators to make sense of the process and therefore lead to better process decisions. They can also be easily adapted to similar processes. For example, the mill filling model can be applied to any SAG mill design or the stockpile model to any coarse-ore stockpile without changing the model itself. Hence while process knowledge is indispensable for developing the model, applying it to other situations is relatively straightforward and no more difficult than for the data-driven approach.

Dynamics

Many of the simulation models for process equipment are based on steady-state process models. Although models need the ability to deal with dynamics, the transient effects occur over different time scales in different equipment. For example, hydrocyclones have a residence time in seconds, and therefore dynamic behaviour can be ignored for most purposes (Rajamani and Herbst, 1991). However, residence time in mills and stockpiles are typically tens of minutes and tens of hours, respectively, and therefore need to be considered. Both black- and white-box models need to incorporate the dynamic aspect into their architecture. White-box models do this by including the first-principle mass or energy conservation equations in form of ordinary differential equations that govern the underpinning processes in the equipment of interest. On the other hand, black-box models can include these dynamics by incorporating past values of the input variables into the regressions (Casali *et al,* 1998b; Zhou, Lu and Chai, 2014).

Process insights

Process plants are often described as data rich but information poor. Process control operators typically watch several monitors displaying operating status of hundreds of field equipment, numerous operating trends, alarms and more. A high level of complexity makes it difficult for control room operators to mentally analyse data and take the right corrective decisions (Li *et al,* 2011). Therefore, soft sensors should not be seen as simply providing more data in an already complex environment, but an opportunity to reduce the level of complexity and cognitive workload on process control operators. To that end, soft-sensors should be designed to synthesise data and present it in an intuitive, easy-to-understand form that helps the operator interpret the process state and to have a high degree of trust in the control system.

CONCLUSIONS

Wei and Craig (2009) conducted a series of interviews and surveys about automation in grinding circuits, and one of the main results that can be highlighted is the ‘instrumentation wish-list’ that the respondents from the industry specified. Particle size distribution, mill volumetric filling, cyclone overflow/underflow density and size distribution are within the main answers. In this article, three soft sensors that aim to fulfil this wish list are presented. Particle size distribution out of stockpile feeders can be inferred using a 3D white-box ‘digital twin’ of the stockpile that can predict size segregation. Mill volumetric filling (balls, rock and slurry) can be inferred using the well-established JKMRC MillFIT

which uses a semi-mechanistic power model to back-calculate these process unknowns. Finally, a prototype of a soft sensor for hydrocyclones is proposed to allow for online estimation of key process variables like circulating load, water split and product size to flotation.

All the above soft sensors are based on the white-box approach and rely mostly on well-understood process models. This approach, in contrast to black-box machine learning models, enables confidence in predictions and the behaviour of the sensor at the industrial scale, where signals can be faulty, noisy and inconsistent at times.

Further work is required to validate these sensors and to, in time, connect them directly into the plant's control system instead of being used as decision support tools for operators. All this work aims to bring more automation and autonomy to mineral processing plants, which tend to fall short in this aspect compared to other industries or even the operation of some mines—especially underground, where fully autonomous operations are becoming more common.

ABSTRACT

Classification devices provide a link between comminution and flotation. Basically, it determines which particles are diverted back for additional grinding and which ones pass to downstream flotation. Therefore, the classifiers play an important role in the performance of a mineral processing circuit.

Hydrocyclones are the most common classifiers used in wet grinding, despite being associated with poor classification efficiency. Hydrocyclones are widely used due to advantages related to low maintenance as well as reduced capital and operating cost. Other classifiers, such as fine screens, have much better classification efficiency compared to hydrocyclones. The major challenge of using screens in an operation, however, is their large footprint and increased maintenance requirements relative to hydrocyclones.

Some researchers have demonstrated that switching from hydrocyclones to screens, as the classifier device in a ball milling circuit, resulted in a 20 per cent increase in plant throughput and significant improvements in coarse particle recovery, resulting in a 6 per cent increase in overall flotation recovery. However, it is known that these benefits of improved classification are very much ore specific, ie depending on the ore response. Therefore, there is a need to estimate the benefits of improved classification in pilot scale testing before the plant could consider the potential classifier upgrade.

This paper presents the results of two pilot-scale grinding tests where the ore sample was processed using different classifiers: a traditional hydrocyclone and hybrid classification involving the use of a semi-inverted hydrocyclone followed by a screen. The size specific energy and circulating load were used to compare the performance of the grinding circuit. The grinding product was subject to mineral liberation analysis and the impact of classification efficiency on the mineral liberation is discussed in the paper.

INTRODUCTION

Mining companies require innovations that lead to new, better, and more efficient processes to achieve productivity improvements and more sustainable development. An area of interest to the mining industry is the ability to improve classification.

In wet grinding circuits, hydrocyclones became the dominant classifier in the 1950s, and despite its relatively poor process performance, it is often described as the workhorse of the mining industry and is used extensively for size separation (Dündar *et al,* 2014).

The importance of classification in a closed-circuit grinding circuit has been reported by many researchers (Hukki, 1968, 1979; McIvor, 1985, 2009; Dorr, 1929; Schlepp and Turner, 1990). Data from plant trials, where hydrocyclones were replaced by screens, indicate that lower bypass of fines and sharper separation can improve breakage rates and throughput (Dündar *et al,* 2014).

Frausto *et al* (2017, 2021) highlighted the potential benefits associated with improved classification. That work compared hydrocyclones and Derrick multi-deck screens at the Mexican mine Minera Saucito, where they could switch between cyclones and screens within their secondary ball milling stage. It was shown that the improved classification efficiency of screens resulted in a 20 per cent increase in throughput, and significant improvements in coarse particle flotation, resulting in a 6 per cent increase in overall lead flotation recovery. In this case, the improved classification was achieved by sharper separation, reduced bypass of fines back to the grinding circuit, and because the particle density does not influence how the screens classify material, which is not the case with hydrocyclones. Based on these findings, it can be concluded that the benefit of improved classification will also depend on the ore material that is being processed.

Currently, fine screens require massive floor space and are currently limited in application to low-capacity plants of a few hundred t/h. At high throughputs, screens are less efficient and attract high capital and running costs. Despite the reported benefits of improved classification of screens, not many plants have replaced hydrocyclones. This is because hydrocyclones have a relatively simple design (no moving parts), are robust and have a relatively small footprint for very high capacities compared to the screens.

Hybrid classification provides a potential solution, combining the benefits of both hydrocyclones and screens. A hybrid classification circuit consists of a hydrocyclone coupled with a screen that is used to scalp the coarse particles contained in the hydrocyclone overflow. The purpose of such a hybrid system is to take advantage of the high throughput attribute of the hydrocyclone in the first classification stage and the sharp separation characteristic of the screen in the second stage. A hybrid system addresses the limitations of these two classifiers. The poor classification performance of the hydrocyclone can be addressed by placing the screen in series with the cyclone. The tonnage to the screens is reduced because it is only fed the cyclone overflow and not the entire classification feed stream.

The hybrid classification strategy should ensure that less of the coarse low density particles report to the overflow, resulting in more of the particles fed to flotation being in the recoverable size fractions. The expected result is a higher recovery. Alternatively, the milling circuit grind could be coarsened achieving the same recovery level, and the circuit throughput increased.

The objective of this study is to measure the benefits of hybrid classification in a small pilot scale test program. The advantage of this approach is that it allows an evaluation of the effects of improved classification for an ore without the need for an expensive plant trial.

EXPERIMENTAL METHOD

In order to evaluate and demonstrate the performance of a hybrid screen-cyclone configuration, two pilot scale tests were conducted. One using a cyclone (base case, Figure 1) and the second using a hybrid screen-cyclone configuration as the classifier (hybrid classification, Figure 2). The aim was to conduct these tests with similar mill grinding parameters, in terms of the circulating load of 250 per cent and a targeted product P_{80} of 75 µm. The Size Specific Energy (SSE) and the degree of mineral liberation were then used to compare and assess the benefits of the hybrid classification and hydrocyclone classifier. The Size Specific Energy represents the energy required to generate a unit mass of material below a certain size. The Size Specific Energy of generating 75 µm material ($SSE_{-75\ \mu m}$) is commonly used for comparing the energy efficiency of grinding circuits.

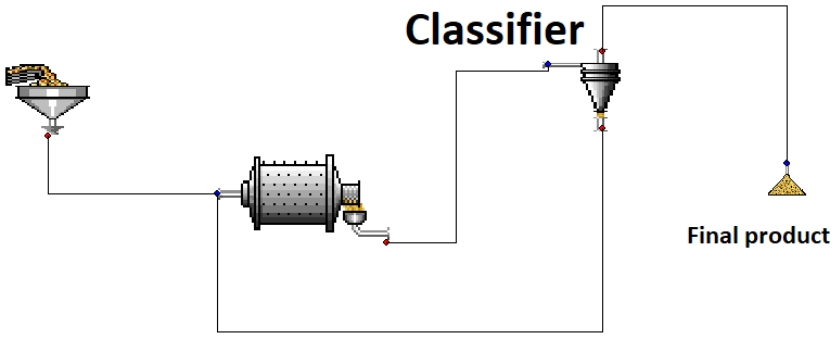

FIG 1 – The locked-cycle pilot test configuration which used a hydrocyclone as the classifier.

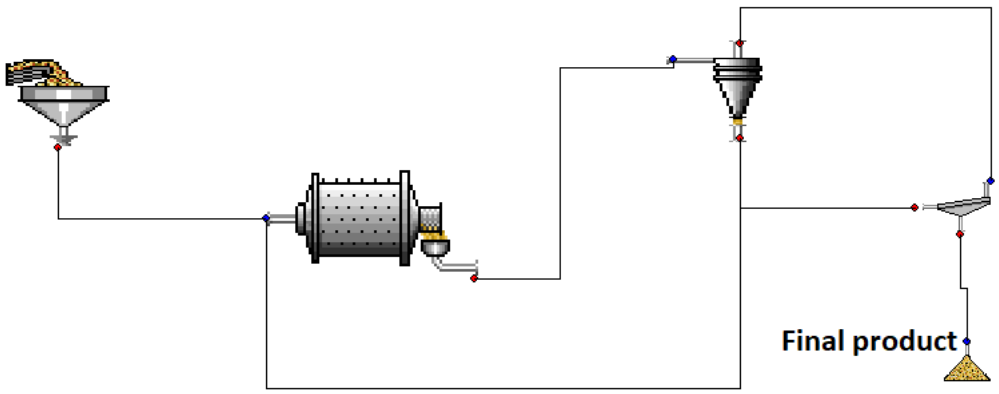

FIG 2 – The locked-cycle pilot test configuration which used a hydrocyclone and screen as the classifier.

Sample preparation

The sample used in this study was a base metal ore sample. The ore sample was crushed below 3 mm and representatively split into batches which was then used as mill feed material during testing. The specific density for the tested material was 2.8 t/m^3.

Initial simulations to determine the testing parameters

Prior to any testing, the pilot scale testing procedure was simulated using JKSimMet software to determine the required grind size for the mill discharge so the targeted circulating load could be achieved. In order to determine the grinding time required to achieve the required mill discharge P_{80}, an initial grinding test was conducted. The mill load was sampled at two grinding times, and these collected samples were sized. Using the measured P_{80}, F_{80}, the rock mass, the grinding time and the estimated mill power draw, the Operating Work Index (OWi) was calculated. The OWi values were then used to calculate the Specific Energy (SE) required to achieve the targeted grind size. Using the SE and the power draw, the required grinding time was calculated. The estimated grinding time was used in the locked-cycle pilot scale test as the initial grinding time.

The locked-cycle pilot scale testing procedure

Hydrocyclones cannot be easily scaled down and tested in the laboratory because the cut size is a strong function of the cyclone diameter. Small cyclones cut too fine. It is also difficult to operate a cyclone continuously at small scale because of the difficulties in matching the capacities of the mill and screen. But the performance of a hydrocyclone is dependent on the interaction with the grinding process. It is, therefore, very difficult to evaluate the improvements in performance (both in grinding and in flotation) of a change in hydrocyclone efficiency in the laboratory. However, JKMRC has a pilot scale 250 mm diameter hydrocyclone and a 1.8 m diameter mill that can be used in conjunction to study the grinding-classification interaction. However, it's not logistically possible to operate them together in a continuous mode. Instead, a locked-cycle methodology was adopted that allowed the de-coupling of the screen, cyclone and mill and thus allowed each equipment to be operated in batch mode.

The locked-cycle pilot testing procedure consisted of the following steps:

- Steel balls were added to the mill.
- 200 kg of ore was added to the mill.
- Sufficient water was then added to achieve a 70 per cent solids by weight.
- The mill was run for the calculated grinding time.
- The mill discharge was collected into drums with the aid of water to rinse the contents out of the mill.
- Steps 2–5 two were repeated until sufficient material was prepared for the hydrocyclone rig.
- The mill discharge was then placed into the cyclone sump.
- Classification was then used to split the mill discharge into coarse and fine material:
  - Using the cyclone as the classifier (base case as shown in Figure 1).
  - Using the cyclone-screen configuration as the classifier (hybrid classification as shown in Figure 2).
- The coarse material was dried and the dry mass measured.
- The grinding time for the next grinding stage (cycle) was then calculated.
- Fresh feed material was added to the coarse material to maintain the initial mass and then step 2 to 11 were repeated.
- The test was stopped after four or five locked-cycle tests had been completed.

The cyclone was operated in the semi-inverted position for the hybrid classification case as this allowed the achievement of a much coarser cut size.

The locked-cycle testing was performed for four cycles for the hybrid classification case and five times for the base case.

For the hybrid classification case, the cyclone overflow stream was collected and sized using Kason screens with a 100 µm screen aperture, Figure 2.

The final product (cyclone overflow stream for the base case and the screen undersize material for the hybrid classification) was sized using four sieve sizes and the material was sent for chemical assaying and MLA analysis. The feed and internal streams within the grinding circuits were sized using a root 2 series of screens.

RESULTS AND DISCUSSION

The locked-cycle testing

Although the locked-cycle laboratory test was conducted as a series of batch experiments, they were performed in such a way as to ‘simulate’ continuous operation. JKSimMet software was used to simulate this continuous mode operation to smooth and mass balance the experimental results. The grinding time and the mass of material were used to calculate the throughput for each stream. In order to match the throughputs of the feed and product streams, the mass of the product was used to calculate these throughputs. The results of mass balancing for both trials are presented in Figures 3 and 4. Note that the mass throughput and P_{80} for each stream is presented as a fraction of the feed values.

The experimental data was very similar to the mass balanced data, which indicates that the sampling and material sizing was conducted correctly.

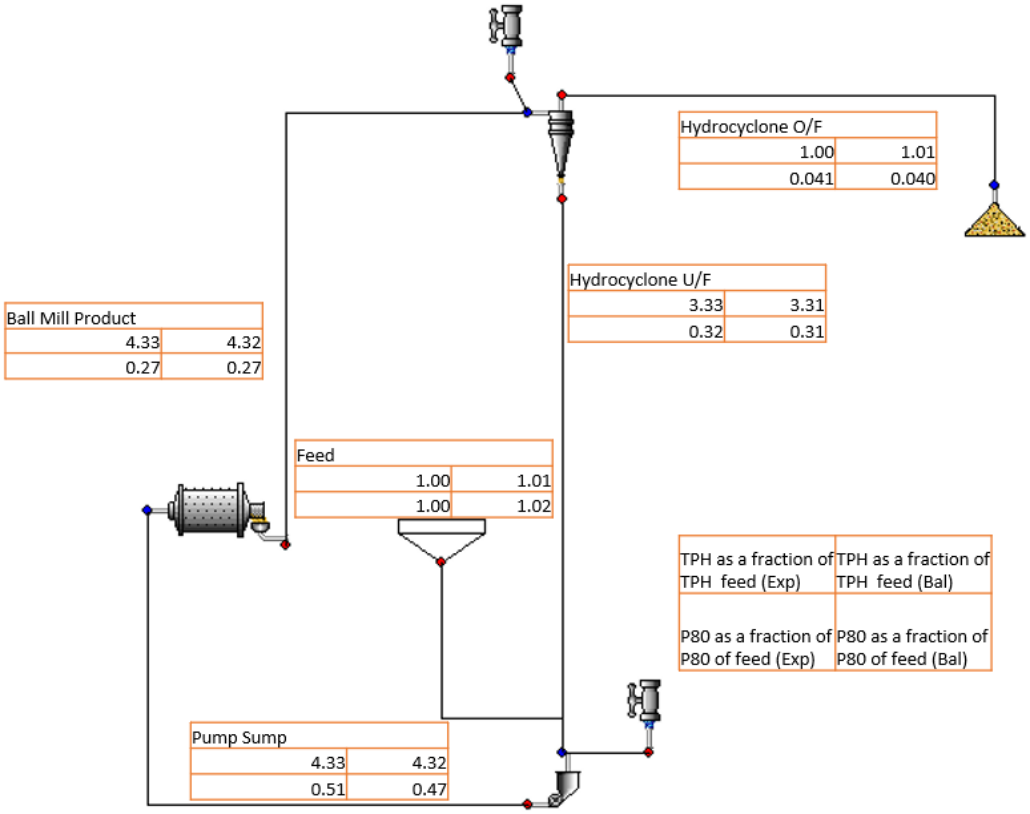

FIG 3 – Experimental and balanced data for the base case.

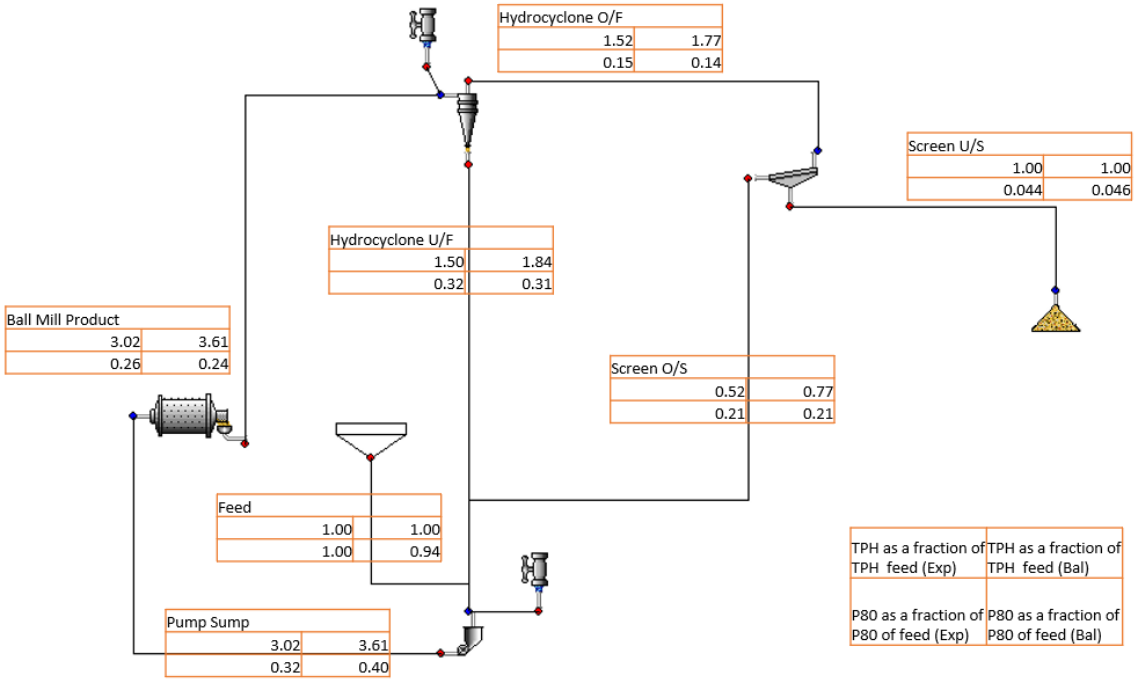

FIG 4 – Experimental and balanced data for the hybrid classification case.

The product size distributions achieved in the last cycle for the base case and the hybrid classification are presented in Figure 5. The measured P_{80} for the base case was lower by 4 µm than the P_{80} for the hybrid classification. Even though the P_{80} in both cases were similar, the product size distribution for the hybrid classification was sharper than for the base case and less fine material was generated.

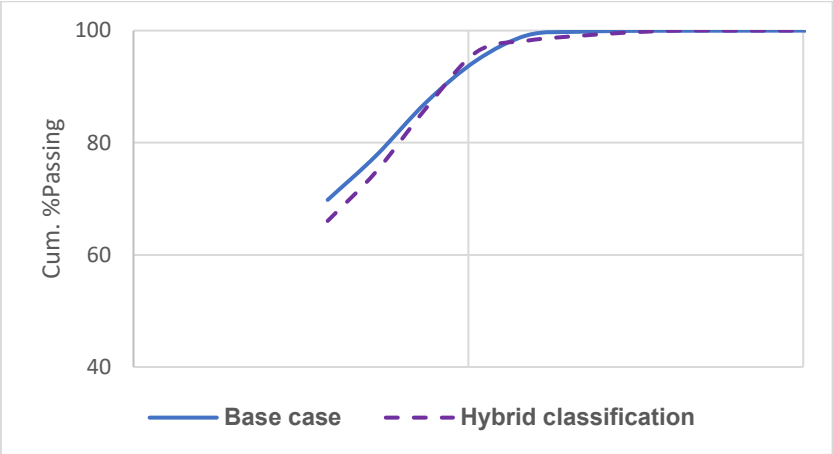

FIG 5 – The measured product size distribution for the base and hybrid classification cases.

The size-specific energy

The relative change in the $SSE_{-75\ \mu m}$ and circulating load for the hybrid classification case compared to the base case were calculated based on the measured data (batch mode) and the mass-balanced JKSimMet data (continuous mode); with the results presented in Table 1. These values, which are calculated based on the measured and balanced data, differ. However, in both cases, the hybrid classification produced a lower $SSE_{-75\ \mu m}$ (between 15–40 per cent) and a lower circulating load (21–39 per cent) compared to the base case. The results in Table 1 indicate that the hybrid classification pilot testing used up to 40 per cent less energy to generate material below 75 µm compared to the base case.

TABLE 1

The relative change of $SSE_{-75\ \mu m}$ and circulating load for the hybrid classification case compared to the base case calculated based on experimental data and JKSimMet mass balanced data.

Hybrid classification	Experiment	Balanced data
Δ $SSE_{-75\ \mu m}$ [%]	-40	-15
Δ Circulation Load [%]	-39	-21

The discrepancy between $SSE_{-75\ \mu m}$ values calculated based on the experimental and balanced data are due to the different amount of material in the feed and product during the batch mode experiment.

The size distribution of material sent back to the mill was found to be coarser and contain less fines in the hybrid classification case than in the base case (Figure 6). It can be concluded that hybrid classification reduces the misclassification of fine material, which is the reason why the circulating load is reduced compared to the base case.

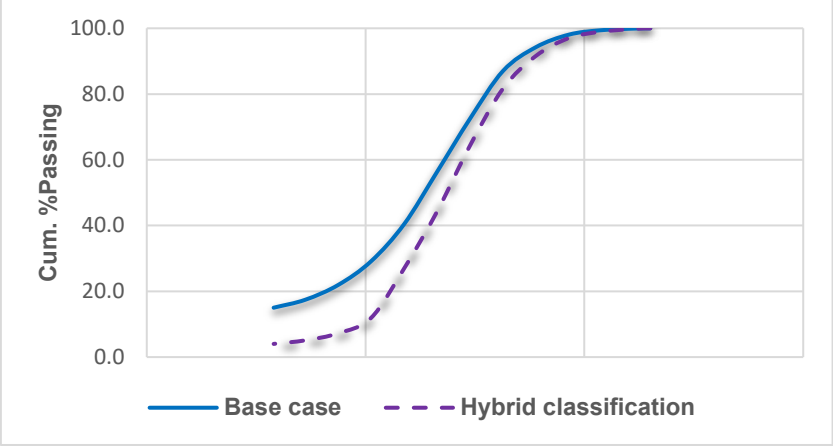

FIG 6 – The particle size distribution for the coarse stream (returned to the mill) for both trials.

MLA and assaying results

Differences in the circulating load and classification efficiency have been previously shown to modify or influence the resulting particle size distribution of the valuable minerals in the comminution product (or flotation feed) (Frausto *et al,* 2017).

Figure 7 shows the particle size distribution of the metal produced in the circuit product (ie flotation feed) by hybrid classification and the base (cyclone) case. The results indicate that hybrid classification produces a product with more metal in the coarser size fractions. This is even though the overall mass size distribution of the product from these two circuits is similar in terms of P_{80}, Figure 5.

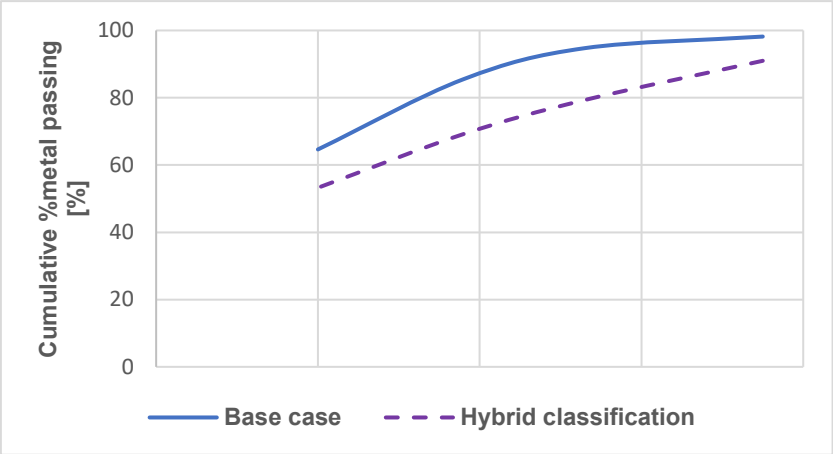

FIG 7 – The cumulative % passing of metal in the product of the cyclone classifier (base case) and the hybrid classification case.

The particle size distribution of the valuable mineral is much finer than the overall solids particle size distribution in the case of the cyclone, but that difference is much reduced in the hybrid classification scenario. The finer particle size of the valuable mineral, when classified using a hydrocyclone, is often observed in plant data. It is a consequence of the valuable mineral having a higher density. Therefore, particles containing the valuable mineral, especially those liberated, are heavier and preferentially report to the cyclone underflow. This increases their circulating load and a finer grind of the valuable mineral within the grinding circuit is the result.

However, for the hybrid classification case, the final stage of classification, which dictates whether a particle reports to downstream separation or is recycled for grinding, is a screen. Screens cut according to size only and therefore are not affected by particle density. Valuable minerals and gangue must achieve a particular size before they report to the screen undersize. Thus, their size distribution in the grinding circuit product is very similar. Any preferential grinding of a valuable mineral over gangue in the mill only affects the amount of each in the circulating load but does not affect the final product.

Another contributing effect may be the coarseness of the cut of the semi-inverted hydrocyclone in the hybrid circuit (in contrast to the hydrocyclone). Particles are less likely to be liberated in the coarser particle sizes, and therefore density differentials between particles will be reduced.

It is important to highlight that a change in preferential breakage caused by a classifier will not necessarily improve the flotation response (ie grade or recovery improvement), but it is likely to have an effect. This effect can be either negative or positive depending on the recovery by size relationship.

The MLA data were analysed to determine whether classification had a significant impact on the degree of liberation of minerals in the grinding circuit product.

Tables 2 and 3 show the mineral liberation distribution for different size classes in the grinding circuit product for the classification with cyclones and the hybrid classification case, respectively. Most of the metal is liberated for particles finer than the Size 4 class in both cases. However, what is very interesting is the improved liberation in the coarser particle sizes (Size 5) in the hybrid classification

scenario. Metal in the coarser sizes when classification conducted with cyclones (Table 2) exhibited a bimodal liberation distribution – it was either completely liberated or present in very poorly liberated classes. Poorly liberated mineral will be very difficult to recover in downstream flotation. However, the liberation of the coarser sizes in the hybrid classification scenario (Size 5 in Table 3) is much improved and isn't bimodal in nature.

TABLE 2

Valuable mineral liberation distribution per size class for the base case classification.

Base case	Very poorly liberated	Poorly liberated	Middlings	Highly liberated	Completely liberated
Size 5 (coarse particles)	30.55	12.78	6.02	2.45	48.2
Size 4	5.09	3.85	6.78	5.54	78.74
Size 3	1.26	2.12	2.61	6.95	87.07
Size 2	0.62	0.71	2.46	9.44	86.78
Size 1 (fines)	1.51	2.18	5.08	7.61	83.62

TABLE 3

Valuable mineral liberation distribution per size class for the hybrid classification.

Hybrid classification	Very poorly liberated	Poorly liberated	Middlings	Highly liberated	Completely liberated
Size 5 (coarse particles)	3.76	2.18	3.06	7.89	83.11
Size 4	2	2.35	5.11	7.47	83.06
Size 3	0.9	0.82	3.64	6.51	88.12
Size 2	0.45	0.64	1.82	13.67	83.43
Size 1 (fines)	1	2.2	2.58	7.87	86.34

Improved liberation when using screens in comparison to cyclones has been previously observed by Frausto Gonzalez (2020) in industrial scale trials. In this industrial work, the presented liberation distribution of the flotation feed was also bimodal in nature in the coarse size fractions when using cyclones whereas this did not occur when using screens. The density effect in cyclones does not only result in preferential deportment of valuable minerals to the underflow but also produces a bias in classification with respect to liberation. Valuable minerals in composite with gangue will be light and preferentially report to the overflow. Cyclones thus promote bypass of very poorly liberated minerals into the grinding circuit product, resulting in a bimodal liberation distribution. In the hybrid scenario, however, screening is the last stage of classification, and in this device, density does not play a role, and bypass of poorly liberated mineral to the grinding circuit product does not occur.

This improvement in liberation after grinding with hybrid classification will significantly positively impact downstream separation performance. Poorly liberated minerals are very difficult to float and, if recovered, bring a lot of gangue into the concentrate, reducing concentrate grade. Without the presence of poorly liberated classes in the feed, the grinding circuit product can be significantly coarsened whilst maintaining (or even improving) flotation recoveries.

The results of this study suggest that hybrid classification can produce the same benefits as observed with screening alone, as observed in the work of Frausto Gonzalez (2020). The hybrid classification has resulted in a significantly coarser metal size distribution (Figure 7), but the overall distribution of metal in the stream is largely in liberated classes (Table 3). Even though there is a significant amount of metal in the coarsest size fraction, it is largely liberated (Table 5). The degree

of liberation of the cyclone product is also high, but this is because most of the metal is located in finer sizes (Table 4).

TABLE 4

Valuable mineral liberation with respect to the entire sample for the cyclone base case.

Base case	Very poorly liberated	Poorly liberated	Middlings	Highly liberated	Completely liberated
Size 5 (coarse particles)	3.87	1.62	0.76	0.31	6.11
Size 4	0.45	0.34	0.60	0.49	6.98
Size 3	0.10	0.17	0.21	0.56	7.01
Size 2	0.07	0.08	0.29	1.13	10.38
Size 1 (fines)	0.88	1.27	2.97	4.45	48.89

TABLE 5

Valuable mineral liberation with respect to the entire sample for the hybrid classification.

Hybrid classification	Very poorly liberated	Poorly liberated	Middlings	Highly liberated	Completely liberated
Size 5 (coarse particles)	0.49	0.28	0.40	1.02	10.73
Size 4	0.26	0.30	0.66	0.96	10.72
Size 3	0.08	0.07	0.32	0.57	7.66
Size 2	0.05	0.07	0.21	1.56	9.55
Size 1 (fines)	0.54	1.19	1.39	4.25	46.66

Using the MLA data, it was possible to calculate the theoretical grade recovery curve achievable in the downstream separation process for the two grinding circuit scenarios (Figure 8). This is the grade and recovery achievable if the separation was perfect. In both classification cases, very high recoveries are achievable at a high-grade, and this is because most of the material has been ground to a size where it has been liberated. The hybrid classification scenario, though, is able to produce a marginally better grade versus recovery curve, even though the metal size distribution has a much coarser P_{80}. It is believed that much bigger differences will be observed between these two curves if a coarser grinding product had been produced.

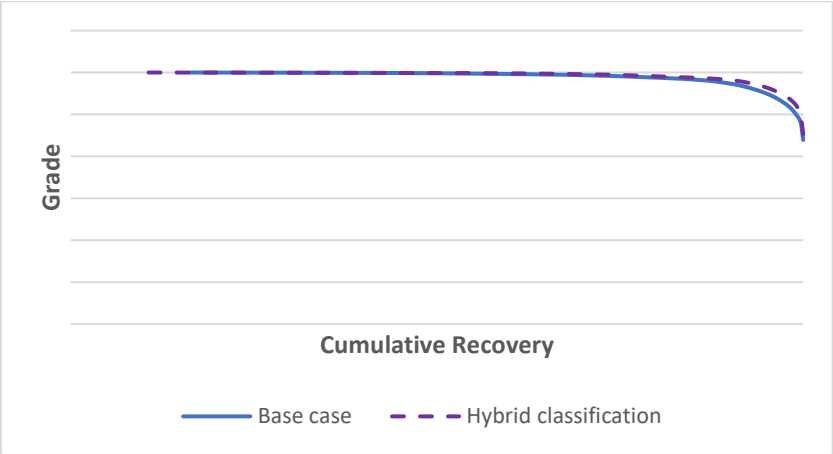

FIG 8 – Theoretical grade versus recovery curves calculated using the MLA data for the Cyclone and Hybrid Classification Regimes.

It is hypothesised that a coarser cyclone product would have resulted in much poorer liberation due to the presence of poorly liberated composites in the coarser sizes. This would translate into much larger differences in the theoretical grade versus recovery curves observed in this study. Unfortunately, this cannot be tested with the current size of the cyclone in the pilot equipment used in this study. Larger cyclones are required to achieve a coarser cut. However, running a larger cyclone would require a much large amount of sample and therefore would be logistically difficult to perform. To overcome these problems, the research team at the JKMRC is planning to develop a test involving the use of laboratory-scale mills tested in conjunction with laboratory screw classifiers and screens. A laboratory scale screw classifier can produce a density biased classification at coarser cut sizes than is possible with a small cyclone. The plan is to produce an experimental procedure that can be performed at a relatively small scale that can explore the difference in mineral and liberation of the flotation feed when operating with density biased classification, size alone based classification and hybrid classification. An ability to perform these types of laboratory experiments would enable mining operations to evaluate the likely effects of poor classification as a function of classifier cut size on the metal and liberation distributions of a grinding circuit product. The ability to do these types of evaluations is required for a mining operation to be able to justify a change in classification strategy.

CONCLUSIONS

In order to evaluate and demonstrate the performance of a hybrid screen-cyclone configuration, two locked-cycle pilot scale tests were conducted using the cyclone (base case) and the hybrid screen-cyclone configuration as a classifier. The experimental testing has produced the following findings:

- Even though the product P_{80} in both cases were similar, the product size distribution for the hybrid classification was sharper than for the base case and less fine material was generated.
- The hybrid classification pilot testing used between 15–40 per cent less energy to generate the -75 µm material compared to the base case.
- Hybrid classification reduces the misclassification of fine material, which is the reason why the circulating load is also reduced by 20–40 per cent compared to the base case.
- Differences in the circulating load and classification efficiency caused by the hybrid classification have modified the particle size and liberation distribution of the valuable minerals in the product (or flotation feed):
    - Hybrid classification produced a product with a coarser metal size distribution than when using hydrocyclones.
    - The change in classifier has had a significant impact on the degree of preferential breakage for the metal of interest.

- Because of improved coarser particle liberation, separability (measured using a theoretical grade versus recovery relationship) is not expected to deteriorate downstream when using hybrid classification, even though the valuable mineral is coarser.
- The cyclone produced a bimodal liberation distribution, and this was attributed to a bypass of poorly liberated mineral particles to the cyclone overflow. This bimodal liberation distribution was not observed when using hybrid classification.

As the benefits of improved classification are also ore dependent, there is a need for development of laboratory-scale continuous testing (for example, a small mill with a screw classifier and/or screen) that will enable measurement of these benefits over a wider range of conditions.

ACKNOWLEDGEMENT

The authors would like to acknowledge tremendous support during the pilot scale testing by students Marcelo Eduardo ávila Castillo, Zuo Meng Gan, Qi Wu and Yuxiang Chen.

ABSTRACT

Equipment wear is strongly related to the performance of grinding circuits. In particular, SAG mills are subjected to the wear of their shell liners and grates. Changes in lifter height and face angle impact mill performance, while classification at the mill discharge is also affected as grates wear out. Moreover, liner mass loss caused by wear affects how operators interpret readings of sensors such as load cells or bearings pressure. Automating and optimising grinding circuits under these constrain becomes challenging due to the nonlinear and dynamic nature of the system. The operation of SAG mill grinding circuits remains largely dependent on human intervention, which frequently results in inconsistencies in performance across shifts, reflecting the operator's personal preferences, experience, and other human factors. The influence of human factors can be reduced by careful training of operators as well as by automation using advanced supervisory control. The latter approaches could benefit from the development of dynamic process models that consider the effects of wear on the performance of equipment over time. This paper presents detailed industrial data showing the effects of wear on SAG mill performance. Additionally, a dynamic SAG mill model that accounts for these phenomena is proposed and demonstrated in a simulated environment. This model is shown to mimic the effect of wear on the performance of industrial scale mills and the operational constraints they are subject to, thus extending traditional SAG mill models. Incorporating wear into modelling and simulation platforms can improve the understanding of the effects that wear can have on the performance of key assets in comminution circuits and may allow the development of more robust model-based advanced process control strategies.

INTRODUCTION

Grinding circuits are energy inefficient, consuming 40 per cent of the energy in mineral processing operations (BCS, 2007). This scenario becomes even more challenging when paired with the expected surge in demand in the next decades for mineral resources (Watari, Nansai and Nakajima, 2020) and the increased complexity of ore bodies (Schodde, 2014). Therefore, the mineral processing industry needs to ensure that grinding circuits are operating at maximum efficiency, contributing in this way to sustainable development.

However, grinding circuits are dynamic systems that are complex to control and optimise. Their performance depends on factors that are changing over time, such as ore properties, delays in equipment responses, maintenance, and wear. Semi-Autogenous grinding mill, Ball mill, and Crusher (SABC) circuits are the most popular configuration of grinding circuits (Zhang, 2016), and the performance of SAG mills is importantly related to the performance of the ball mill circuit and the circuit as a whole.

Wear, in particular, changes the liner/lifter profile of SAG mills over time, as illustrated in Figure 1. These changes affect the charge movement inside the mill and, consequently, material breakage. Wear also changes grate aperture, influencing classification and discharge of material. Moreover, wear causes liners to lose mass continuously, influencing mill weight. The liner mass loss can be significant over time, as illustrated in Figure 2 for eight SAG mills at six different mine sites—mills can lose between 200–500 tons of weight over the liner life cycle. Inaccurate measurements of

charge mass can occur if liner mass loss is not considered when interpreting readings from load cells or bearing pressure.

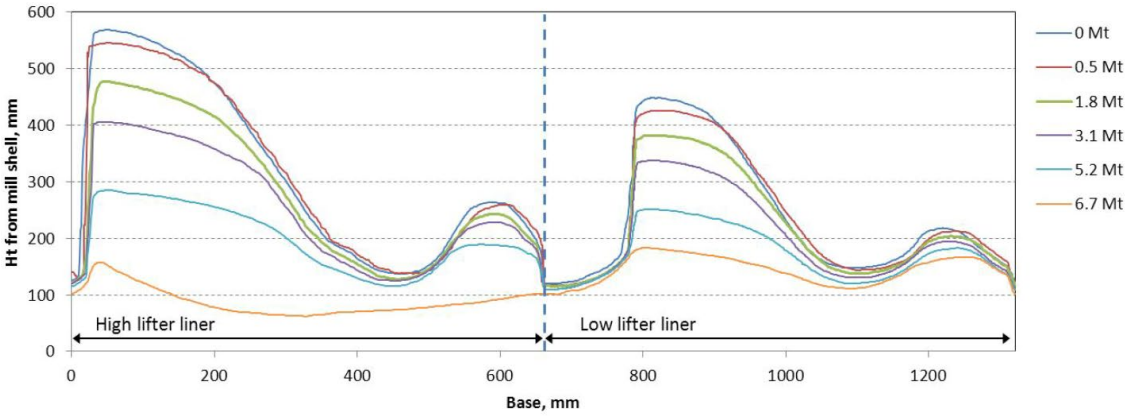

FIG 1 – Liner profile over cumulative tons (Bird, Powell and Hilden, 2011).

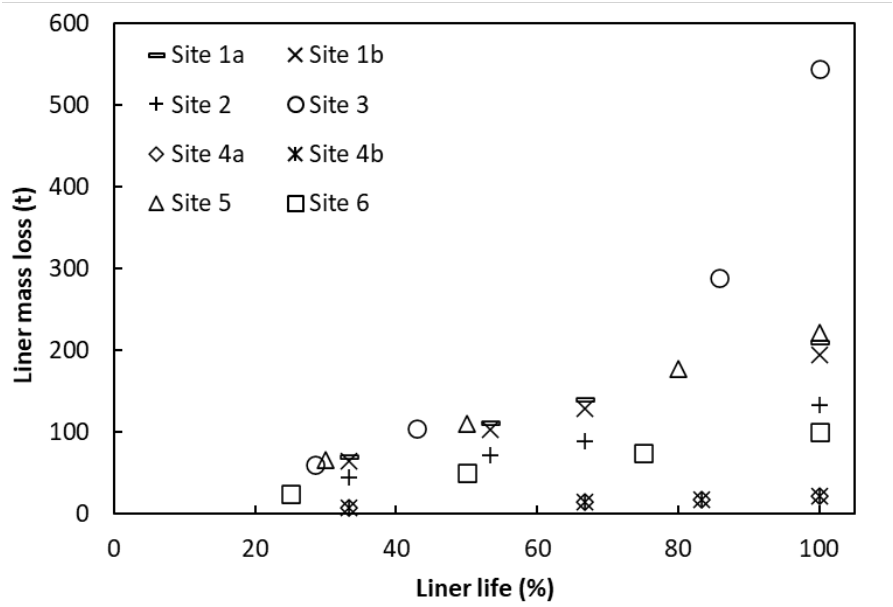

FIG 2 – Liner mass loss over liner life as a percentage of the design diameter. A liner life of 100 per cent corresponds to the moment just before the replacement of liners.

Moreover, the wear of the liner's profile also leads to an increase in the internal mill diameter, as illustrated in Figure 3, for the same mills as Figure 2. As an example, a 36-foot mill can increase its diameter by almost 200 mm over its liner life cycle. All these changes are part of the nonlinear environment of a SABC circuit. This nonlinearity makes automatic control and optimisation a challenging task, which results in regular human intervention in process control.

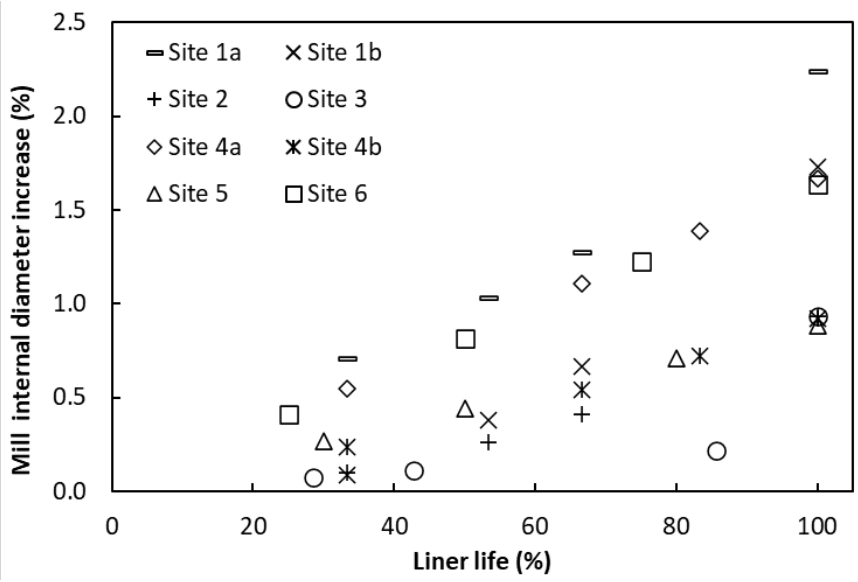

FIG 3 – SAG mills internal diameter increases at six mine sites over liner life. A liner life of 100 per cent corresponds to the moment just before the replacement of liners. Site 1 and Site 4 have two mills, labelled ‘a’ and ‘b’.

However, human decisions are subjected to levels of experience, personal preferences, and other factors that together create inconsistencies. Operator training and advanced supervisory control are options to reduce the effect of human factors on process control. These strategies can be enhanced through the development of dynamic models that can address the impact of wear on equipment performance over time. This article aims to contribute to the development of more accurate dynamic models for SAG mills with models that incorporate the changes described above.

MATERIALS AND METHODS

The investigation uses a SAG mill dynamic model available in a simulation platform that is being developed at JKMRC for design and control in mineral processing. The platform is built on MATLAB Simulink® and allows users to create simulations and process outcomes using a variety of applications. The flexibility of this platform enables the development and testing of dynamic models such as an expanded SAG mill model that includes wear.

A simple, single-stage, open-circuit SAG mill flow sheet was created in this simulation platform, consisting of just a feeder and a SAG mill so the effects of wear can be highlighted and isolated from other variables and equipment. Additional configuration and display blocks are added, as shown in Figure 4.

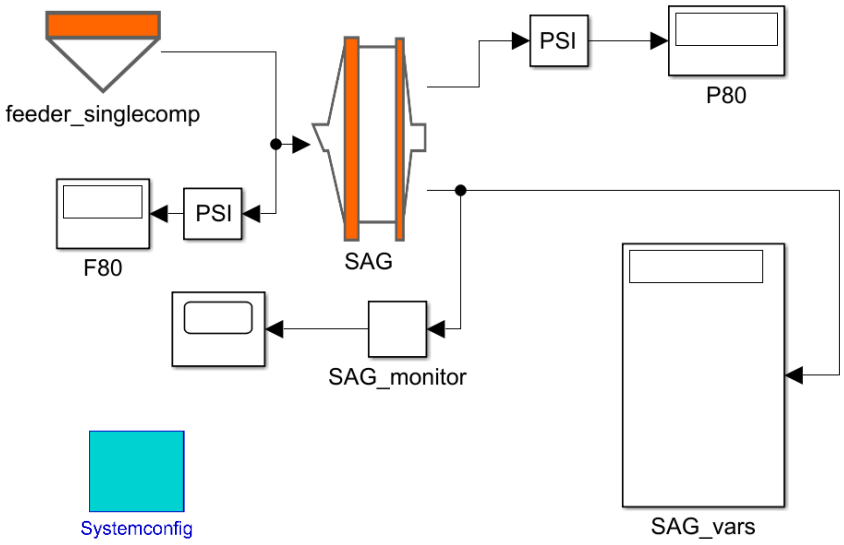

FIG 4 – Simple SAG mill flow sheet in JKMRC dynamic simulation platform.

The SAG mill dynamic model uses a population balance method based on Equation (1):

$$\frac{ds_i(t)}{dt} = f_i - p_i + \sum_{j=1}^{i} a_{ij} r_j s_i - (r_i s_i)$$**Error! Bookmark not defined.**(1)

$$p_i = d_i s_i$$

where:

$s_i(t)$	mass of material in size class *i* at time *t* in the mill
f_i	total flow rate of feed material in size class *i*
p_i	total flow rate of discharge in size class *i*
r_i	breakage rate of particles in size class *i*
a_{ij}	appearance function, which describes the fraction of material broken into size class *i* due to breakage of the size class *j*
d_i	discharge rate of size class *i*

The discharge, d_i, is the product of the transport to the grate and classification at the grate by the Equation (2):

$$d_i = D * c_i$$ (2**Error! Bookmark not defined.**)

where:

D	slurry total discharge rate
c_i	classification function value for size class *i*

The breakage rates model is based on the empirical function of Austin, Menacho and Pearcy (1987) in Equation (3):

$$K_i = \frac{aB\left(\frac{dp_i}{dp_1}\right)^{\alpha_B}}{1+\left(\frac{dp_i}{\mu_1}\right)^{\lambda_1}} + aS\left(\frac{dp_i}{dp_1}\right)^{\alpha S}$$ (3**Error! Bookmark not defined.**)

where:

dp_1	material top size
dp_i	representative *i*-ith size
$aB, \mu_1, \alpha_B, \lambda_1, aS, \alpha S$	model parameters to be fitted

Because operating conditions in the mill (speed, mill filling etc) affect material breakage, Ballantyne, Bonfils and Powell (2017) t_n-family appearance function, described in Equation (4) is used:

$$t_n = M\left[1 - e^{-fmat x^{\alpha}(E_{cs})}\right] \tag{4}$$

$$M = \left[\exp\left(-\frac{n}{437}\right) * \left(1 - \exp\left(-\frac{437^{0.13}}{n}\right)\right)\right]$$

$$fmat = \exp\left(-\frac{c}{\log(10.n)} - d\right)$$

where:

t_n	proportion of material passing through a screen with an aperture nth the geomean of the feed particles
M	saturation % passing (that is achieved at high energy impacts)
$fmat$	material dependent appearance function across the full range of size reduction
x	geomean of upper and lower sieve aperture to prepare the feed
α	Shape of the response of feed particle size and degree of breakage
E_{cs}	impact energy
n	relative progeny size
c and d	fitting parameters that ore-dependent

The main advantages of using Equation (4**Error! Bookmark not defined.**) are the direct calculation of the appearance function for any feed size and input energy and fewer fitting parameters. Impact energy is calculated using the potential energy of rocks and balls inside the mill shell. The drop height for its calculation uses the charge position inside of the mill in Equation (5):

$$Drop\ height = \left(\frac{\left(\frac{DM}{2} + CHSURA\right)}{2}\right) * (\sin(SHLDR) - \sin(TOE)) \tag{5}$$

where:

DM	mill diameter in metres
$CHSURA$	charge surface radius
$SHLDR$	charge shoulder angle
TOE	charge toe angle

The charge position characteristics are outputs of a power model based on Morrell (1993). The drop height is the input for the calculation of the potential energy of rocks and balls in the charge. The impact energy is then calculated by the sum of the potential energies of rocks and balls in each size class of the load. This allows the breakage model to respond to changes in the mill environment, including variations in mill diameter caused by wear.

The dynamic SAG mill model was adapted to account for the liner and grate wear, making the mill diameter, mill length, and grate aperture change over the cumulative tons processed. This affects the calculation of mill power, discharge classification function, appearance function, and population balance.

Moreover, the mill load cell reading was modified to account for the loss of mass due to wear in Equation (6). The liner mass loss is based on the decrease of the mill volume and assuming that liners are made of steel.

$$Load\ cell = charge\ mass + original\ mill\ mass - liner\ mass\ loss \tag{6}$$

The discharge calibration factor and breakage rates were adjusted to make the simulation generate reasonable mill outputs, although the model is not yet formally calibrated. Figure 5 shows the

adjusted breakage curve in the simulation, which resembles the typical shape of the curve for SAG mills.

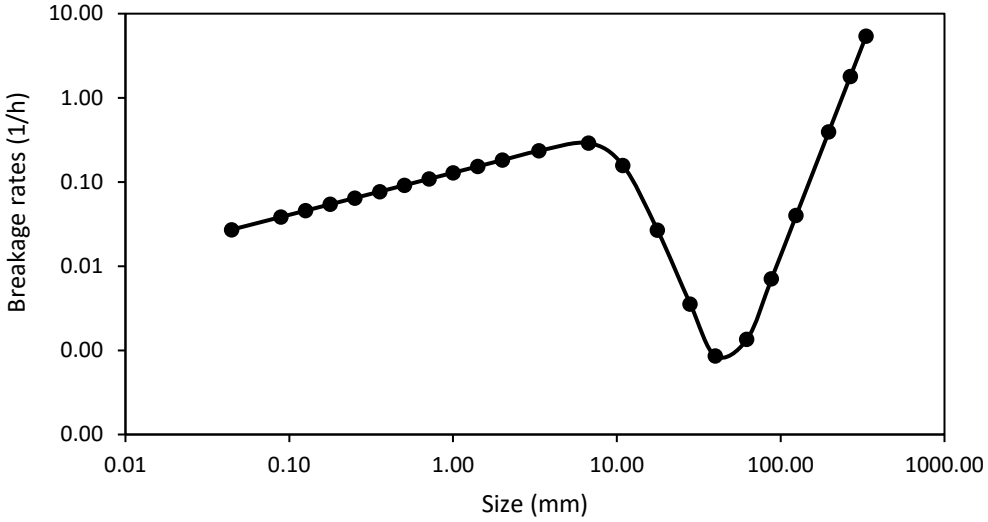

FIG 5 – Breakage rate curve of the SAG mill simulation.

Feed characteristics and mill operating parameters were kept constant in all simulation scenarios. It is worth noting that this is not how mills are operated in their normal liner life cycle, as discussed in the Introduction. In real plants, operators introduce changes in the operating parameters of the mills to compensate for liner wear or other circuit changes.

The simulations and results shown in the next Section are aimed to show the effect of wear, so they are run with wear being the only source of changes in mill performance. The simulations were stopped after the model reached a steady state. The effect of liner and grate wear on mill performance was investigated at different stages of liner life, from 0 per cent to 100 per cent. The 100 per cent liner life corresponds to the liner's state before relining. The SAG mill outputs analysed were power draw, load cell, total filling, void fill fraction, percentage of solids, and P80.

RESULTS AND DISCUSSION

Liner and grate wear models

The plant data from a mine in Chile was obtained to investigate the effect of liner and grate wear on the performance of a virtual mill. This data consisted of mill liner wear reports collected over four years. The grate and liner wear data are present in Figure 6, and the models are detailed in Table 1. The wear models for grate aperture, mill diameter, mill volume, and mill length are based on the percentage of liner life (%LL), assuming that 100 per cent liner life occurs when the mill is relined after processing 8 Mt of feed material. The adjusted R-squared values obtained after step-wise linear regression show that the models reasonably fit changes in grate aperture and mill dimensions over time. A similar approach can be conducted for any of the mine sites shown in Figures 1 and 2.

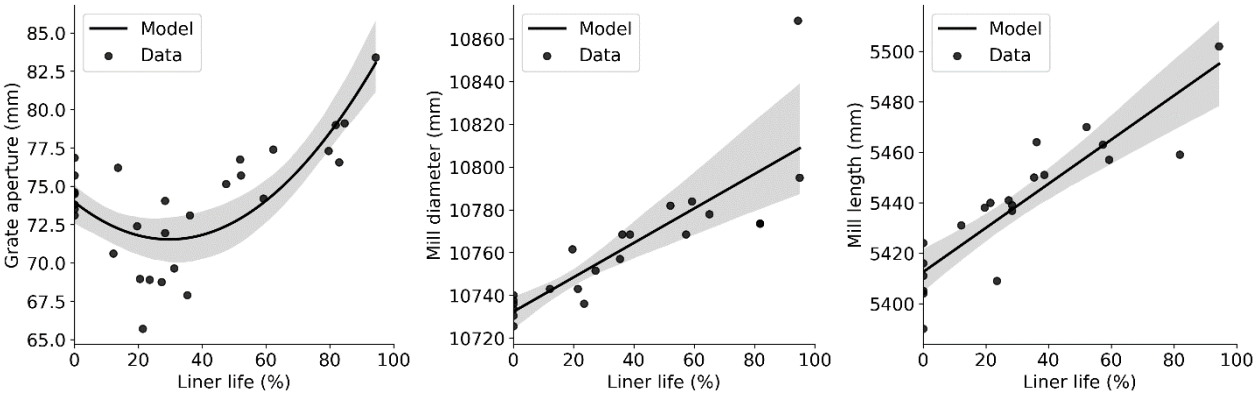

FIG 6 – Grate width, mill diameter, and mill length over the liner life. Grey areas show the 95 per cent confidence interval.

TABLE 1

Wear models for grate and mill dimensions.

Model	Equation	Adjusted R-squared
Grate aperture	$73.96 - 2.04 \times \mathrm{LL} + 0.43 \times \%\mathrm{LL}^2$	0.57
Mill diameter	$10732.43 + 9.98 \times \%\mathrm{LL}$	0.73
Mill length	$5412.51 + 10.93 \times \%\mathrm{LL}$	0.79
Mill volume	$528.02 + 2.84 \times \%\mathrm{LL}$	0.69

The behaviour of grate width over time can be associated with the grate design in Figure 7(a). The initial decrease in grate width is probably due to the charge wearing down the first part of the edges of the aperture, reducing it in Figure 7(b). Further wear of the grate consumes the second part of the edge in Figure 7(c), which start to increase in width. In this model, the difference between the smallest and largest grate aperture was approximately 18 per cent. Grates act as a classification mechanism, and an increase in grate aperture allows the passage of coarser particles, affecting the performance of the pebble crusher, mill throughput and product size. Models of grate aperture can increase the understanding of the effect of grate wear on mill performance.

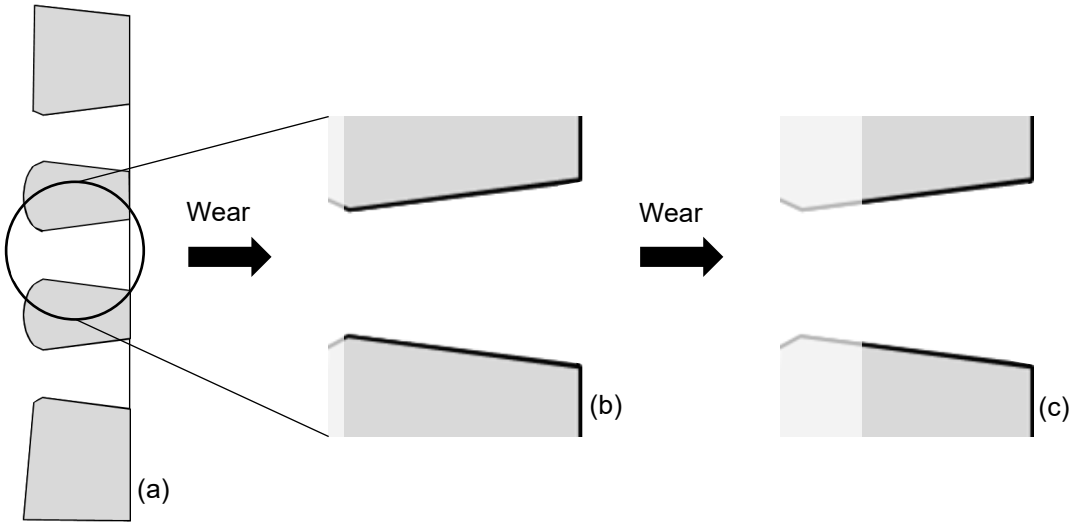

FIG 7 – Profile diagram of stages of the grate width over time. The grate (a) wears down, initially decreasing width aperture (b), and then increasing (c) until the grate is worn down or replaced.

The models in Table 1 also show a continuous increase in mill diameter and mill length over time. This is caused by the wear of liners due to the interaction with the charge, decreasing their profile

height over time and increasing mill internal dimensions. Changes in liner profile affect charge lifting inside of the mill and the amount of impact breakage and abrasion that the ore is subjected to. Thus, product particle size is directly affected, one of the main performance indicators of a SAG mill.

The increase in mill internal diameter and length causes an increase in mill volume. This leads to variations in mill filling and ball filling that can also affect the breakage of material, and impact product size distribution and throughput. Moreover, the change in mill internal dimensions is a result of liners losing mass due to wear. Accounting for this variation in mass leads to more accurate measurements of mill weight and better control decisions for the operator.

Mill performance over liner life

Mill simulation outputs show changes in performance indicators over the liner life, as illustrated in Figure 8. Noteworthy, this effect is not immediate, and substantial differences only occur over weeks. This contrasts with the rapid influence of changes in ore characteristics in mill performance. Mill power draw rose 2.3 per cent, and load cell readings decreased 12.5 per cent at the end of liner life. This is a significant change in the weight caused by liner mass loss, showing the importance to consider this for control and optimisation of a SAG mill, such as for mill filling.

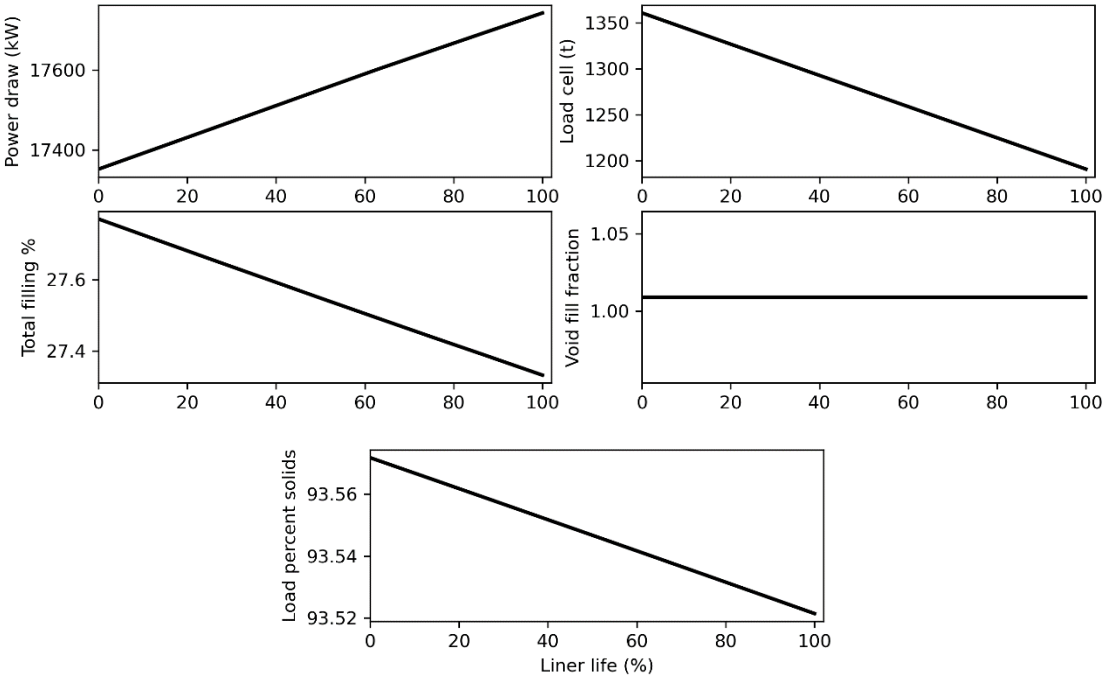

FIG 8 – Modelling outputs for the SAG mill over the percentage of liner life.

Total volumetric filling of the mill reduces 1.6 per cent along with liner life due to the increase in mill volume. Ball filling is constant since it is set as a percentage of the mill volume, creating an effect of virtually adding balls to the mill as the volume increases due to wear. Void Fill Fraction (VFF) is approximately constant over time at about 1. Mill percentage of solids also reduces over time, but less than 1 per cent compared to the initial value or new liners. These results imply that the mill's VFF and the load percent solids are not affected by the wear of the liners in this simulation.

The outputs illustrate the importance of liner wear in the performance of a simulated SAG mill using industrial data. Changes in some performance indicators can be associated with changes in liner profile and liner mass loss caused by wear. Liner wear modifies the behaviour of the charge inside the shell due to a decrease in lift or expansion in shell dimensions. Consequently, liner wear has an impact on the material breakage in the load and the particle size distribution and throughput of the mill. Moreover, mass loss due to wear influence the readings of the load cell that can change significantly over time.

Dynamic SAG mill models which consider liner wear could be used in testing different automated process control approaches and understanding how these strategies react, not only to the rapid

changes in the process but also to the slow changes caused by wear. This could lead to the development of improved control strategies for SAG mills, which contribute to the efficiency of the entire grinding circuit.

CONCLUSIONS

Liner wear affects the performance of SAG mills. This is a dynamic phenomenon that contributes to the nonlinearity of mills and grinding circuits, making automatic control challenging. Thus, human intervention in process control becomes the norm in the mineral processing industry at the cost of inconsistencies in performance between operators. Dynamic SAG mill models that account for wear can contribute to the development of novel controls that can decrease inconsistencies caused by human factors.

This paper illustrates the impact of liner wear on the performance of a virtual SAG mill. Industrial data shows a change in liner profile, grate aperture, and liner mass loss due to liner wear over time. The wear models were incorporated in a dynamic SAG mill simulation. Then, scenarios of progressive wear were simulated, showing its effect on some performance indicators of the mill and its importance for process control. Wear modelling can expand the current models for SAG mills and grinding circuits, opening opportunities for the creation of more robust model-based advanced process control strategies.

Future work involves a simulation of P80 over time, focusing on making the breakage rates change over time, as was discussed and shown by Toor (2013). After ensuring that all SAG mill outputs are reasonable, control strategies can be implemented to achieve the target product size and throughput.

ABSTRACT

In mineral processing industries grinding is the most energy-consuming process. A tumbling mill is an essential grinding equipment widely used for particle size reduction. Power consumption, impact forces and trajectory paths are critical parameters for characterising a tumbling mill to determine grinding efficiency. The effect of lifters and mill speed plays a vital role in such parameters. However, most of the studies ignore the impact of the lifter and do not investigate the effect of slurry dynamics on charge motion. The focus of the present work is to prepare a computational model that can accurately predict the complex multi-phase dynamics of charge particles, air and slurry inside the mill using a model that couples computational fluid dynamics (CFD) and the discrete element method (DEM). The details of impact forces with lifter profiles and mill speed variations will be refined even further using the CFD-DEM coupling approach. The slurry-air free surface is modelled using the volume of fluid (VOF) method, and the charge motion is modelled using the DEM. The phases are coupled using the interface momentum exchange between the charge and the fluid slurry. The coupled model is validated against experimental results from the positron-emitting particle tracking (PEPT) data. The validated model compares the effect of slurry content on charge dynamics with the dry DEM model. The presence of slurry is observed to dampen the tangential and shear contact forces.

INTRODUCTION

Comminution, which includes crushing, grinding, and other controlled size reduction processes, is the first stage of mineral production (beneficiation). Crushing is the initial stage of comminution followed by grinding, where the particles are further reduced from small grits (<5 mm) to dust (<30 μm), which makes it the core of comminution. Tumbling mills are the most extensively used machine for grinding at the grain level. The feed to such mills consists of water and preprocessed ore particles. Grits breakdown into smaller particles due to the compressive forces and the frictional force between the particles and the mill shell. The water in the feed forms a slurry with the finer-sized particles, allowing the ground ore particles to exit the mill through a grate. The dynamics of particles in water/slurry would behave differently compared to dry grinding. It is believed that slurry consisting of fine particle fractions exhibits an increased viscosity in a wet tumbling mill, significantly affecting the grinding efficiency at higher particle load (Napier-Munn *et al,* 1996).

Although tumbling mills are extensively used in mineral industries, these mills are highly energy inefficient. According to Schönert's (1986) survey for copper production milling, out of 60 per cent of the total energy input, only less than 5 per cent is utilised for effective grinding. A thorough understanding of the charge and slurry dynamics can be of great help in energy-efficient mill design. However, none of the classical theories incorporated the effect of lifters on the mill power draw. The tumbling action inside a mill strongly depends on the size, shape, and number of lifters. Thus, to improve the economy of the tumbling mills, research on the tumbling mills configuration is crucial.

In comminution, Mishra and Rajamani (1992) were the first to develop code that understood the grinding mechanism of ball mills using discrete element method (DEM). Cleary (2001) investigated the effect of lifter patterns based on power draw in a 2D mill over various mill speeds. The lifter

pattern was found to be insensitive to mill speeds less than 70 per cent of the critical speed. Djordjevic *et al* (2004) made considerable progress using 3D DEM modelling and studied the effect of the number of lifters and its coefficient of friction on energy consumption in a tumbling mill. Makokha and Moys (2006, 2007) encountered that using cone shape lifters resulted in more cataracting events, which improved grinding efficiency and discharge rate. Powell *et al* (2011) used EDEM® software to produce a liner wear model based on collision energy distribution for mill liner design. Bian *et al* (2017) investigated the impact of mill speed, lifter height, and lifter number on particle trajectory and particle streamflow inside the mill. Mill speed and lifter height were found to significantly impact mill-work efficiency, whereas lifter numbers were found to have a notable impact on particle stream characteristics. Gutiérrez *et al* (2019) used DEM to simulate the material transport in a mill with different lifter profiles. They concluded that combining inclined lifters with helicoidal pulp lifters can effectively increase material flow at the mill's discharge, though they may be difficult to install. DEM simulations can significantly improve work efficiency and characterise particulate streams depending on the product output.

A large portion of the studies done in a tumbling mill has used the DEM strategy to get the particulate dynamics. To appropriately capture the dominant phenomena occurring in a multi-phase flow where gas or fluid interaction with particles is involved, computational fluid dynamics (CFD) coupled with DEM gives a detailed understanding of such issues. Using the CFD-DEM simulation approach on high speed stirred mills (IsaMill), Jayasundara *et al* (2011) investigated the flow properties in terms of particle velocity field and mill power draw, concluding that slurry density and viscosity have a significant impact on charge motion. They then compared it with the PEPT experiments for validation under similar conditions. Similar work was carried out by Mayank *et al* (2015a) to predict the charge motion in a tumbling mill but with a different coupling approach. Later, Mayank *et al* (2015b) developed a two-way coupled model to account for slurry's effect on solids and investigated the effect of different slurry concentrations on charge dynamics and vice versa. All the results were validated with an equivalent PEPT (Positron Emission Particle Tracking) experiment of lab-scale mills, and in some cases, an excellent agreement was found.

Cleary *et al* (2006), investigated slurry transport and other mill operational issues using smoothed particle hydrodynamics (SPH) coupled with DEM approach. Advection was observed to be perfect because in SPH, mass is discretised rather than the control volume. Many other researchers like Cleary (2015); Robinson *et al* (2014); Sun *et al* (2013), used the same SPH-DEM approach to study the solid-liquid flow in a tumbling mill. It was found that one of the few advantages of using Lagrangian methods is that they use straightforward convection models without the need to calculate fluxes. However, extremely fine resolution is required to reproduce precise fluid motion (ie the number of SPH particles). As a result, applying such a model for large scale practical system like industries is difficult.

The aim of this work is to evaluate the lifter effect on tumbling mill dynamics using a computational model capable of accurately predicting the complex multi-phase dynamics of charge, air, and slurry inside the mill by combining CFD and DEM. The dynamics of particle-particle collision forces were studied extensively using the CFD-DEM coupling approach, by varying lifter profiles and mill speeds. This model is compared to the dry DEM model to study the effect of slurry content on charge dynamics. The tangential velocity variation along the diametric line passing through the centre of circulation (COC) has been compared.

METHODOLOGY

The methodology used here is based on the work carried out by Mayank *et al* (2015b). The volume of fluid (VOF) approach is used to simulate the slurry-air free surface, and DEM is used to represent the charge particle motion. The interface momentum exchange between the charge and the fluids is used to integrate the phases. The flow is two-way coupled, with mutual effects between the fluxes of both phases, such that charge motion influences fluid phase motion and vice versa. The model accounts for the influence of slurry on solids in the tumbling mill. For more details, readers can refer to Mayank *et al* (2015b) work.

Experimental validation of the coupled CFD-DEM model

Using an advanced technique called Positron Emission Tracking (PEPT), developed by Parker *et al* (1997), comparable tests were done to validate the coupled model. Figure 1 compares the tangential velocity predicted by dry DEM, pure CFD, one-way and two-way coupled CFD-DEM models to PEPT data along the line passing through the mill's centre to the centre of circulation (COC) extended to the lifter assembly. The experimental PEPT results were shown to be overpredicted by the tangential velocity of the particles computed by the dry DEM model, because of the unaccounted shear damping effects due to the presence of slurry. Without a doubt, the pure CFD completely contradicted the experimentally anticipated tangential velocity profile. The two-way coupled model, on the other hand, has the best agreement with the experimental results because it can account for the slurry's drag as well as the slurry's shear damping effects on the particles while modelling.

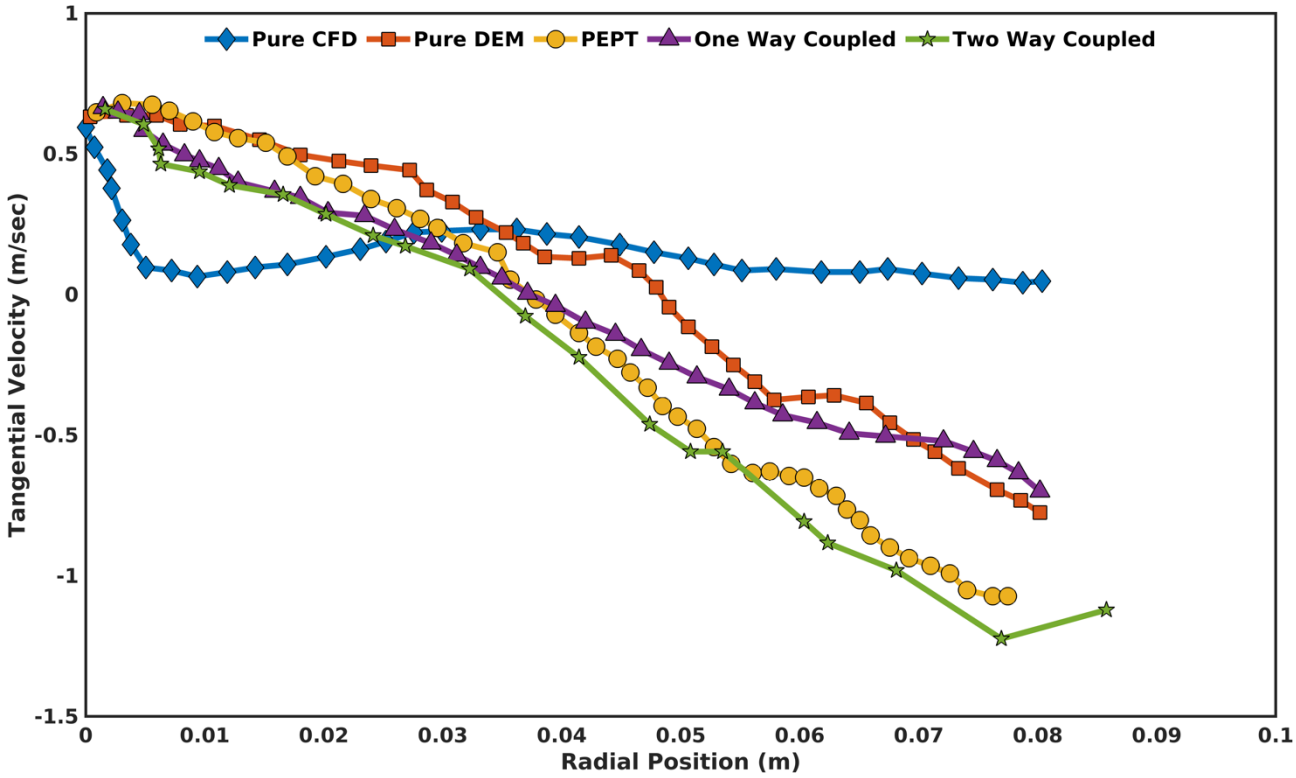

FIG 1 – Comparison of tangential velocity of charge particle predicted by different models against PEPT data.

Even a qualitative comparison of numerically predicted time-averaged solid concentration contours (Mayank *et al,* 2015b) for two-way CFD-DEM coupling model data to analogous experimental PEPT data for mill loading of 20 per cent by volume and 60 per cent critical speed, corresponding to a rotational velocity of 4.852 rad/sec, revealed the best agreement with the experimental results of all other models.

NUMERICAL SIMULATION

DEM model

Initial simulation validated the discrete element method to predict the charge motion inside a tumbling mill accurately. A set of dry DEM simulations were conducted, varying the speed of the mill. The particles were modelled as spherical balls of a diameter of 5 mm and density 2650 kg/m^3. The time step size for the simulation was chosen to be 1e-05 sec. Tumbling mill has a diameter of 300 mm and a length of 270 mm. The mill is equipped with 20 lifters uniformly spaced with a 20 mm height and varying lifter face angles (0°, 20° and 60°) as well as different mill speed (60 per cent, and 75 per cent of N_c). In addition, the simulated data is analysed using a coarse-grained temporal average approach (Artoni and Richard, 2015; Babic, 1997). After the simulation

reached steady-state, instantaneous DEM data were continually recorded at every 0.001 second for 1 second, which is roughly comparable to a drum revolution. Around ~59 000 particles were initialised position by filling a cylindrical corresponding to 31.25 per cent mill loading. Each particle was initially assigned to zero velocity. The commercial code LIGGGHTS® opensource software was used to solve the particle motion equations. The non-linear spring dashpot model inbuilt into the software was used to model the contact forces.

Pure CFD model

The pure CFD Model of the slurry-air system was also simulated to find the free surface profile. Two kinds of slurries were modelled as an incompressible fluid one with a density of 1103 kg/m^3 and viscosity 1.068e-06 N-sec/m^2 based on 15wt. per cent solid fraction and another with density 1332 kg/m^3 and viscosity 1.378e-06 N-sec/m^2 based on 40wt. per cent solid fraction. The viscosities are calculated using Ishii and Mishima (1984) model. The water level was kept constant at 21.67 per cent. The open-source CFD solver OpenFOAM® was used to solve the fluid flow governing equations. The slurry air multi-phase system was modelled using the volume of the fluid model. The $k-\epsilon$ model present in OpenFOAM® was used to model turbulence. A sliding mesh model was used to incorporate the rotation of the mill. The fluid flow governing equation was discretised using the finite volume method, where the pressure velocity coupling was done using the PISO algorithm.

Two-way coupled CFD-DEM model

A numerical model is developed using CFDEM® coupling, which uses a coupling to transfer momentum between the particles and the particles and fluid. CFDEM® coupling is open-source software for coupled CFD-DEM simulations. It uses the CFD framework of the open-source CFD code OpenFOAM® and the DEM framework of the open-source code LIGGGHTS®.

RESULTS AND DISCUSSION

Figure 2 shows the comparison between the fluid volume fraction for various mill configurations at 75 per cent of N_c with slurry containing 15wt. and 40wt. per cent solid fraction. The lifter face angle has a pronounced effect on the relative occupancy of the slurry. As observed in Figure 2, apart from the shear charge motion the presence of lifters seems to transport further the slurry resulting in a higher shoulder height. Therefore, the resultant region of occupancy of the slurry elongates with increasing lifter face angle at the expense of the occupancy near the centre of circulation.

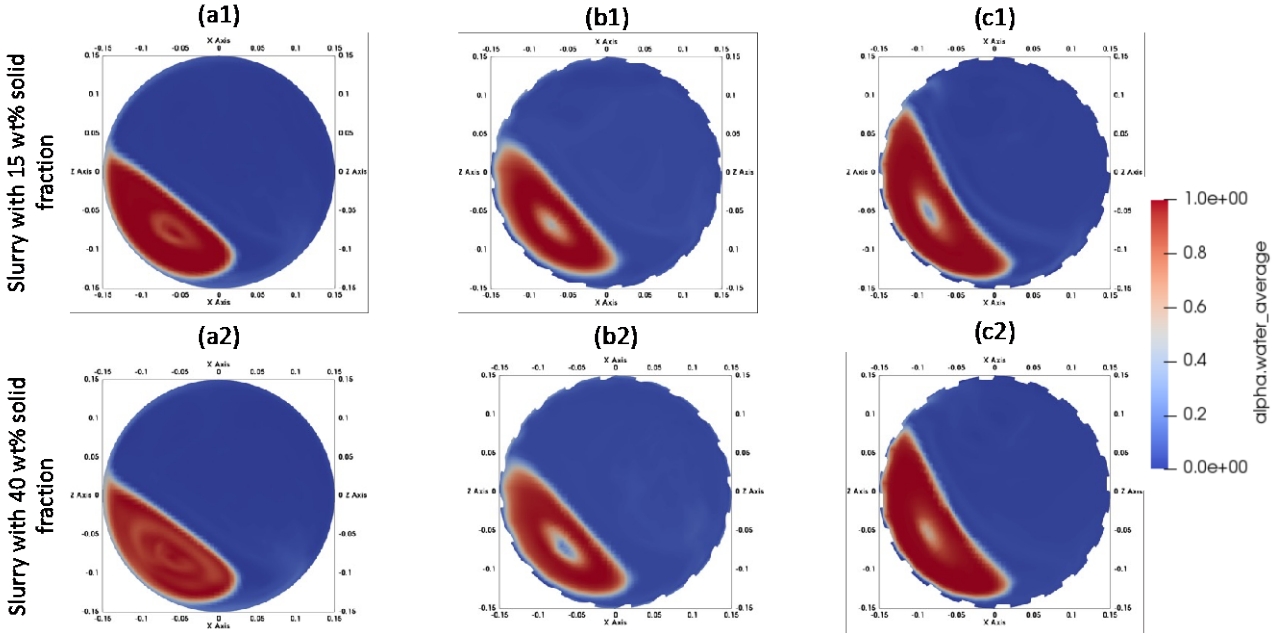

FIG 2 – Fluid volume fraction profile for various mill configurations: 0° lifter face angle (a1,a2); 20° lifter face angle (b1,b2); 60° lifter face angle (c1,c2) at 75 per cent of N_c.

The solid concentration profile is a critical metric for assessing flow energy dynamics and understanding the behaviour of the solids associated with the milling process. Figure 3 illustrates the charge particle solid concentration profile for various mill configurations at 75 per cent of N_c with a slurry containing 15wt. and 40wt. per cent solid fraction. The ascending region near the mill shell had a high solids content, which is a direct indication of high-pressure areas. Even the highest shear stress values are typically found near these regions. From Figure 3, the high solid content was observed to dilate with increasing lifter face angle. The particles are densely packed in the ascending part of the layer; however, as the lifter face angle increased, a gradual increase in porosity in the cascade region was observed. It occurs due to increased centrifugal force, which pushes particles further up from the shoulder, allowing them to fly freely under gravity's influence. From Figure 3, it is evident that the position of the charge particles (kidney-shaped region) does not vary considerably with slurry viscosity.

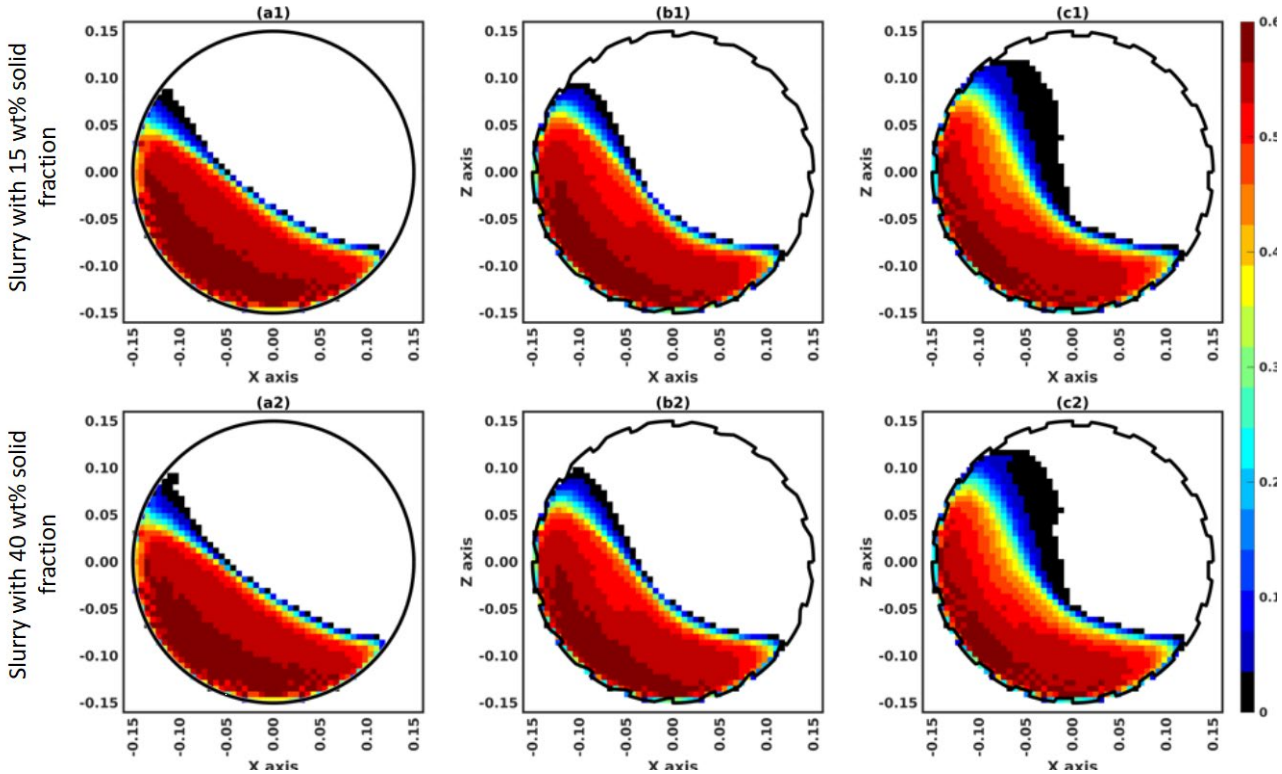

FIG 3 – Charge particle solid concentration profile for various mill configurations: 0° lifter face angle (a1,a2); 20° lifter face angle (b1,b2); 60° lifter face angle (c1,c2) at 75 per cent of N_c.

Figure 4 depicts the tangential velocity magnitude along the radial line for direct comparison between the dry DEM and two-way coupled CFD-DEM data. The tangential velocity at the mill shell was 20–25 per cent less than the mill speed in the absence of lifters. However, with lifters, tangential velocities were found to be nearly identical to mill speed for both coupled and dry DEM cases. For the 20° lifter profile, the difference was found to be 5–10 per cent whereas for the 60° lifter profile, 1–5 per cent difference was observed. Insignificant differences were observed in the tangential velocity near the mill shell between dry DEM and coupled CFD-DEM predictions for both slurries. Tangential velocity decreases linearly with distance as we approach the centre of circulation while remaining close to the mill shell. According to (Yamane *et al*, 1998), as the radial distance decreases, the charge particles slip, and the velocity deviates from linearity. However, in the case of dry DEM modelling, the velocity variation from linearity seems to differ marginally.

In the tumbling mill, the particles are densely packed in the ascending region of the layer (ie below the equilibrium surface), and porosity gradually develops in the cascade region, moving to a free surface where the cataract region becomes highly porous. The gradual evolution of porosity is primarily caused by an increase in free flight high-speed particles. The magnitude of high-speed particles is greater towards the mill centre in the absence of slurry than in the presence of slurry, resulting in an increasing cataracting profile without slurry. The dry DEM model overpredicts the charge particle path because shear forces from the slurry, which dampen particle motion, are not

considered. In the ascending region, the charge particle tangential velocity profile difference was significantly smaller. The presence of slurry appears to have little effect on the velocity of the charge particle due to the densely packed area, ie high packing density.

The cataracting profile appears to be completely dependent on the slurry rheology, and the effects become more prominent as the lifter face angle and mill speed increase. Figure 4(c2) shows a decrease in tangential velocity magnitude due to an increase in slurry viscosity. Although typically, the multi-phase effects need to be studied with respect to slurry fine fraction variation as the viscosity plays a vital role in charge particle motion.

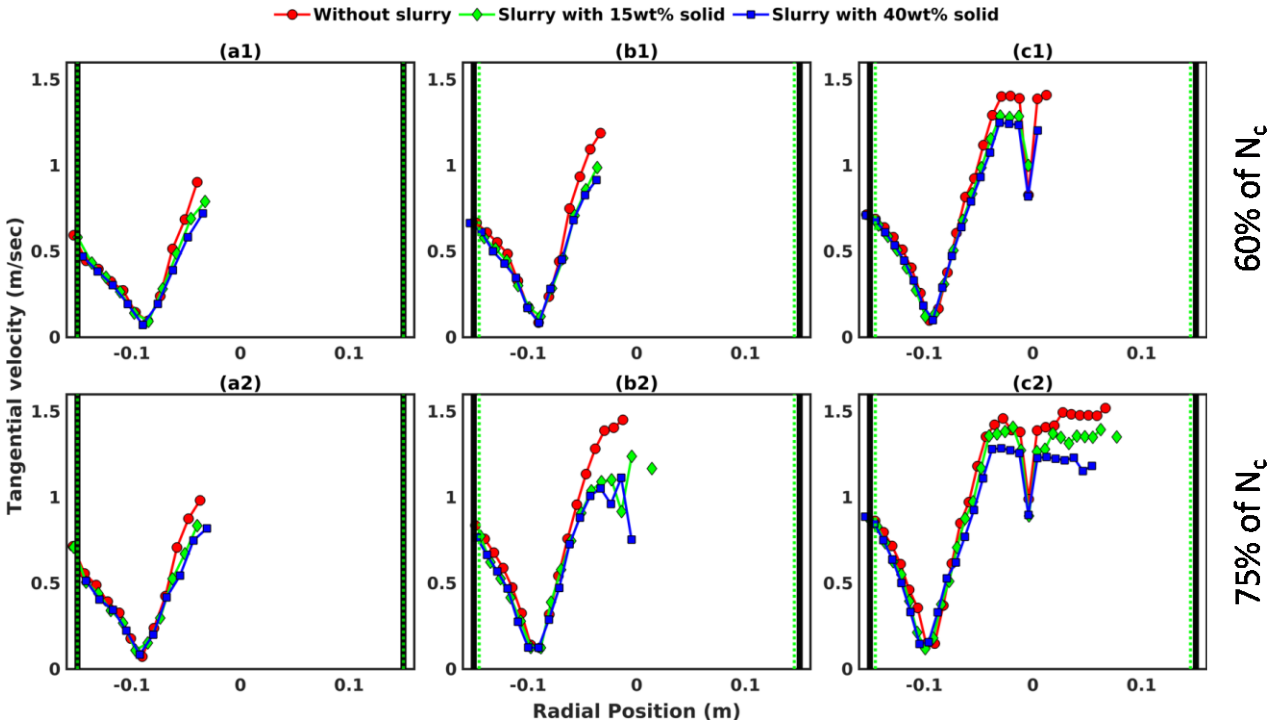

FIG 4 – Tangential velocity plot along the radial line connecting COC and Mill centre at 0° lifter face angle (a1,a2); 20° lifter face angle (b1,b2); 60° lifter face angle (c1,c2).

In Figure 5, the toe and shoulder angles of charge particles were plotted against variations in mill speed and lifter face angle for both scenarios. The lifter profile has no significant effect on the toe angle Figure 5b, but it substantially impacts the shoulder angle Figure 5a for both dry DEM and coupled CFD-DEM models. It is noteworthy that there is a significant change in the dynamics of granular flow as the mill speed increases. With increasing lifter face angle, a substantial number of particles were lifted to a sufficiently higher location, allowing maximum energy to be imported to the charge particles and thus higher grinding efficiency. Figure 5a and 5b show that the presence of slurry significantly reduced the shoulder angle, but only marginally reduced the toe angle. However, the charge particles' shoulder and toe angles do not appear to vary significantly with slurry viscosity.

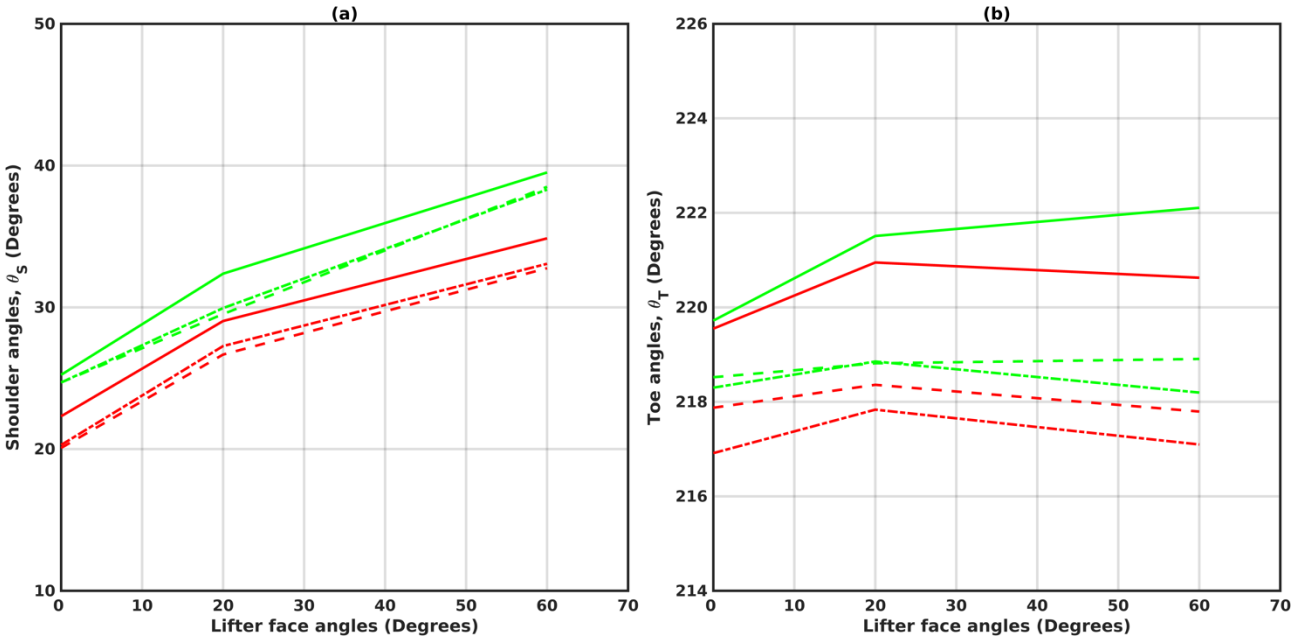

FIG 5 – Variation of the shoulder angle (left) and toe angle (right) with the lifter face angles.

The methodology for calculating power consumption was adopted from work by Bbosa (2013) based on the distribution of the mass of charge particles (simplify) and the average angular velocity. The spatially averaged mass and averaged angular velocity distribution was determined for each voxel to subsequently calculate the torque contribution of each voxel in the grid. Figure 6 depicts how the power consumption for the various mill critical speed ranges rise as the lifter face angle increases. The lifter face angle has a more decisive influence on mill speed. Without a doubt, the power consumption data for dry DEM must be larger than the coupled CFD-DEM simulation results, and the explanation is simple: there is slurry damping of particle motion.

The difference between the power draw values for 60 per cent of mill critical speed is significantly higher than other mill speeds. Typically, the motion occurring at 60 per cent of the mill critical speed is a nice blend of cascading and cataracting regimes that appear to be substantially influenced by slurry. In comparison, cascading and rolling regimes prevail at low mill speeds (50 per cent of N_c), whereas cataracting and centrifuging regimes dominate at high mill speeds (75 per cent of N_c). When comparing the two slurries used in the current study, a significant decrease in power draw was observed due to an increase in viscosity, indicating that the contribution from the slurry is well accounted for in the CFD-DEM model.

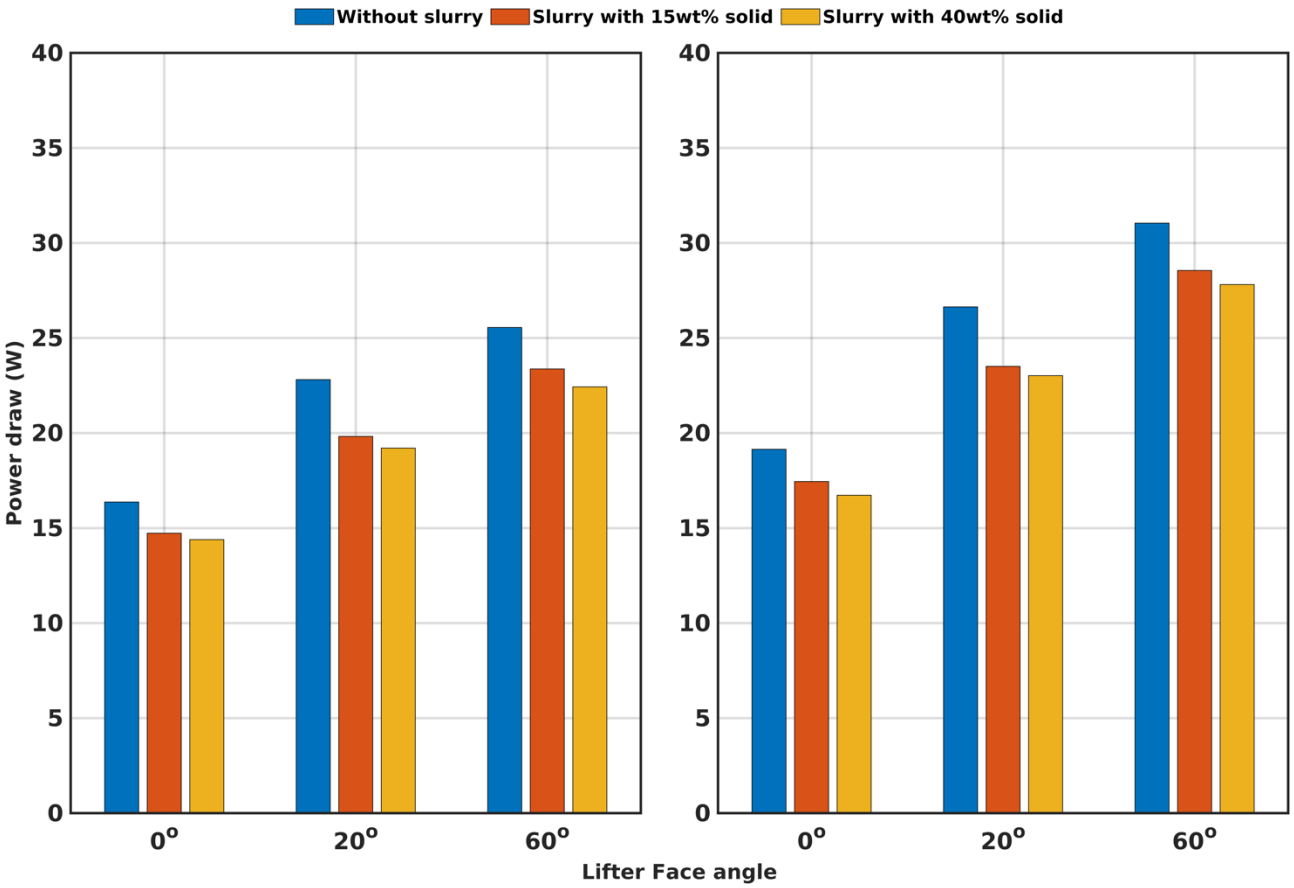

FIG 6 – Power consumption comparison between dry DEM and CFD-DEM coupled simulations data.

CONCLUSION

The coupled CFD-DEM approach is an excellent tool for accurately computing and characterising the charge particle dynamics inside a tumbling mill. On the contrary, the dry DEM model overpredicts particle dynamics because of the unaccounted effects of slurry shear forces. It was observed that raising the lifter face angle and mill speed made the particle streams denser and increased the number of high-speed particles in both scenarios with and without a slurry. Although in presence of slurry, the number of high-speed particles appears to decrease with increasing viscosity. Slurry appears to mitigate the dominant effect of high mill speed on solids concentration. The solids concentration appears to outweigh the dilating impact of speed at lower speeds. From no slurry to slurry, there was a 6–8 per cent shift in shoulder angle and a ~1 per cent shift in toe angle. In the presence of slurry, the shoulder and toe angles of the charge particles do not appear to vary significantly with slurry viscosity. At 60 per cent N_c, there is a ~16 per cent increase in the power draw of charge particles in the tumbling mill from no slurry to slurry, which is the most significant difference seen in all cases. The difference in power draw between the two slurries was approximately 3 per cent due to the dampen particle motion from the slurry. The current study successfully developed a computational model that accurately predicts the complex multi-phase dynamics of charge, air, and slurry inside the mill by combining computational fluid dynamics and the discrete element method.

ABSTRACT

Tumbling mills are grossly inefficient, using only 5 per cent of the total energy supplied for actual breakage. A significant proportion of this inefficiency is unavoidable owing to geometric limitations; rotating drum systems are prone to exhibiting certain regions (energy barriers) that resist particle entry thereby restricting the transfer of energy. Though such systems are inherently inefficient, improved modelling schemes may lead to slightly enhanced efficiency through better microscale predictions of key breakage drivers (stress, force). Central to achieving such incremental advances is the development of a universally accepted rheology for dense granular flows. Armed with a better understanding of these macro-scale ingredients, classical process modelling offers an efficient, spreadsheet friendly framework for recovering the spatial distributions of the comminution drivers. At this real-time level of process control, it should be possible to tune comminution operations towards more energy efficient configurations – the ultimate goal of this research. The present work employs validated DEM data to recover the full continuum field which will ultimately serve as a basis for calibrating process model outputs based on different rheological hypotheses. Such a continuum-based approach captures tensor properties like the shear stress and strain rate – both of which are necessary to developing a dense granular rheology. Moreover, DEM captures this data at the momentum transfer timescale of 10^{-6} s – no other measurement technique is capable of this level of spatial and temporal resolution. Importantly, the confidence in this DEM data is strengthened because it has been validated at the continuum scale using Positron Emission Particle Tracking (PEPT) kinematic measurements. Validated DEM data is derived from batch experiments conducted within a 300 mm ID laboratory drum using three and five millimetre glass beads at 60 and 75 percent critical speed; such mill speeds are typically encountered in the tumbling mill industry. Dimensional analysis is conducted using critical rheological parameters (shear rate, shear stress, granular temperature etc), which are key to not only developing a granular rheology but ultimately will be used to tune our mechanistic models.

INTRODUCTION

Researchers in the comminution industry have been trying for decades to optimise tumbling mill efficiency. Stemming from the fact that they consume about 4 per cent of the available electrical energy globally (Kolev *et al*, 2021), the slightest improvement in efficiency translates into significant cost savings. Being a complex multiphase phase flow that is difficult to describe using classical, fundamental physics, a significant proportion of the optimisation research in the tumbling mills community has been dedicated to the development of purely empirical models (Bbosa *et al*, 2011; Austin, 1990; Morrell, 1992). Such *black-box* models are extremely powerful provided they are applied within their domain of applicability – outside of this, their use is limited and can be detrimental to downstream processes. In addition, empirical models inherently lack detail concerning the internal dynamics within the mill which ultimately drive energy efficiency. These weaknesses necessitate the development of predictive fundamental models that explain the mechanisms of breakage and energy dissipation occurring within the mill – only then can one truly optimise the performance of tumbling mills.

This paper introduces a unique way to treat the data derived simulation and experiment. On the one hand, simulation provides the opportunity to obtain dynamic properties like shear stress, shear rate, power dissipation at the momentum transfer timescale of 10^{-6} s. At such a timescale, there is simply no experimental technique that can be used to validate these properties *in situ*. This has led experimentalists to argue the validity of the DEM data. Positron Emission Particle Tracking (PEPT) is a nuclear imaging technique capable of providing data (solids fraction, velocity) at a timescale of 10^{-3} s and spatial resolution of a millimetre. Clearly, this is too coarse a timescale to validate the dynamic data from DEM. Whilst it may be true that there is no way to experimentally validate this simulated data at the microscale, if the predictions are coarsened out to the mesoscale, then the DEM continuum fields can be validated using PEPT data. These DEM kinematic fields have been validated in the previous phase of work at the continuum scale using PEPT data (Moodley and Govender, 2020); the results from that study showed statistical agreement.

In order to develop a fundamental model that describes the underlying mechanisms that drive breakage, the relationship between shear stress and shear rate in a dense granular system must be known – such a relationship does not exist in the literature (Kumaran, 2004). In the absence of such a fundamental relationship, researchers resort to using dimensional analysis to characterise the system. There are two leading theories using dimensionless numbers that describe dense granular flows in three dimensions namely the μ(I) (Jop, Forterre and Poliquen, 2006) and modified – Pe number rheologies (Pähtz *et al*, 2019; Chialvo and Sundaresan, 2013); both require knowledge of fundamental properties like the shear rate, granular temperature and shear stress to be utilised.

The μ(I) rheology assumes that the granular medium behaves like an incompressible fluid and captures its behaviour locally. Based on a coulombic-like friction, it relates an effective friction coefficient μ (ie the ratio of the shear stress (τ) to the pressure (P)) to the dimensionless inertial number (I) in the following manner:

$$\mu(\mathrm{I}) = \left|\frac{\tau}{\mathrm{P}}\right| \text{ with } \mathrm{I} = \frac{|\dot{\gamma}|\mathrm{d}}{\sqrt{\mathrm{P}/\rho_m}} \tag{1}$$

where $\dot{\gamma}$ is the shear rate, $|\tau|$ is the magnitude of the deviatoric shear stress, *P* is the pressure, ρ_m the material density and *d* is the particle diameter. In essence, it compares the typical time scale of microscopic rearrangements to macroscopic deformation. Using an exhaustive experimental programme, the effective friction (μ) was determined to be related to I in the following manner:

$$\mu(I) = \mu_s + \frac{\mu_2 - \mu_s}{I_0/I + 1} \tag{2}$$

The exponential expression above implies that below a certain minimum friction (μ_s), no material flow occurs. Mathematically speaking, flow is possible if-and-only if $\left|\frac{\tau}{P}\right| > \mu_s$. The phenomenological nature of the model means that as the value of I increases (implying a shear dominant flow where $I \gg 1$), $\mu \approx \mu_s$. The parameters μ_s, μ_2 and I_0 are material specific and, in the case of spherical glass beads have been experimentally quantified as $\mu_s = \tan(20.9^0)$, $\mu_2 = \tan(32.76^0)$ and $I_0 = 0.279$. The solids fraction has been determined to decrease linearly with the inertial number:

$$\emptyset = \emptyset_{max} - \beth I \tag{3}$$

where $\emptyset_{max}$ is the maximum possible solids fraction ($\emptyset = {}^{\rho}/_{\rho_m}$ defined as the ratio of bulk to material density of the particulate flow) and ב is a positive constant usually equal to 0.2. Unfortunately, this equation is only valid for low values of I since if $I > {}^{\emptyset_{max}}/_{\beth}$, this will result in negatively valued solids fractions. Thus, the $\mu(I)$ rheology is restricted to the case of dense granular flows where the value of I is typically low. Apart from the obvious local dependence of the rheology *viz* does not account for long range effects prevalent in dense granular flows, an interesting omission from this rheology is the effect of velocity covariance (fluctuations). Such fluctuations influence the behaviour in granular beds in similar manner as they do in a gas through the thermodynamic temperature; thus it is aptly termed the granular temperature (T) and computed as follows:

$$\mathrm{T} = \frac{1}{3}\left(\langle \grave{U}_1^2 \rangle + \langle \grave{U}_2^2 \rangle + \langle \grave{U}_3^2 \rangle\right) \tag{4}$$

where $\langle \grave{U}_i^2 \rangle$ denotes the ensemble average (or root mean square) of the fluctuating velocity. Computing T allows for the prediction of particle movement which is particularly beneficial to mixing processes; such movement is underpinned by a gradient driving force principal where particles are more likely to flow from a region of high temperature to that of low temperature. Using DEM, we are able to obtain the binned granular temperature in each of the three principal directions as:

$$\langle \grave{U}_i^2 \rangle = \frac{\sum_1^N (U_i - \overline{U})^2}{N} \tag{5}$$

where U_i and $\overline{U}$ are the individual particle velocity and the mean velocity within each bin respectively. Despite some authors including the rotational degrees of freedom in the granular temperature calculation, this work is restricted to fluctuations due to translational particle velocity. It is generated as a result of the shear stress between particles and is diffused through the bed due to particle collisions and kinetic flux (Cleary, 2007). Researchers argue the validity of such a property (and kinetic theory in general) in a granular medium since in gases the collisions are perfectly elastic meaning the system is in equilibrium. In a granular medium, the collisions are dissipative in nature implying that the system in a constant state of non-equilibrium thus requiring a constant supply of energy to maintain fluidisation (Goldhirsch, 2008). Amidst these valid arguments, studies conducted by Goldhirsch (2001) and Khain (2007) have demonstrated the benefits of applying hydrodynamic and kinetic theories to granular flow. A rheology that incorporates this property is the modified Pe based rheology proposed by Pähtz *et al* (2019) which builds upon the original rheology proposed by Chialvo and Sundaresan (2013). Both of these rheologies are underpinned by a dimensionless number that is defined as follows:

$$\mathrm{Pe} \equiv \frac{\dot{\gamma} \mathrm{d}}{\sqrt{\mathrm{T}}} \tag{6}$$

where T is the granular temperature whilst the rest of the symbols have been previously defined. It can be interpreted as the ratio between the rates of macroscopic shearing motion ($\dot{\gamma}$) and kinetic rearrangements ($\frac{\sqrt{\mathrm{T}}}{\mathrm{d}}$). This differs from the $\mu(\mathrm{I})$ rheology that assumes the particle rearrangements are driven by pressure whereas, in this case, it is by the actual relative motion differences between particles. In addition, the authors propose that the coulombic friction (μ) scales with the Pe only according to the scaling parameter (C_μ) as follows:

$$\mu = C_\mu \sqrt{\mathrm{Pe}} \tag{7}$$

Equation 7 has been confirmed for both dilute and dense flow conditions except for scenarios where non-local effects dominate like sediment transport and gravity flows. The authors demonstrate that C_μ varies with the tangential friction coefficient and not the normal coefficient of restitution. This implies that μ encompasses the effects of anisotropies of the particle assembly (Pe) and the tangential contact force network (C_μ). In summary, the larger Pe number indicates a predominantly convective flow whilst a lower Pe indicates a diffusion dominated flow. Building upon the results of Chialvo and Sundaresan (2013), Pähtz *et al* (2019) introduced a dimensionless temperature gradient $\mathrm{M} \equiv \frac{\mathrm{d}|\nabla T|}{T}$ which accounts for the inhomogeneity associated with non-local effects whose effects are highlighted near the yield stress limit. Thus, the rheology makes use of either M for inhomogeneous flows or Pe for uniform flows in order to describe behaviour around a particular yield stress ($\mu_s{}^*$) which is dependent on the flow profile. The relationship between T and $\mu_s{}^*$ remains an open question.

Problem statement and objectives

The Discrete Element Method (DEM) has been used for decades now to simulate granular systems by discretising particles at a microscale resolution. Due to the computational limitations, DEM has been used to simulate the media charge in tumbling mills and infer probability of breakage. This time scale is ideal to characterise dynamic information like the shear stress, shear rate and granular temperature. Unfortunately, information at this scale is impossible to validate. This is because there is no experimental technique that can provide reliable information at the necessary spatial and temporal resolution. It is for this reason that researchers have questioned the validity of the predictions thereof. This paper serves to provide a solution to this dilemma. The kinematic DEM

outputs (velocity fields, solids fraction) have been previously validated at the mesoscale using Positron Emission Particle Tracking (PEPT). Upon applying advanced coarse graining schemes (Artoni and Richard, 2015; Babic, 1997) to discrete kinematic data, the resultant outputs yielded excellent statistical agreement between PEPT and DEM at the mesoscale. Such results support the hypothesis that there is more confidence in the DEM kinetic outputs (shear stress, shear rate, granular temperature) at the mesoscale because of the validated the kinematic data (solids fraction, velocity fields). This paper is organised in the following fashion:

1. The authors begin by detailing the experimental configuration of the DEM simulations.
2. Next, the methodology used to develop the continuum scale descriptions of the kinetic data is presented.
3. Thereafter, the kinetic data derived from the simulations (shear stress, shear rate, granular temperature) are presented. This data is subsequently combined to produce rheological predictions.
4. Finally, conclusions are drawn, and future work is suggested.

METHODOLOGY

DEM

A short methodology detailing DEM will now be presented; for further details, see Moodley (2022). ROCKY-DEM was used for the rotating drum particle simulations. The relatively large particle sizes (3 mm and 5 mm) operated in a dry, batch environment ensured that only gravity and inter-particle contact were relevant. The total contact force acting on a particle is broken up into the normal and tangential components with respect to the contact plane. The present work used the linear spring dashpot contact model (Cundall and Strack, 1979) to describe the normal component of the contact force: $F_n = K_{nl}S_n + C_n\dot{S_n}$ where K_{nl} is the normal contact stiffness, C_n is the normal damping coefficient, S_n is the contact normal overlap $\dot{S_n}$ is the time derivative of the contact normal overlap, ie velocity. For the tangential component of the contact force, the Linear-spring Coulomb limit model was selected. It is elastic in nature but also considers the frictional forces. The elastic component, at time *t*, is given by $F_{\tau,e}^t = F_\tau^{t-\Delta t} - K_\tau \Delta S_\tau$ where $F_\tau^{t-\Delta t}$ is the value of the tangential force at the previous time, ΔS_τ is the tangential relative displacement of the particles during the timestep (10^{-8} s this work) and K_τ is the tangential stiffness. The friction component of the model is introduced by assuming that the tangential force cannot exceed the Coulomb limit given by $F_\tau^t = \min\left(\left|F_{\tau,e}^t\right|, \mu F_n^t\right)\frac{F_{\tau,e}^t}{\left|F_{\tau,e}^t\right|}$, F_n^t is the contact normal force at time *t* and μ the friction coefficient. The Coulomb limit, μF_n^t, is the point at which the surface contact begins to shear and thus particles start to slide over one another. The Cauchy stress tensor is obtained directly from ROCKY-DEM and is based on the force generated by particle collisions. It is restricted to contact stress only because in granular matter with solid particles there is almost no random motion, therefore the kinetic stresses are negligible. Random motion is almost instantly killed in highly dissipative media like solid particles. It is only important for perfectly elastic collisions like for molecules of a gas. The 3D stress tensor $\left(\sigma_{ij}^p\right)$ is computed in the following manner:

$$\sigma_{ij}^p = \frac{1}{V_p}\sum_{c=1}^{N_p^c} x_i^c f_j^c \tag{8}$$

where V_p is the volume of the particle, x_i^c is the contact location of particle-particle pair *ij*, f_j^c is the contact force of pair *ij*, and N_p^c is the number of contacts of particle *p*. The nine component stress tensor consists of three normal and six deviatoric components. An important characteristic of this stress tensor is the requirement that all $\sigma_{ij} = \sigma_{ji}$ ie the deviatoric components are symmetric. The trace (or normal) components form the pressure (p) contribution whilst shear comprises of all deviatoric components and the overall stress tensor is expressed as $\sigma_{ij} = \left(\sigma_{ij}\right)_{\text{dev}} + \text{tr}\left(\sigma_{ij}\right)$ as follows:

$$\begin{pmatrix}\sigma_{11} & \sigma_{12} & \sigma_{13}\\ \sigma_{21} & \sigma_{22} & \sigma_{23}\\ \sigma_{31} & \sigma_{32} & \sigma_{33}\end{pmatrix} = \begin{pmatrix}(\sigma_{11}-\mathrm{p}) & \sigma_{12} & \sigma_{13}\\ \sigma_{21} & (\sigma_{22}-\mathrm{p}) & \sigma_{23}\\ \sigma_{31} & \sigma_{32} & (\sigma_{33}-\mathrm{p})\end{pmatrix} + \begin{pmatrix}\mathrm{p} & 0 & 0\\ 0 & \mathrm{p} & 0\\ 0 & 0 & \mathrm{p}\end{pmatrix} \quad (9)$$

where:

$$\mathrm{p} = \frac{1}{3}.(\sigma_{11}+\sigma_{22}+\sigma_{33}) \text{ and } \left(\sigma_{ij}\right)_{\text{dev}} = \tau_{ij} \quad (10)$$

The rotating drum was 300 mm in diameter, 270 mm long and fitted with 20 lifter bars. The rotating drum was drawn in AutoCAD™ and imported into the ROCKY-DEM platform. In each experiment, the drum consisted of either 60 000, 5 mm glass beads or 270 000, 3 mm glass beads with a particle density of ρ = 2500 kg/m^3. In either case, the particles occupied 31 per cent of the inner drum volume. The glass beads employed in the experimental work were first conditioned by rotating them in the drum for an extended period of time. This ensured that all rough edges, usually associated with new batches of beads, were thoroughly smoothed out. A natural and desirable consequence of conditioning is the evolution of a narrow size distribution which was measured to be normally distributed about the mean particle size with a maximum deviation of 0.5 mm. The narrow size distribution is known to prevent crystallisation in the packing structure. The problem of crystallisation can be significantly exacerbated in DEM simulations comprising of perfectly spherical particles with identical diameters. Accordingly, the measured distribution of particle size (and mass) was introduced into the simulation via a Gaussian distribution. Typical comminution speeds of 60 per cent and 75 per cent of critical speed (N_c) were investigated (Rose and Sullivan, 1957).

The standard material properties for the DEM simulations are given in Table 1 whilst the material interaction parameters are shown in Table 2. The frictional properties shown in Table 2 are the final values used (after systematically tuning the parameters against PEPT data) for each of the static μ_s, dynamic μ_d and rolling μ_r friction coefficients whilst C_r represents the coefficient of restitution (Chandramohan, 2005).

TABLE 1

Summary of material parameters for DEM simulations.

Item	Material	Density (kg/m^3)	Youngs modulus (GPa)	Poisson's ratio
Azimuthal wall	HDPE	950	0.8	0.46
Side wall	Perspex	1190	0.3	0.38
Lifter bars	Nylon	1200	3	0.4
Beads	Glass	2600	70	0.15

TABLE 2

Summary of contact interaction parameters.

Interaction pair	μ_s	μ_k	μ_r	C_R
Glass – HDPE	0.29	0.05	-	0.7
Glass – Nylon	0.53	0.1	-	0.28
Glass-Glass	0.9	0.4	0.01	0.66
Glass-Perspex	0.29	0.05	-	0.7

Data averaging process

To ensure an equitable comparison scale, we must convert the discrete particle data shown in Figure 1a, to average data per bin or voxel shown in Figure 1b. Only then can a coarse graining scheme can be employed to produce a smoother, more continuous field as shown in Figure 1c. We begin by explaining how particle level data in Figure 1a is converted to binned data in Figure 1b; this is the concept of data binning.

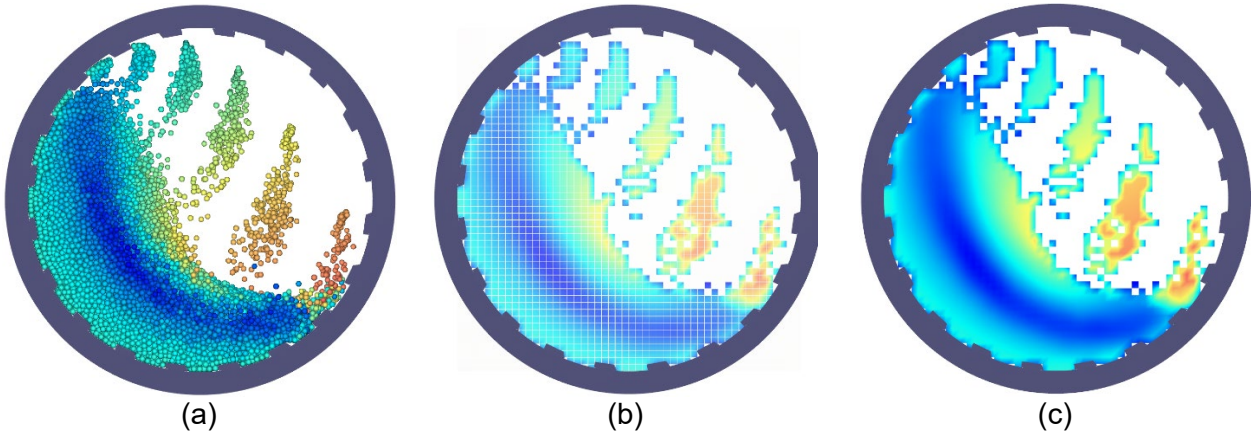

FIG 1 – Illustration of coarse graining process ranging from: (a) Discrete elements each coloured according to an arbitrary particle property ψ_p with colourmap values ranging from high to low (red to blue), (b) Binned particle properties coloured per voxel, (c) Continuous property after applying smoothing kernel.

Let's define $\psi_{\mathrm{p}}(\vec{x}_p)$ as a property of particle *p* flowing within a tumbling mill system operated at steady-state. We now seek the average particle property $\bar{\psi}$ at some probe point $\vec{x}$. The average property at the probe point can be thought of as the weighted contributions of nearby particles. To illustrate this effect, consider a data set *x* that is represented using the histogram shown in Figure 2.

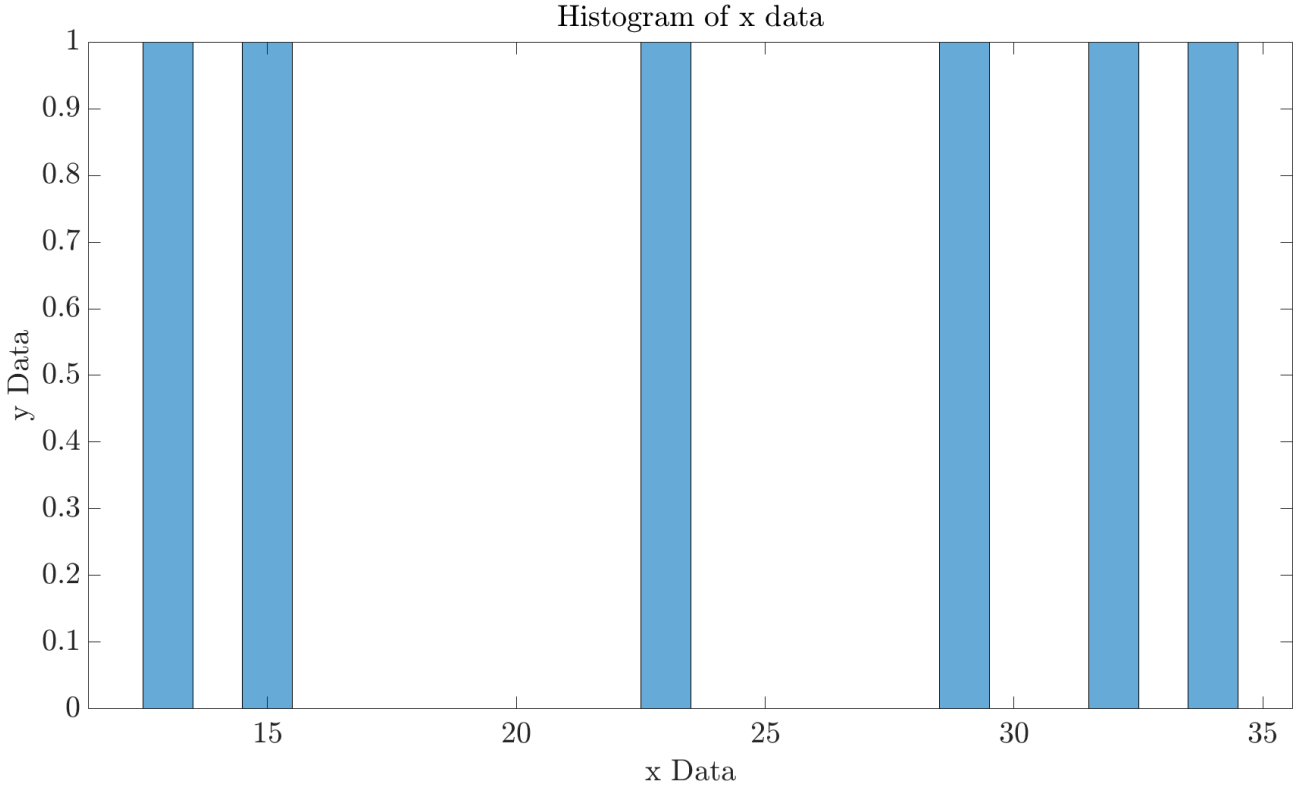

FIG 2 – Histogram of an arbitrary data set.

In this data set, there are several 'bins' wherein there is no data, for example the bins in between 15 and 23. However, we would still like to estimate the probability density at those points. In order to do so, we create a weighted average of the nearby points. This can be understood by considering the point corresponding to $x_0 = 17$. This lies in between 15 and 23 in our data set – bins that have data. We average these points nearby and count them as if they were present in this bin. In order to achieve this, a kernel function is overlayed onto each point in the histogram. We have utilised a

Gaussian function to serve as the basis for the weighted average. A 2D function which defines the kernel estimator of the probability density of any real values of *x* is shown in Equation 11:

$$\hat{f}_h(x) = \frac{1}{N.h}\sum_{i=1}^{N}\frac{K(x-x_i)}{h} \tag{11}$$

where x_i are random samples from an unknown distribution, *N* is the sample size, *K* is the kernel smoothing function, and *h* is the bandwidth or smoothing radius. The *h* represents how far away are we going to consider the effects of neighbouring data points on the point of interest. Using this kernel function estimator, we can approximate a probability density distribution as depicted in Figure 3.

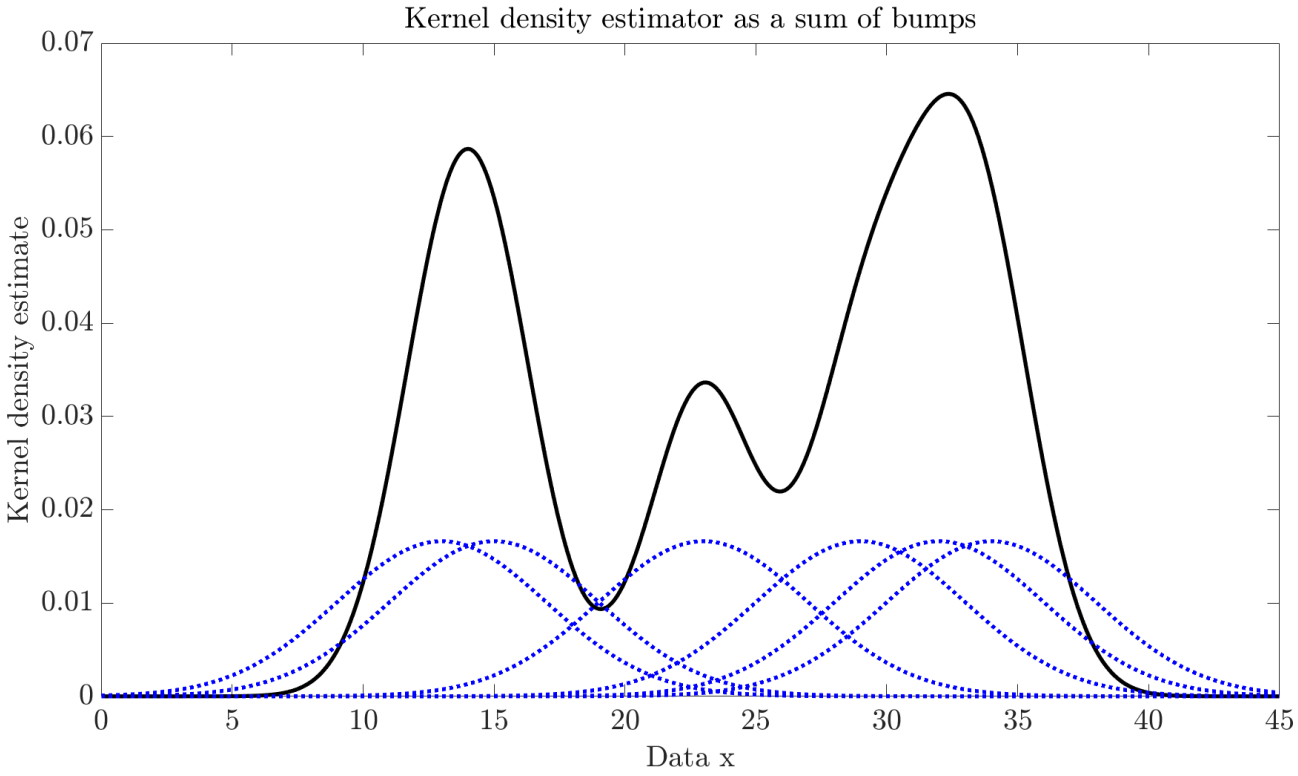

FIG 3 – Illustration of the benefit of using a kernel density estimate to replace missing data from bins.

The way to interpret Figure 3 is to consider a single point on the *x*-axis – say x_0 = 17 – and move your finger vertically upwards. Notice that since we chose a smoothing radius of 2 in this case, the Gaussian curves that intersect your finger are centred at x = 13, 15 and 23. Thus the kernel density estimate will be a weighted sum of these three values. In other words, this serves as an estimate of the frequency $\left[\hat{f}_h(x)\right]$ at the point x_0 = 17. In essence, we count these neighbouring points as being virtually present in the bin centered at x_0 = 17. A caveat of this kernel function is that all curves should satisfy the following relationship given by Equation 12.

$$\int_{-\infty}^{\infty} K(x - x_i)dx = 1 \tag{12}$$

Equation 2 means that we count every observation one time but we spread out how we count it over an area. In summary, a kernel allows us to take a finite set of data points and spread them apart over the *x*-axis. This enables data from one point to contribute to the calculation at various other points. So even Figure 3 only has six data points, we can see that the kernel centered over each data point spans the entire *x* range which enables us to estimate the density at any point. Now, this explains how kernel averaging is done statistically; unfortunately, in the case of granular systems, we must make some adjustments.

As depicted in Figure 3, to ensure that such averages are smoothly and uniformly computed at any probe point, we introduce a spatial smoothing function $G(\vec{x})$ that is continuous and differentiable. A popular form of the spatial smoothing function $G\left(\overrightarrow{\Delta x}\right)$ is built upon a Gaussian kernel $K\left(\overrightarrow{\Delta x}\right)$ such

that for each probe point $\vec{x}$ and particle centroid $\vec{x}_p$, the Gaussian smoothing function is given by Equation 13.

$$G(\overrightarrow{\Delta x}) = |W|^{-0.5} K(\overrightarrow{\Delta x}) \tag{13}$$

where $\overrightarrow{\Delta x} = \vec{x} - \vec{x}_p$ is the displacement between the probe point $\vec{x}$ (centre of a given voxel) and the centroid of particle $\vec{x}_p$;

$$W = \begin{bmatrix} w^2 & 0 & 0 \\ 0 & w^2 & 0 \\ 0 & 0 & \left(L/2\right)^2 \end{bmatrix}$$

and

$$K(\overrightarrow{\Delta x}) = \left(\frac{\pi}{4}\right)^{-3/2} \exp\left[-4\left(\frac{\overrightarrow{\Delta x}}{W^{0.5}}\right)^T \left(\frac{\overrightarrow{\Delta x}}{W^{0.5}}\right)\right]$$

denotes the spatial Gaussian kernel function where $\left(\frac{\overrightarrow{\Delta x}}{W^{0.5}}\right)^T$ reads the 'transpose of $\left(\frac{\overrightarrow{\Delta x}}{W^{0.5}}\right)$' and *W* is the bandwidth matrix where *w* is the smoothing length in the azimuthal plane while smoothing in the *z*-direction is over half the drum length *L*. The *w* in this equation is the same as the *h* in Equation 11. Using the previously defined coarse graining ingredients, the average particle property is then given by Equations 14 to 16.

$$\rho\bar{\psi} = \sum_p w_p m_p \psi_p \tag{14}$$

$$\rho(\vec{x}, t) = \sum_p w_p m_p \tag{15}$$

And:

$$w_p = K(\overrightarrow{\Delta x}, W) \tag{16}$$

where m_p is the mass of particle *p*, $\rho = \rho(\vec{x})$ is the average density at the probe point, and w_p a normalised weighting function (normalised spatial Gaussian kernel function) centered on the probe point $\vec{x}$. The property fluctuation $\tilde{\psi}_p$ is given by:

$$\tilde{\psi}_p = \tilde{\psi} - \tilde{\psi}_p(\vec{x}_p) \tag{17}$$

which is an improvement to the original work by Babic (1997).

Artoni and Richard (2015) showed that $\bar{\psi}_p(\vec{x}_p)$ can be approximated by:

$$\bar{\psi}_p(\vec{x}_p) \cong \bar{\psi}(\vec{x}) + (\vec{x}_p - \vec{x})\vec{\nabla}\bar{\psi}(\vec{x}) \tag{18}$$

So the property fluctuation, which is now said to be insensitive to coarse graining width, reduces to:

$$\tilde{\psi}_p = \tilde{\psi} - \bar{\psi}(\vec{x}) - (\vec{x}_p - \vec{x})\vec{\nabla}\bar{\psi}(\vec{x}) \tag{19}$$

Artoni and Richard (2015) also showed that the gradient of the average property (like, say, the shear rate) is:

$$\rho\vec{\nabla}\bar{\psi} = \sum_p(\vec{\nabla}w_p)m_p\psi_p - \bar{\psi}\sum_p(\vec{\nabla}w_p)m_p \tag{20}$$

The above methodology was used to calculate the smooth, average particle property distributions at each voxel within the azimuthal plane of interest. The basic properties include:

- Shear rate tensor: $\dot{\gamma}_{ij}$
- Granular temperature tensor: θ_{ij}

RESULTS AND DISCUSSION

The data is analysed for both three- and five-millimetre DEM data gathered over speeds of 60 and 75%N_c. We extract both the 2D azimuthal maps and perform analysis along centrally located radial lines taken perpendicular to the free surface. To extract the azimuthal profiles, we apply the following steps to the DEM data:

1. Discretise the azimuthal plane of the drum into voxels of dimensions ($d \times d \times \ell$) where d = 6 mm and ℓ = 285 mm is the drum length.
2. Bin the particle positions:
    - Once the simulation is running at steady state, the DEM data is binned at N = 1000 consecutive 10^{-3} s timesteps which is approximately a single revolution of the drum.
    - We apply coarse graining using a Gaussian smoothing kernel on the DEM data simply to smooth out the pixilation introduced by the bin edges. The effects of this convolution mediated smoothing are detailed in Moodley and Govender (2022).

Stresses

The stress field is an important entity in terms of the analysis of tumbling mills. It is a continuum representation of the average force per unit area of the contacting particles which ultimately drives fines production. The overall shear stress, deviatoric shear stress and pressure components are shown in Figure 4. Given that we were unable to validate the DEM data in the cataracting regime due to the poor PEPT tracer coverage, the profiles are necessarily truncated to the region below the free surface.

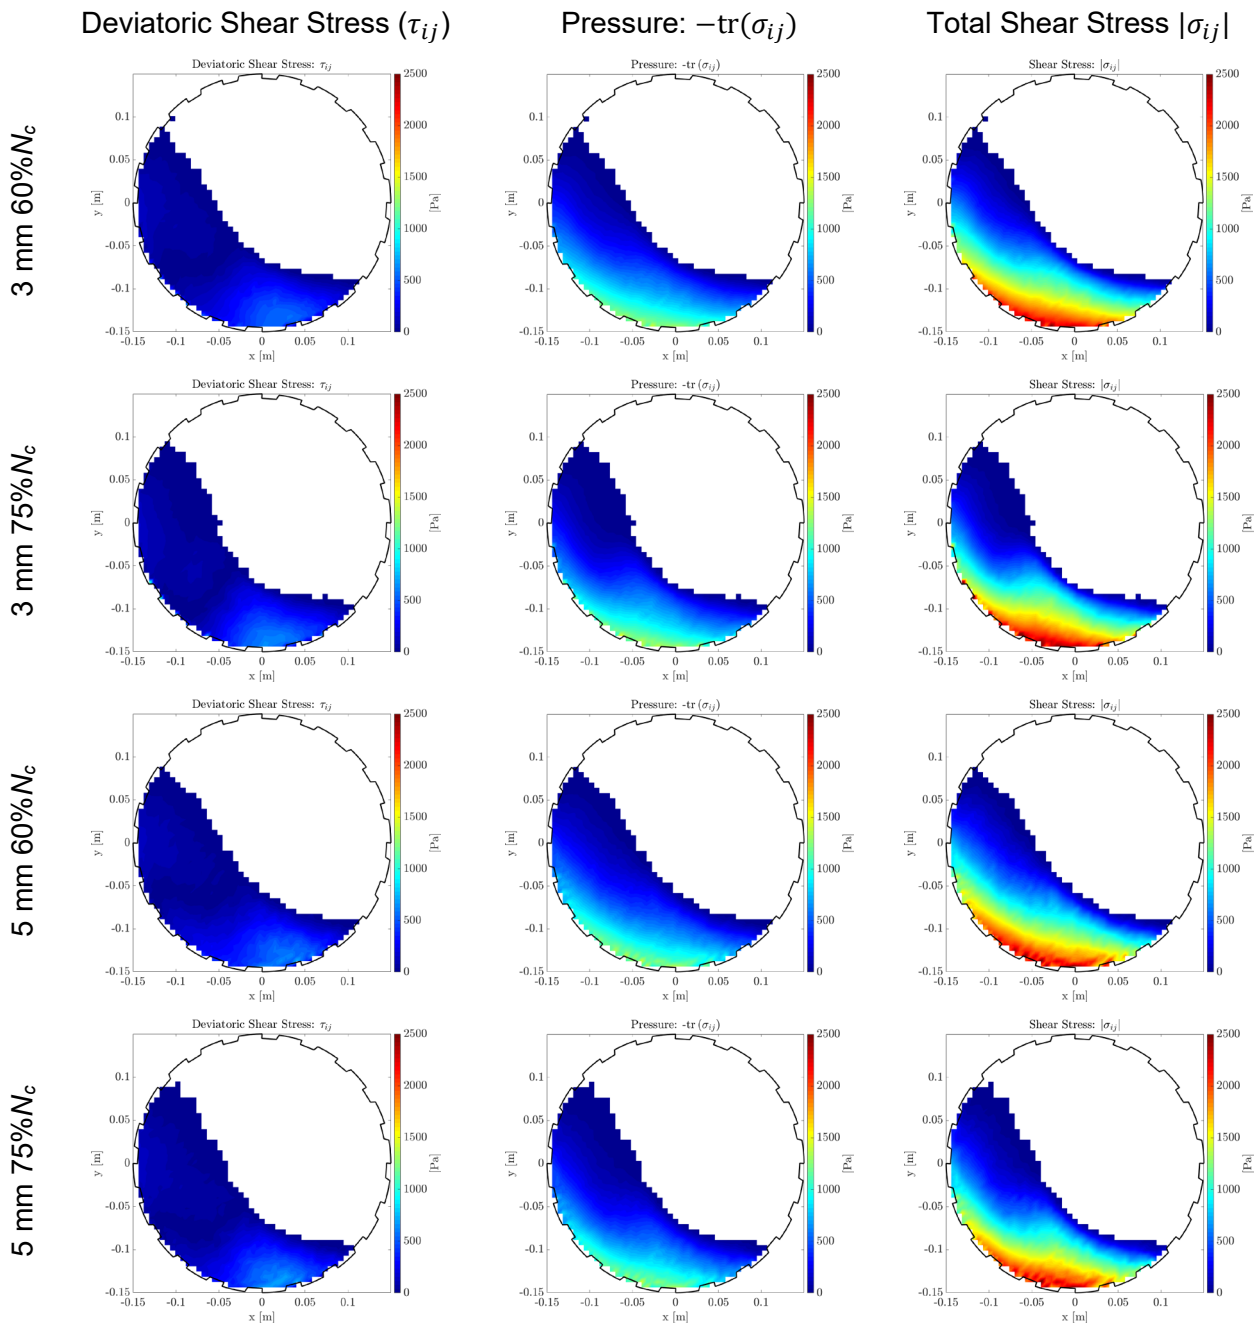

FIG 4 – Stress profiles.

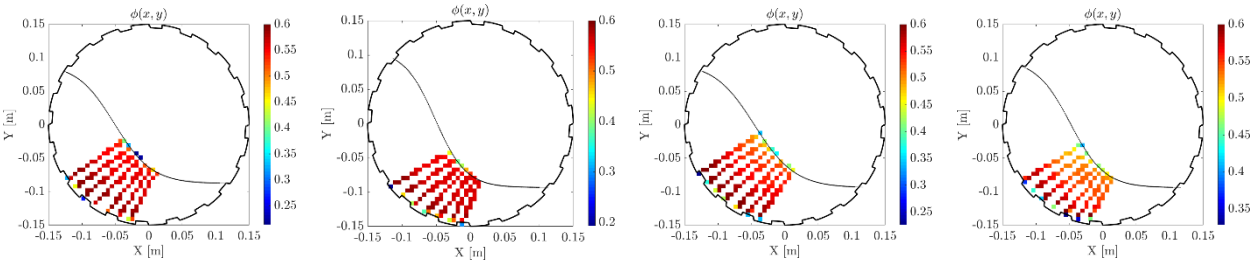
The magnitude of the shear stress profiles range from 0 to 2500 Pa. The average pressure (or normal stress) dominates over the deviatoric stress by a factor of approximately two ie $2\langle\tau_{ij}\rangle \sim \langle P\rangle$; this relationship is similar to that reported by Govender and Pathmathas (2016). The stresses at the free surface are small, but non-zero. The maximum magnitude of the Total Shear Stress (denoted by the red hotspot) occurs near the toe region and in particular, along the mill shell. The deviatoric profiles exhibit a more concentrated smaller region of higher stress (light blue hotspot near the toe region) compared to the pressure. This implies that shear type contacts are more concentrated in a region and normal type contacts occur over a wider area. The particles near the free surface exhibit liquid like behaviour and therefore have a lower solids fraction compared to the particles towards the base of the bed which exhibit solid body rotation. In fact, these particles often form a rigid layer near the lifter bars. This implies that there is a higher probability of collisions near the base of the drum which is supported by the Pressure data. The deviatoric stress would rely on large velocity differences which is why is it predominantly concentrated near the turbulent toe region of the bed.

A radial analysis was undertaken for each of the 5 mm and 3 mm bead sets, in which centrally located slices were chosen and data along these slices binned. Thus, an error bar analysis, based

on the standard deviation, is introduced. The slices were taken perpendicular to the free surface. Being centrally located within the bed has its advantages, discussed by Govender (2016), which are that the properties are homogeneous, and the flow is unidirectional and fully developed with maximum thickness of the flowing layer. The slices taken from each of the corresponding solids fraction maps (Moodley and Govender, 2020) are shown in Figure 5.



(a) 3 mm 60%N_c (b) 3 mm 75%N_c (c) 5 mm 60%N_c (d) 5 mm 75%N_c

FIG 5 – Centrally located slices taken from the solids fraction maps (Moodley and Govender, 2020).

The data from the slices in Figure 5 are subsequently collated to produce Figure 6.

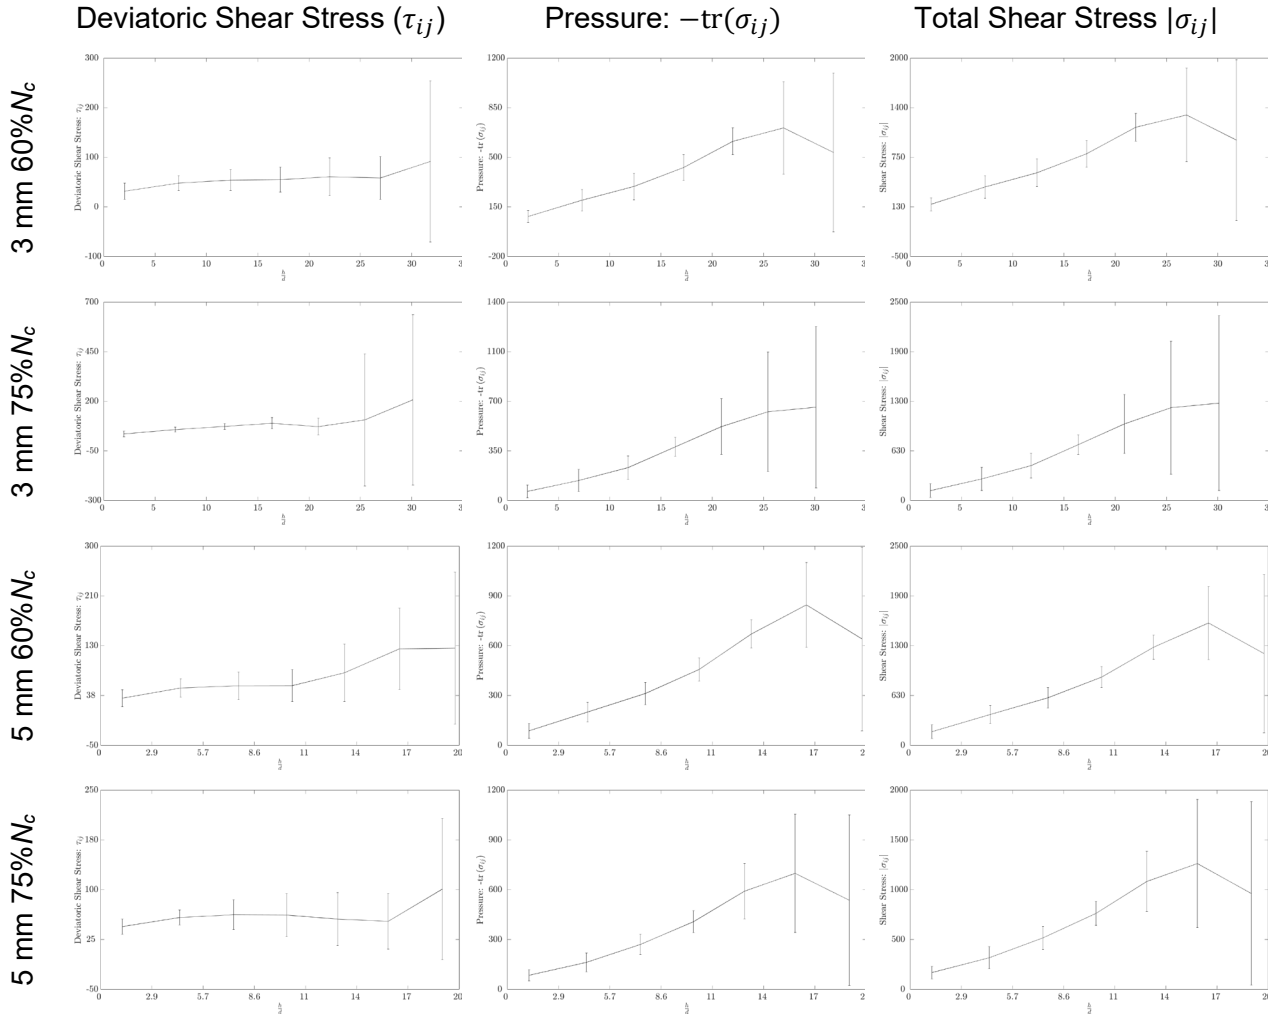


FIG 6 – Binned stress profiles.

The profiles in Figure 6 are generated by binning all the data in the respective bins arranged along with the bed depth where a value of $\mathrm{h/d} = 0$ corresponds to a location on the free surface. The error bars are more pronounced near the azimuthal walls indicating that we have low confidence of stress

in this region. This region corresponds to the hotspots of the deviatoric and pressure stresses seen in Figure 4. The fact that the profiles for the devaitoric shear stress are rather flat as we move from the free surface towards the middle of the bed indicates that it would be difficult to use these values to characterise the flow in these regions. The Pressure values show significant changes with depth which could be the reason it is incorporated in the $\mu(I)$ rheology. To a first order approximation, the pressure profile varies linearly with depth. It is interesting to note that for all experiments, except the 3 mm at 75%N_c, there is a drop-off in magnitude of the pressure near the azimuthal wall and seeming rise in deviatoric shear stress in this region. The effective friction profiles, $\mu(\mathrm{I}) = \left|\frac{\tau}{\mathrm{P}}\right|$, are given in Figure 7.

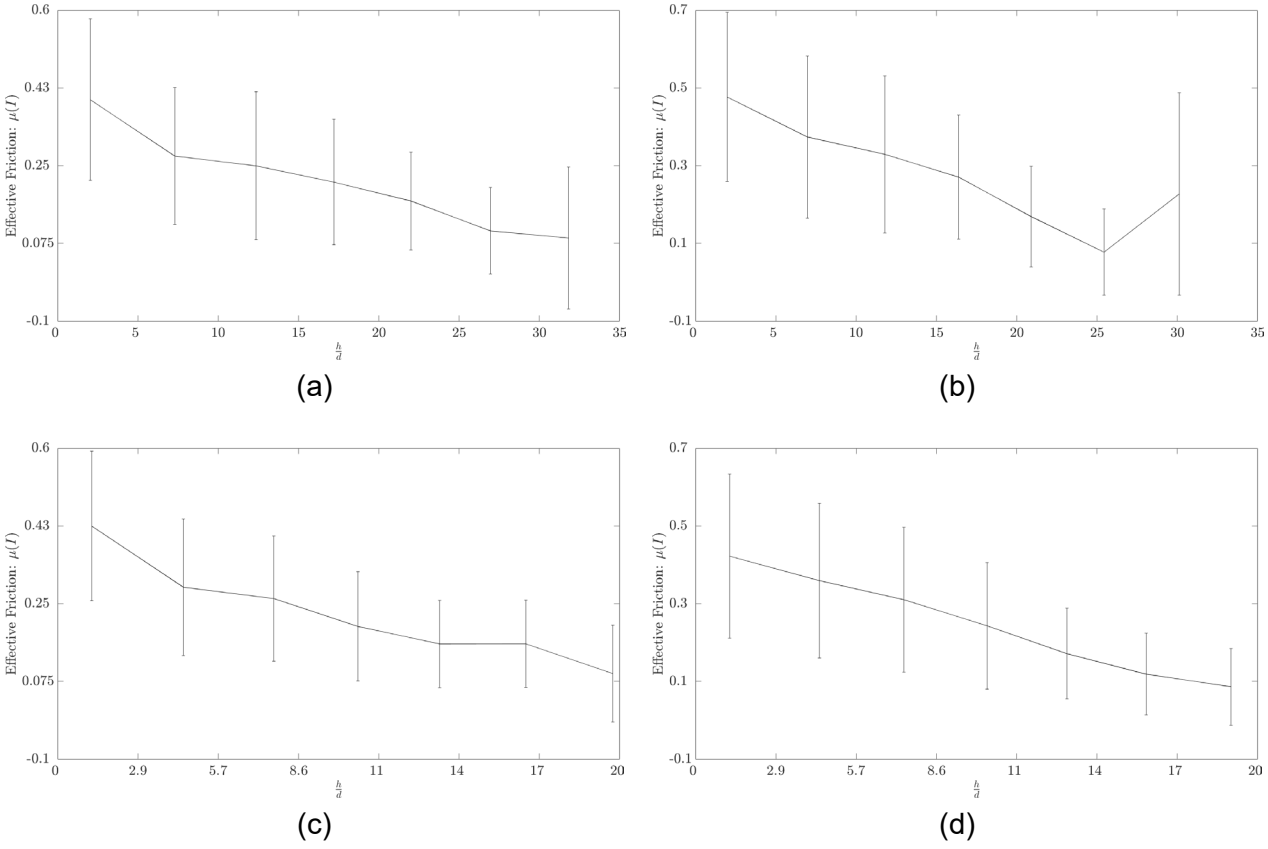

FIG 7 – Effective friction profiles. (a) 3 mm 60%N_c; (b) 3 mm 75%N_c; (c) 5 mm 60%N_c; (d) 5 mm 75%N_c.

The effective friction coefficient captures the relative contributions of shear and normal stresses to the $\mu(\mathrm{I})$ rheology. The values range from ≈ 0.5 at the free surface to ≈ 0.1 at the azimuthal shell. In the case of both bead sizes, we notice that the effective friction is directly proportional to the mill speed. To a first order approximation, the effective stress profile decreases linearly with depth. The 3 mm 75%N_c profile has a sudden increase in effective friction near the azimuthal shell. The reasons for this will have to be investigated but it is hypothesized that the region near the lifter bars may induce slip velocity.

Shear rate

Tumbling mills must produce consistent product grinds upfront or face potentially detrimental effects on downstream processes. Slurry transport through the mill is one of a variety of parameters that influence grinding efficiency. Accurate determination of the shear rate is vital to quantify the slurry viscosity – a key parameter in evaluating slurry transport. Figure 8 shows the magnitude of the shear rate, produced using the Artoni and Richard (2015) model, for the DEM data.

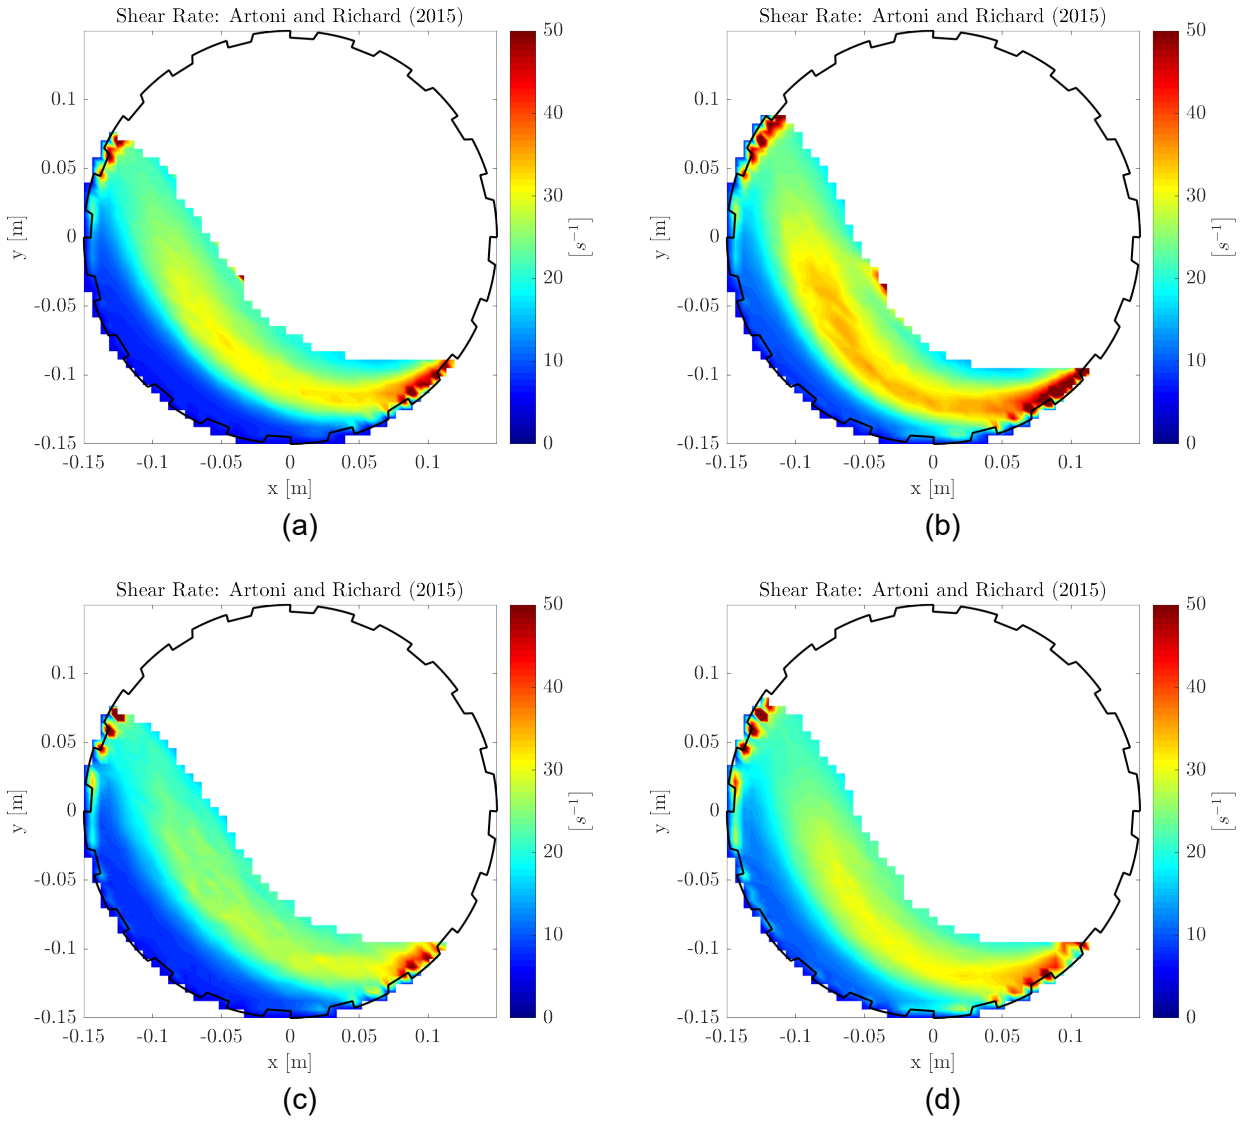

FIG 8 – Shear Rate profiles: (a) 3 mm 60%N_c; (b) 3 mm 75%N_c; (c) 5 mm 60%N_c; (d) 5 mm 75%N_c.

The shear rate varies between 0 and 50 s^{-1} for all configurations. It is also evident that the larger speeds produce larger shear rates, which is expected due to the increased particle velocities. The shear rate hotspot (red) is concentrated near the toe region across all configurations. The flow in this region is known to be highly turbulent and induces velocity fields which are highly chaotic; see *cf* Moodley and Govender (2020) for further details.

Figure 9 suggests that the shear rates are largest near the free surface $(\mathrm{h/d} = 0)$ and decrease steadily with depth. The higher speeds (75%N_c) result in slightly higher shear rate values for both glass bead sizes.

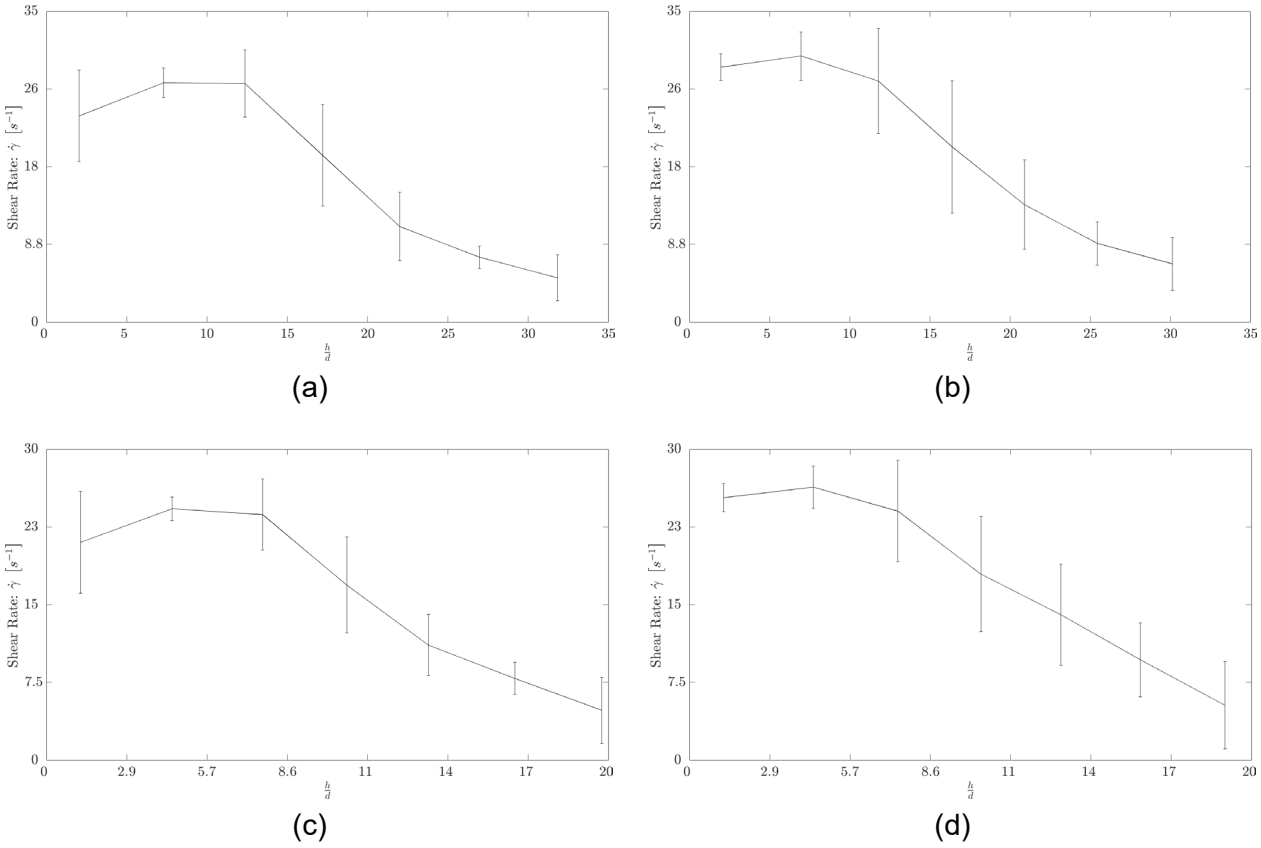

FIG 9 – Binned shear rate profiles. (a) 3 mm 60%N_c; (b) 3 mm 75%N_c; (c) 5 mm 60%N_c; (d) 5 mm 75%N_c.

Inertial number

Combining the shear rate and pressure profiles allows one to evaluate the inertial rheology of the system; the azimuthal Inertial number fields are shown in Figure 10.

The inertial number spans a range of $0.1 < \mathrm{I} < 0.7$. Figure 10 suggests that there is predominantly shear dominated flow (red hotspots) near the shoulder region of the free surface. This is expected due to the inertial regime that is characterised by high shear rates. This gradually reduces until it is replaced by low inertial numbers (pressure dominated flow) near the azimuthal wall as depicted by the relatively cooler (blue) colours.

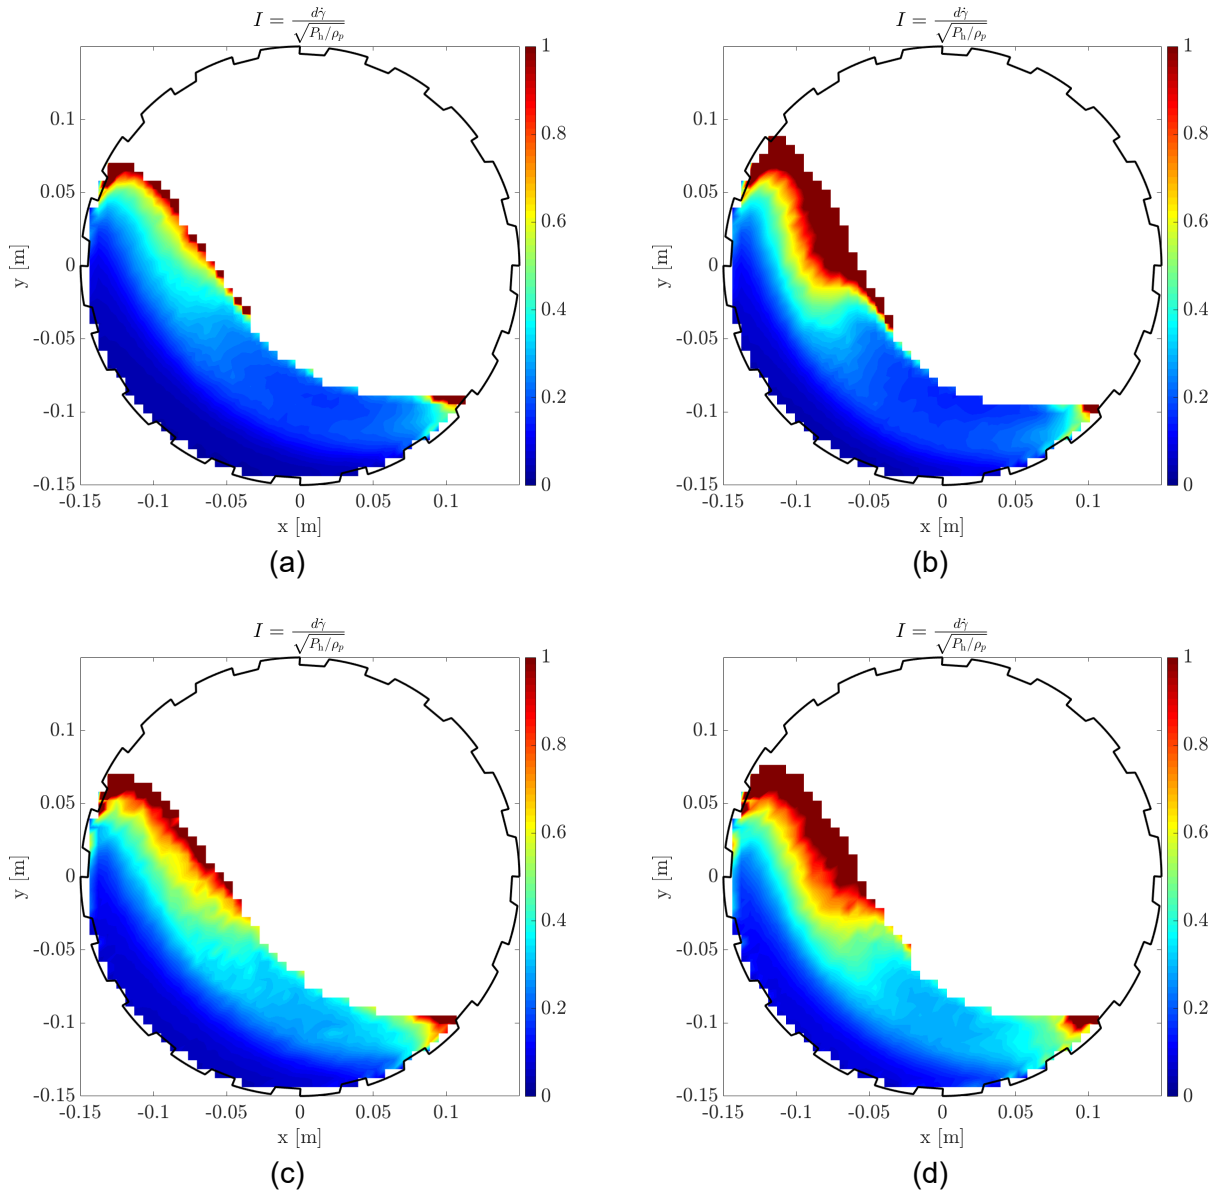

FIG 10 – Inertial Number profiles. (a) 3 mm 60%N_c; (b) 3 mm 75%N_c; (c) 5 mm 60%N_c; (d) 5 mm 75%N_c.

Visual inspection of Figure 11 suggests that the inertial number varies similarly for both bead sets. The higher speeds (75%N_c) result in slightly higher, but statistically insignificant, inertial number values. The inertial number drops exponentially from the free surface as the depth increases until it begins to remain relatively constant as it approaches the azimuthal wall (flattish profile). These flattish profiles near the azimuthal wall are expected since the bed exhibits a high solids fraction (≈ 0.6); this results in the formation of stress chains which is not accounted for in the rheology. The results indicate that the Inertial number rheology may only be used for modelling the dilute inertial regime near the free surface.

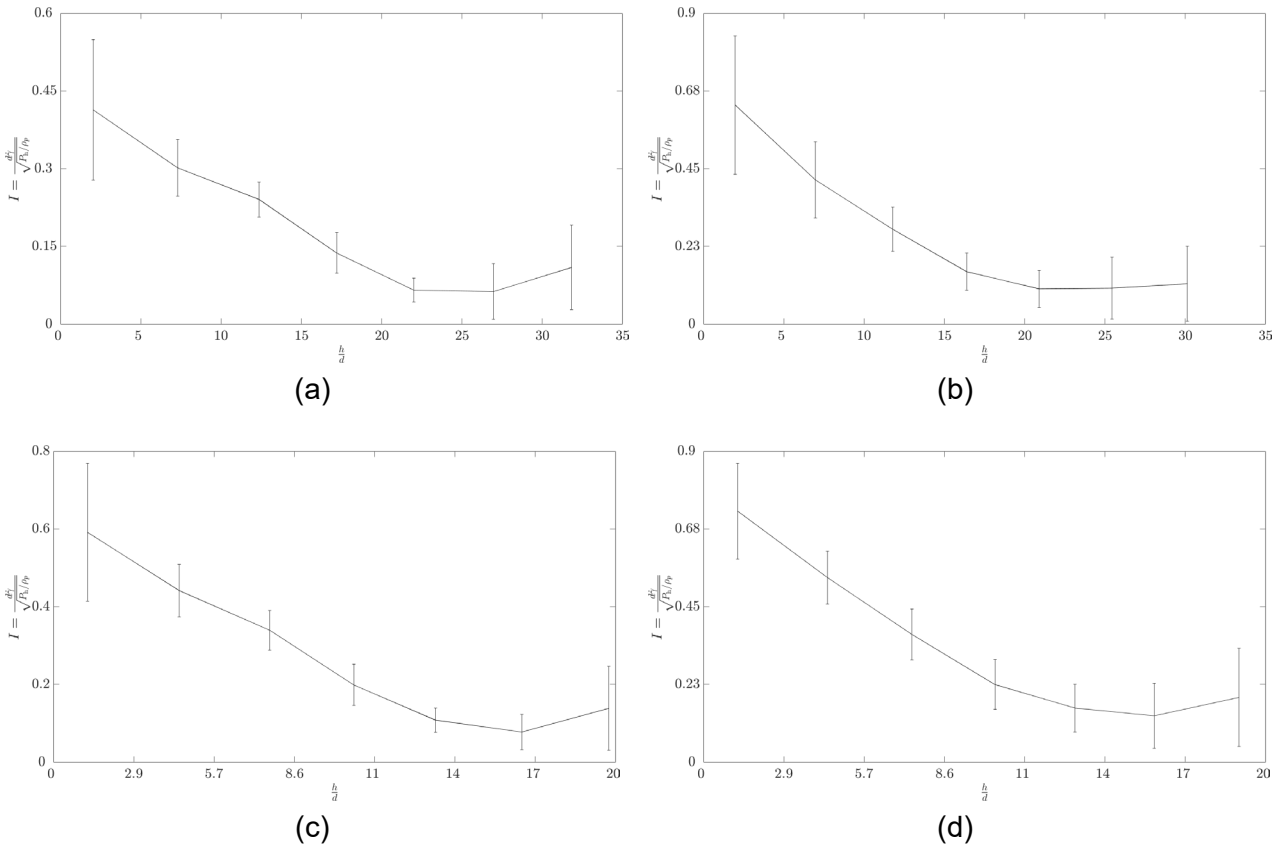

FIG 11 – Binned Inertial Number profiles. (a) 3 mm 60%N_c; (b) 3 mm 75%N_c; (c) 5 mm 60%N_c; (d) 5 mm 75%N_c.

Granular temperature

Figure 12 represents the granular temperature profiles across all configurations. There are large velocity fluctuations present in the toe region (red hotspots) probably due to the cataracting particles re-entering the charge in this highly turbulent, chaotic region. These hotspots are more pronounced at higher rotational speeds (75%N_c) owing to the increased particle velocity.

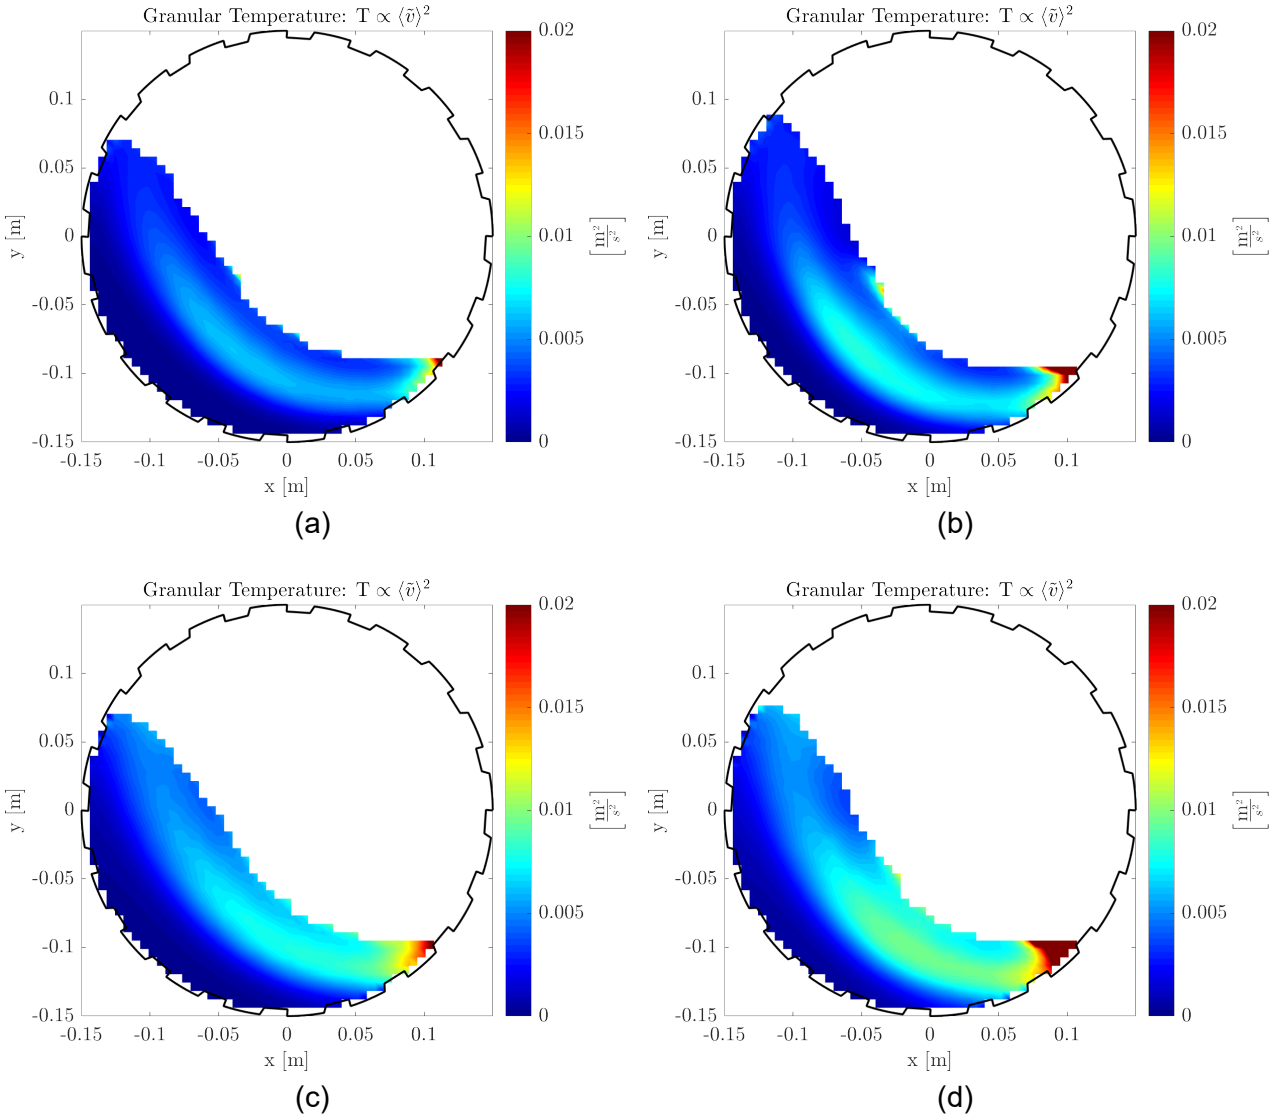

FIG 12 – Granular temperature profiles. (a) 3 mm 60%N_c; (b) 3 mm 75%N_c; (c) 5 mm 60%N_c; (d) 5 mm 75%N_c.

Visual inspection of Figure 13 suggests that the granular temperature varies similarly for both bead sets. The granular temperature ranges from 0.006 m^2/s^2 to 0.001 m^2/s^2. It initially rises just below the free surface $(\mathrm{h/d} = 3 \text{ to } 5)$ before decreasing exponentially with bed depth. Putting the information derived from the granular temperature, shear rate and shear stress data together enables one to investigate the modified – Pe number rheology.

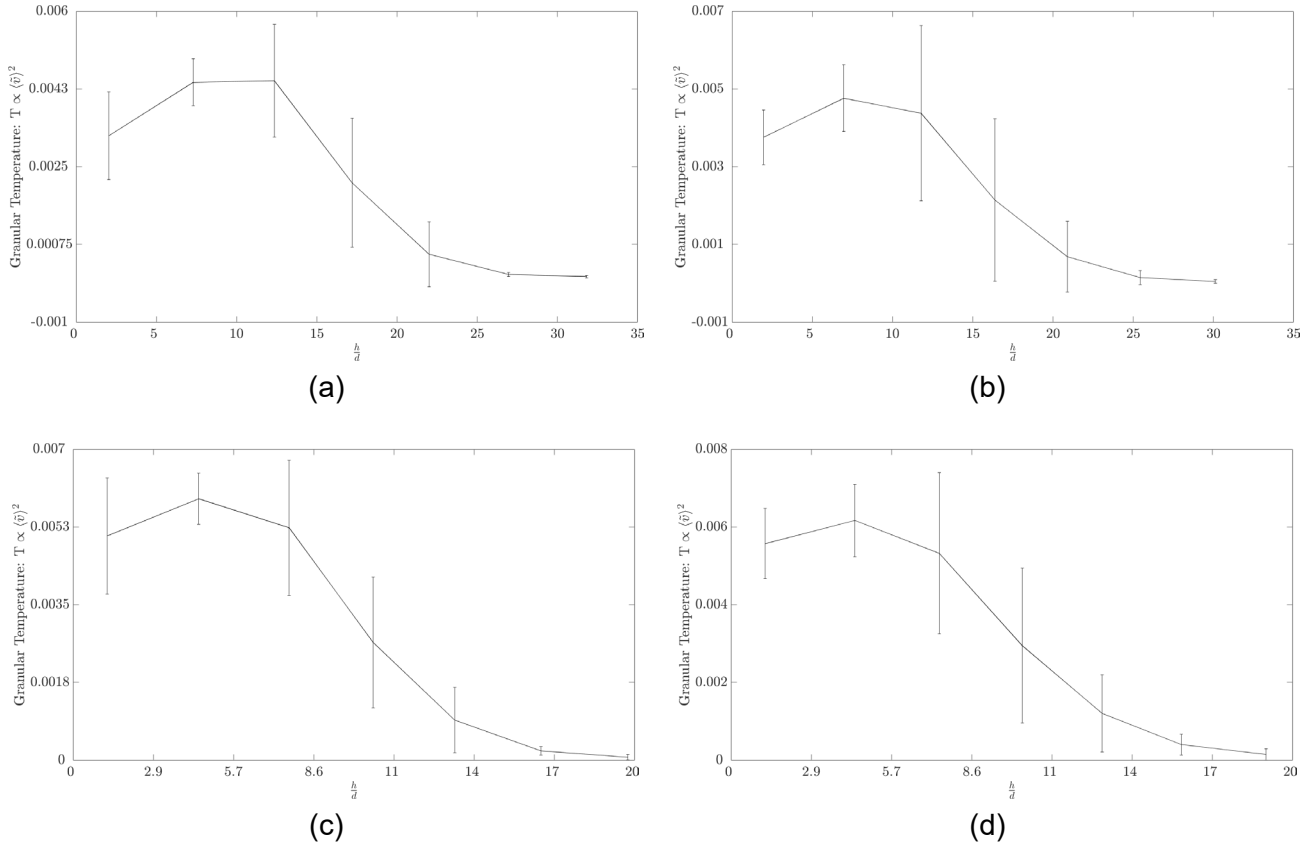

FIG 13 – Binned Granular Temperature profiles. (a) 3 mm 60%N_c; (b) 3 mm 75%N_c; (c) 5 mm 60%N_c; (d) 5 mm 75%N_c.

Modified Peclet number

Figure 14 represents the modified Peclet number profiles across all configurations. There is a relatively large region of large Pe values (red hotspots) lining the azimuthal wall all the way from the middle of the base of the drum towards the shoulder region. These hotspots correspond to regions of predominantly advective flow. On the other hand, lower values (cooler blue colours) which occupy an arguably larger proportion of the drum, correspond to a predominantly diffusive flow profile (Chialvo and Sundaresan, 2013).

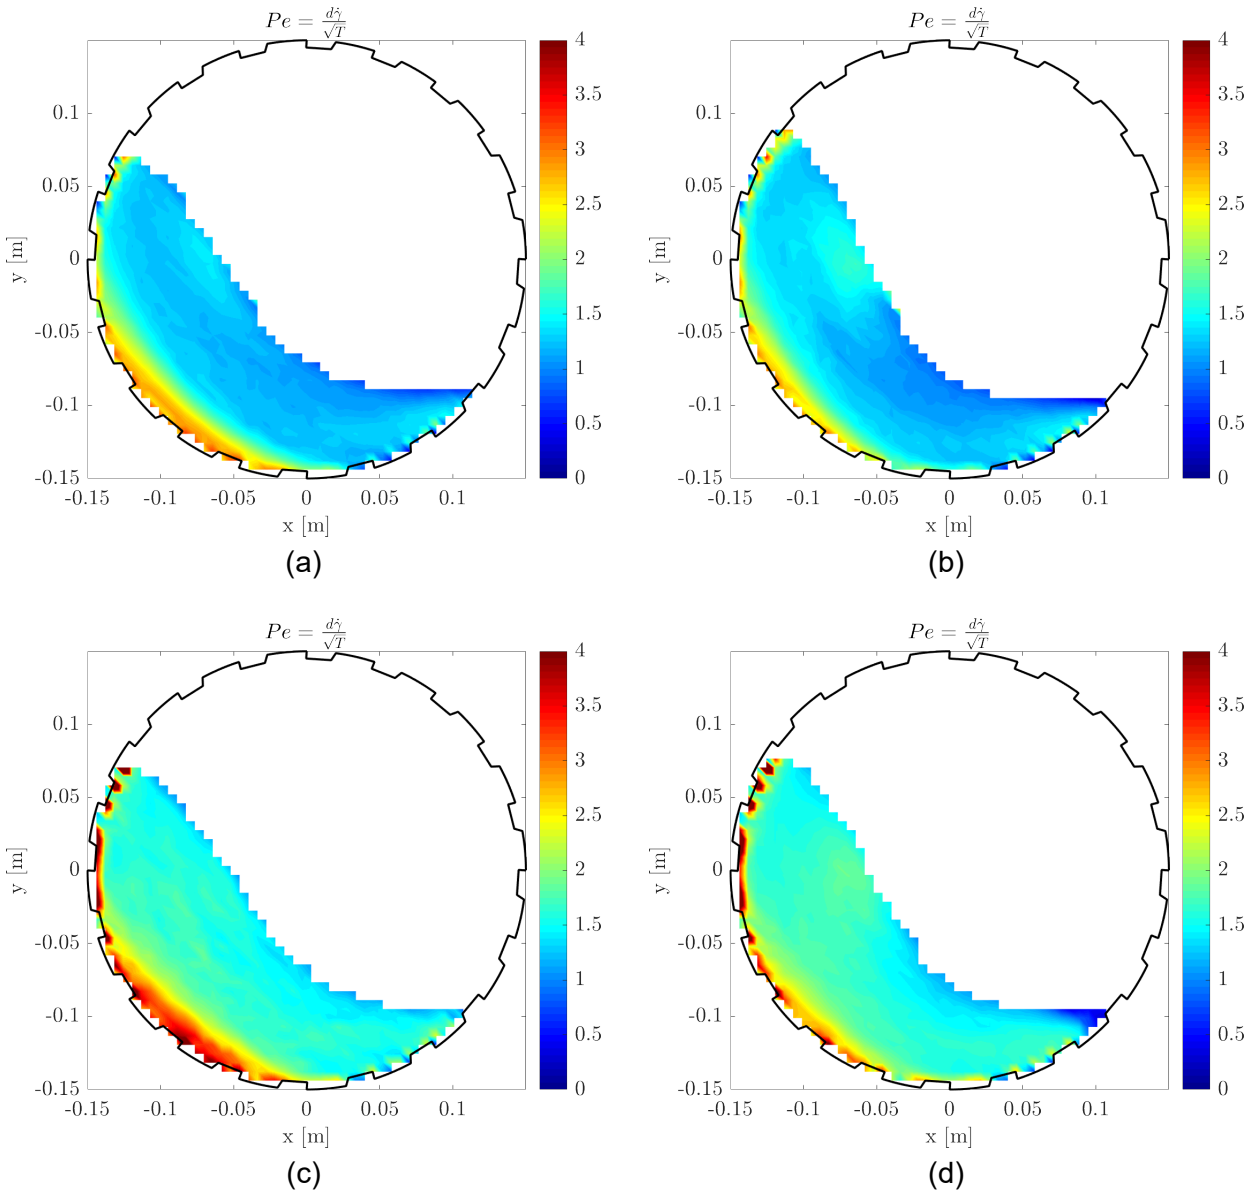

FIG 14 – Modified Peclet number profiles. (a) 3 mm 60%N_c; (b) 3 mm 75%N_c; (c) 5 mm 60%N_c; (d) 5 mm 75%N_c.

Visual inspection of Figure 15 suggests that the modified Pe number varies similarly for both bead sets. The modified Pe number ranges from 0.8 to 1.2. It is relatively constant between the free surface (h/d = 0) until approximately halfway through the bed. This implies that it is very difficult to delineate these regions based on the value of the Pe number – a fact that makes granular materials extremely complex to model. Thereafter it increases exponentially before steadying just before reaching the azimuthal shell. The higher speeds (75%N_c) result in slightly higher, but statistically insignificant, modified Pe number values.

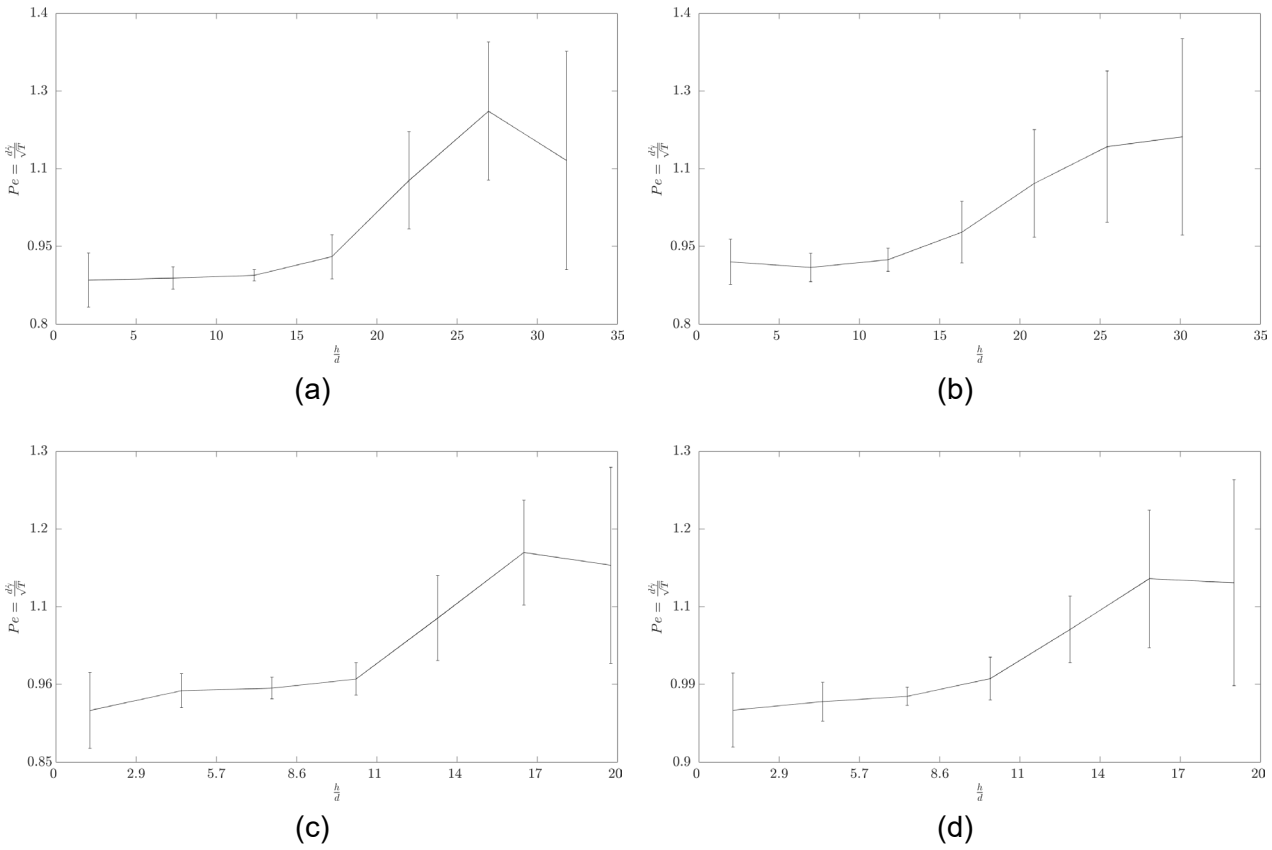

FIG 15 – Binned Modified Pèclet Number profiles.

CONCLUSIONS

The goal of this work was to investigate critical rheological parameters (shear rate, shear stress, granular temperature etc) which are key to not only developing a granular rheology, but will ultimately be used to tune our mechanistic models. The shear stress, comprising of both deviatoric and normal tensorial components, was found to vary between 0 to 2500 Pa. The maximum shear stress occurs along the base of the bed closest the azimuthal wall which is where the highest solids fraction is prevalent. These particles in this region have high probability normal collisions resulting in high values of Pressure in this region. In fact, the average pressure (or normal stress) dominates over the deviatoric stress by a factor of approximately 2 ie $2\langle\tau_{ij}\rangle\sim\langle P\rangle$. The effective friction $[\mu(\mathrm{I}) = \left|\frac{\tau}{\mathrm{P}}\right|]$, in the case of both bead sizes, is directly proportional to the mill speed and decreases linearly with increasing depth. The shear rate varies between 0 and 50 s^{-1} for all configurations. It is also evident that larger speeds produced larger shear rates, which is expected due to the increased particle velocities. Future work in this regard will involve the comparisons of the Povall *et al* (2021) derived granular temperature to those from Artoni and Richard (2015).The inertial number spans a range of $0.1 < \mathrm{I} < 0.7$ with shear dominated flow near the free surface and pressure dominated flow near the mill shell – a fact that is supported by the shear stress tensorial analysis. Due to the inertial number not accounting for the force chains prevalent towards the middle of the bed, the inertial number rheology may only be used for modelling the dilute inertial regime near the free surface. The granular temperature ranges from 0.006 m^2/s^2 to 0.001 m^2/s^2 with hotspots near the highly chaotic, turbulent toe region of the bed. Future work in this regard will involve the comparisons of the Artoni and Richard (2015) derived granular temperature to those from ROCKY-DEM. The modified Pe number ranges from 0.8 to 1.2 with a diffusive flow profile near the free surface region and an advective profile near the mill shell. The Pe number rheology showed a good ability to delineate behaviour near the mill shell but was poor in describing behaviour in the dilute inertial regime. Future work will involve incorporating the dimensionless temperature gradient $\mathrm{M} \equiv \frac{\mathrm{d}|\nabla T|}{T}$ which accounts for the inhomogeneity associated with non-local effects whose effects are highlighted near the yield stress limit. Ultimately, the relationship between T and μ_s*will be investigated.

ACKNOWLEDGEMENTS

The authors would like to extend their gratitude to fellow PTG members for their expertise in troubleshooting occasional coding irregularities. Finally, the authors are grateful for the continued financial support received from Mintek. The authors acknowledge ROCKY-DEM for the generous academic licensing of the DEM software.

ABSTRACT

Batch experiments in a 0.6 m diameter mill have shown that improvements of about 13 per cent in the efficiency of energy utilisation can be realised in ball mills by replacing 25 per cent of the ball charge by an equivalent volume of cost-free critical size pebbles from AG/SAG mills.

For a mill of a given size, speed and charge filling, the rate of size reduction of ore particles depends on (i) the frequency of grinding media collisions (ii) the probability of capture of ore particles between the colliding grinding media (iii) the probability of fracture of the captured particles. The probability of fracture depends on the magnitude of collision energy. The distribution of collision energy into shear and impact events determines the relative strengths of attrition breakage and impact breakage. The efficiency of energy utilisation depends on which of the two mechanisms of breakage is more desirable in a particular milling stage.

In this paper collision data from a series of DEM simulations of a mill charged with steel media and a mixture of steel media and pebbles is presented in energy spectra and spatial distribution maps. The data provides the necessary detail to elucidate the improvements in the efficiency of energy utilisation in ball mills when using a mixture of pebbles and steel media.

INTRODUCTION

Most mineral processing concentrators are now treating low-grade, more competent and complex ores than before. To remain profitable ways of reducing operating costs are sought. It is estimated that comminution contributes 30–50 per cent to the total cost of mineral processing (Zhang, 2016; Clermont and De Haas, 2010; Jankovic *et al*, 2006). Key to the cost of comminution is energy consumption and grinding media consumption.

The conventional grinding circuit for processing hard ores (eg copper-gold ores) typically consists of semi-autogenous grinding (SAG) primary mills, followed by one or two parallel ball mills per primary mill. Most research has been focused on stabilising and expanding throughput in SAG mills. The research has led to the inclusion pre-crushers before mills, operating the mills with very high steel ball loads and pebble crushing. It has been reported that pebble crushing can expand throughput by more than 15 per cent (Powell *et al*, 2015).

Ball milling is considered to be a well-understood grinding method. Most optimisation studies on ball milling are site-specific, where variables such as mill speed, ball filling level, ball top-up size, liner-lifter design and pulp density are optimised for varying feed properties (eg size distribution, hardness and mineralogy) to achieve an acceptable product size distribution. Ball mills are known to be costly to operate because of the cost of ongoing ball replacement. This cost can be as much as the cost of mill power consumption (Daniel *et al,* 2010).

Pebble milling is an alternative to ball milling. The main advantage of pebble milling is the cost-free grinding media. However, larger mills are required to draw an equivalent power and the availability of sufficient competent pebbles, particularly large ones, can be a concern.

Nkwanyana and Loveday (2018, 2017) reported on experimental work, which explored the use of the critical-size pebbles from a SAG mill as grinding media in ball mills (ie replacing a proportion of steel balls by an equivalent volume of pebbles). This provides the freedom to adjust the proportion of pebbles if the availability of pebbles varies. The data showed that any proportion of pebbles up to 25 per cent could be used in the ball mills, with no change in throughput and product size distribution, and the process is referred to as 'composite milling' in this paper.

The experimental results were a pleasant surprise, given that production of fines is normally considered to be proportional to power draw (or specific energy input) (Hilden and Suthers, 2010; Musa and Morrison, 2009; Levin, 1992). In this paper, it is contended that the production of fines in a mill is proportional to power draw if the following conditions hold:

- The distribution of power into dissipation through media collisions and dissipation through viscous stresses in the slurry remains the same when power draw changes.
- The distribution of the power dissipated in media collisions into head-on impacts (impact power) and shear (shear power) remains the same when power draw changes.

The distribution of the power dissipated in media collisions is influenced by the operating conditions such as speed, media filling level, and lifter-liner design (Cleary and Owen, 2019a; Djordjevic *et al,* 2004; Powell, 2001). It is also influenced by the shape and size distribution of media (Cleary and Owen, 2019b; Cleary, 2019; Weerasekara *et al*, 2016).

The shape and size distribution of critical size pebbles from SAG/AG mills are variable and inherently different from that of steel balls used in ball mills. The charge bed can be expected to dilate when steel balls and irregular shaped pebbles are mixed (Sinnott *et al,* 2011). Therefore, when comparing the production of fines from ball milling and composite milling, it should not be simply expected to be proportional to mill power draw; it is necessary to analyse the relative strengths of head-on impacts and shear events, and the charge packing.

This paper presents data from DEM simulations of a mill charged with steel balls and a mixture of steel balls and pebbles. The objective is to explain the experimental results reported in Nkwanyana and Loveday (2018, 2017). This paper is limited to an analysis to shear power, and makes the assumption that attrition is linked to shear power, and it is the dominant mechanism for the production of -75 µm material in a mill processing feed of size F_{80} <1 mm. It is acknowledged that head-on impacts also contribute to the production of -75 µm material. Future work will explore the contribution of both the mechanisms.

DEM SIMULATIONS

Overview

It is hypothesized that a 25/75 mixture of pebbles and balls results in the same production rate of fines as a load of steel balls only, despite a reduction in the specific energy input. This is because the shape of pebbles in a 25/75 mixture alters the distribution of collision power, in such a way that the shear power is comparable to that in a mill loaded with steel balls only.

For a mill of a given size, speed and charge filling, the rate of size reduction of ore particles depends on: (i) the frequency of grinding media collisions; (ii) the probability of capture of ore particles between the colliding grinding media; (iii) the probability of fracture of the captured particles. The probability of fracture depends on the magnitude of collision energy (shear/impact). DEM simulations of a mill give insight into this type of information. ROCKY-DEM®, a commercial software package, was used to carry out the simulations.

The first set of simulations briefly investigated the effect of shape, material and size grinding media on the distribution of collision power. The second set of simulations was set-up to replicate the regrind mill experiments and the secondary stage mill experiments described in Nkwanyana and Loveday (2018, 2017). The third set of simulations investigated the effect of mill diameter, mill speed and filling level on the distribution of collision power when changing from ball milling to composite milling.

Table 1 shows the set-up of the simulations. Table 2 shows the seasoned size distributions of media used in the first set of simulations. The seasoned loads simulate steady state size distributions in a mill topped-up with 37.5 mm and 75 mm media (assuming the wear of media can described by the surface area model (Vermeulen *et al,* 1983)).

TABLE 1

Simulation set-up.

	First set of simulations	**Second set of simulations**	**Third set of simulations**
Mill dimensions (D × L)	1.2 m × 0.3 m	0.6 m × 0.5 m	1.2 m × 0.3 m
Mill speed	29 rev/min (75% *Nc*)	38 rev/min, 43 rev/min (69% *Nc*, 75% *Nc*)	26 rev/min, 29 rev/min 32 rev/min (68% *Nc*, 75% *Nc*, 83% *Nc*)
Mill filling	33%	25%, 33%	28%, 33%, 40%

TABLE 2

Media size distribution for the first set of simulations.

Size (mm)	**Seasoned Load 1 mass (%)**	**Seasoned Load 2 mass (%)**
-75.00 + 65.00	-	43.62
-65.00 + 53.00	-	31.51
-53.00 + 37.50	-	19.03
-37.50 + 26.50	78.34	4.48
-26.50 + 19.00	15.71	1.03
-19.00 + 13.20	5.95	0.32

For the second and third set of simulations, the steel balls were spheres and the rounded pebbles were an equal mixture (on mass basis) of four shapes shown in Figure 1. The size distribution of the media used in the second set of simulations is shown in Table 3. For the third set of simulations, the size distribution of steel balls and pebbles were set-up to be the same as that of steel balls in secondary stage mill shown in Table 3.

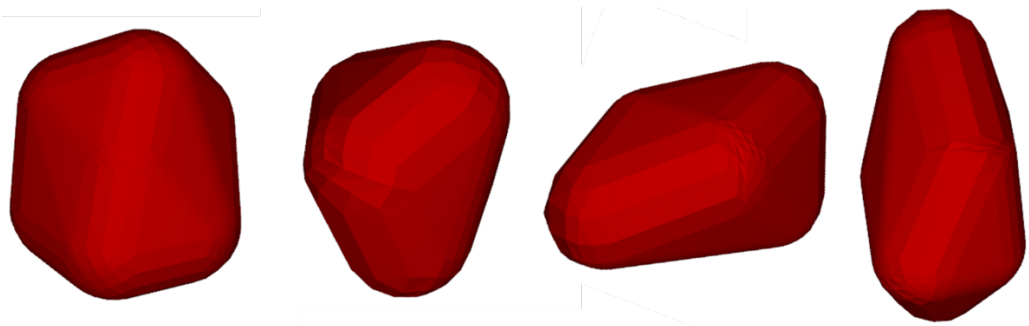

FIG 1 – Rounded pebble shapes.

TABLE 3

Media size distribution for the second and third set of simulations.

Size (mm)	Steel balls for regrind mill	Pebbles for regrind mill	Steel balls for secondary stage mill	Pebbles for secondary stage mill
-75.00 + 63.00	-	7.65	13.26	7.54
-63.00 + 53.00	-	12.10	24.34	22.36
-53.00 + 37.50	-	29.22	47.76	37.48
-37.50 + 26.50	78.34	23.02	11.25	21.27
-26.50 + 19.00	15.71	23.68	2.59	9.06
-19.00 + 13.20	5.95	4.33	0.81	2.30

Mill geometry

Figure 2 shows the 1.2 m diameter mill (left) and 0.6 m diameter (right). The material property of the mills was defined by three parameters, which were the density = 7850 kg.m^{-3}, Young's modulus = 1 × 10^{11} N.m^{-2} and Poisson's ratio = 0.3.

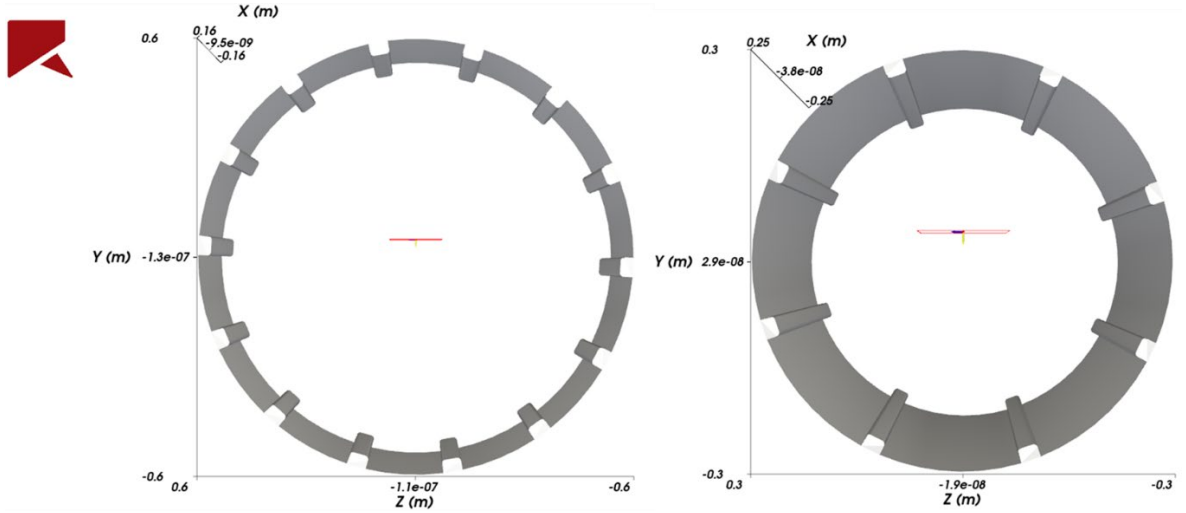

FIG 2 – Mill geometries used in the simulations.

Material contact parameters

The Hertzian spring-dashpot law was chosen to model normal contact force, and the Mindlin-Deresiewicz law was chosen to model the tangential contact force. These contact force laws have been used widely in simulation studies which had energy dissipation as a parameter of interest (Weerasekara *et al*, 2016; Bbosa *et al,* 2016; Carvalho, 2013; Sarracino *et al,* 2004). Table 4 shows the material interaction parameters used in the simulations.

TABLE 4

Material interaction parameters.

Contact type	Coefficient of friction	Coefficient of restitution
Steel-Steel	0.2	0.3
Steel-Rock	0.25–0.3	0.3
Rock-Rock	0.35–0.4	0.2

The choices of the coefficient of restitution were based on the following research work: Carvalho and Tavares (2013); Tavares and Carvalho (2010); Weerasekara and Powell (2010); Kulya (2008); Dong and Moys (2002), which used the same contact model as that used in the simulations. The coefficient of friction for steel-rock and rock-rock was adjusted between the ranges shown, such that the power draw (calculated by the torque method) and the power dissipation (calculated from collision energy losses) were comparable, and similar to the power draw measured from the 0.6 m diameter mill loaded with media only. This adjustment had a negligible effect on the distribution of power between shear and impact events.

RESULTS AND DISCUSSION

The effect of media shape, size and material

The simulations investigated the effect of shape, size distribution and material of grinding media, on the distribution of power which is dissipated in media collisions. Figure 3 shows the snapshots of the charge in motion (colour-coded by translational speed, dark blue corresponding to almost 0 m/s and orange corresponding to highest speed of ~4.6 m/s).

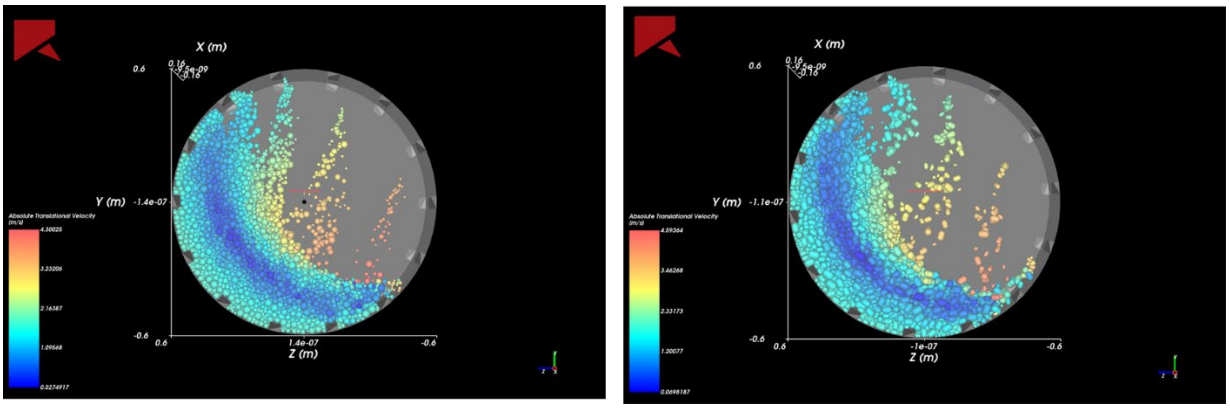

FIG 3 – Snapshot of the charge in motion (Left: spheres, Right: sphero-cylinders).

The primary source of energy dissipation during a collision is related to the inelastic nature of the contact force (F_c). The dissipation work done by this force (W^{diss}) and power (P^{diss}) are calculated using Equations 1 and 2. The integral is defined over the entire collision interval (loading and unloading):

$$W^{diss} = -\int F_c . v_c^{rel} dt \tag{1}$$

$$P^{diss} = \frac{\sum_{k=1}^{k}(W^{diss})}{\Delta t_{out}} \tag{2}$$

where v_c^{rel} is the instantaneous relative velocity at the contact point, *k* is the number of collisions occurring within the time interval Δt_{out}. The total contact force is given by Equation (3):

$$F_c = F_n . \hat{n}_c + F_t \tag{3}$$

where F_n and F_t are, respectively, the normal and tangential components of the contact force, calculated by contact models mentioned in section 2.3. Additionally, $\hat{n}_c$ is the normal unit vector of the contact.

The shear work (W^{shear}) is calculated using Equation (4):

$$W^{shear} = -\int F_t . ds_t \tag{4}$$

where ds_t is the sliding distance, that is, the displacement parallel to the tangential plane of the contact. The integral is defined over the entire collision interval. The difference of Equations 1 and 4 gives the impact work.

Figures 4 and 5 show the variation in the distribution of power when the shape of media is changed from spheres to sphero-cylinders.

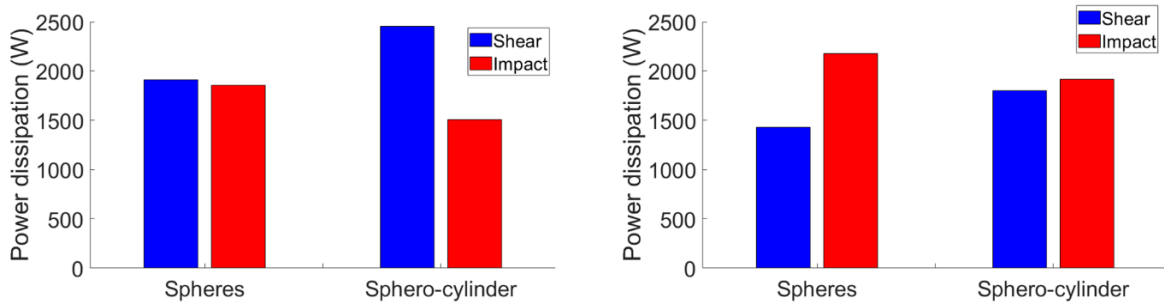

FIG 4 – Power dissipation of steel media: 37.5 mm top-up size (left) and 75 mm top-up size (right).

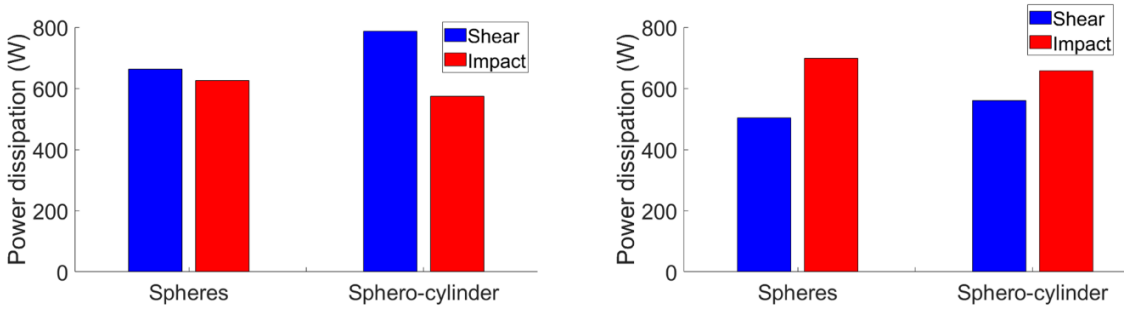

FIG 5 – Power dissipation of rock media: 37.5 mm top-up size (left) and 75 mm top-up size (right).

It is evident in Figures 4 and 5 that the shape of media has a notable influence on the distribution of power. For simulations of steel media with top-up size of 37.5 mm, changing from sphere to sphero-cylinder increased the proportion of shear power from 51 per cent to 62 per cent. For simulations of steel media with top-up size of 75 mm, changing from sphere to sphero-cylinder increased the proportion of shear power from 40 per cent to 48 per cent. The impact component reduced proportionately. Similar trends can be deduced from the simulations of rock media.

The non-spherical media are not able to rotate as easily as the spherical ones, which causes them to slide rather than rolling. The increase in the proportion of shear power in Figures 4 and 5 reflects the increase in the incidences of sliding contacts instead of rolling contacts within the load; similar results have been observed by Cleary (2019).

The effect of grinding media shape on specific breakage rates has been studied experimentally by the following authors: Simba and Moys (2014); Ipek (2006); Shi (2004); Kelsall *et al* (1973). The differences in specific breakage rates, resulting from different media shapes, have been attributed to the changes in the contact surface area. The data presented in Figures 4 and 5 demonstrate that, in addition to the changes in the contact surface area, the differences in specific breakage rates are caused by the changes in the relative strengths of grinding mechanisms (ie head-on impacts versus shear events).

It is evident in Figures 4 and 5 that the size of media also has a notable influence on the distribution of power. For simulations of spherical steel media, changing the top-up size from 37.5 mm to 75 mm reduced the proportion of shear power from 51 per cent to 40 per cent. For simulations of sphero-cylinder steel media, changing the top-up size from 37.5 mm to 75 mm reduced the proportion of shear power from 62 per cent to 48 per cent. The impact component increased proportionately.

Additional simulations using steel media of mono-sizes of 60 mm, 50 mm, 40 mm, 30 mm and 20 mm (and seasoned loads simulating topping up with these sizes) were carried out. The simulations are not reported here, but it can be mentioned that the data showed similar trends, the proportion of impact increases with media size.

The effect of media size on specific breakage rates is detailed in Austin *et al* (1984); and other authors, eg Katubilwa and Moys (2009); Teke *et al* (2002); Herbst and Lo (1989), have demonstrated similar effects. Comparing media of same shape and material, the data presented in Figures 4 and 5 demonstrate that the response of specific breakage rates of ore particles to changes in media size is also a result of changes in the relative strengths of grinding mechanisms.

It is evident in Figures 4 and 5 that the grinding medium material has a marginal influence on the distribution of power. For simulations of spheres with top-up size of 75 mm, changing medium material from steel to rock increased the proportion of shear power from 40 per cent to 42 per cent. For simulations of sphero-cylinders with top-up size of 75 mm, changing medium material from steel to rock reduced the proportion of shear power from 48 per cent to 46 per cent.

The data in in Figures 4 and 5 suggests that in composite milling there may be a complex interrelationship between grinding medium size, shape and material, and the distribution of the power dissipated in collisions. The following sections explore this interrelationship.

Ball milling versus composite milling – power dissipation

Lab-scale mill (0.6 m diameter) simulations

The simulations replicated the experiments in terms of media filling level, mill rotational speed, and medium size distribution and material (described in Nkwanyana and Loveday (2017, 2018)). The simulations did not include the slurry. The following assumptions were made prior to the analysis of the simulation data:

- The slurry does not change the flow behaviour of the grinding media significantly, as mentioned by Cleary *et al* (2006) and observed by Katubilwa and Moys (2011).
- The ratio of shear power to impact power in a simulation that includes the slurry is approximately the same as that in a simulation that does not include the slurry; ie the drag force from the viscous slurry only dampens the collisions.
- The influence of media shape on the distribution of power into dissipation through media collisions and viscous stresses in the slurry is negligible.

Figures 6 and 7 show the distribution of power dissipated in collisions in ball milling and composite milling. The data used to construct the plots is from simulations which set-up were using the coefficients of restitution listed in Table 4. However, similar trends were also observed using the following coefficients of restitutions: steel-steel = 0.5, steel-rock = 0.5, 0.4, and rock-rock = 0.3, and are reported elsewhere (Nkwanyana, 2021).

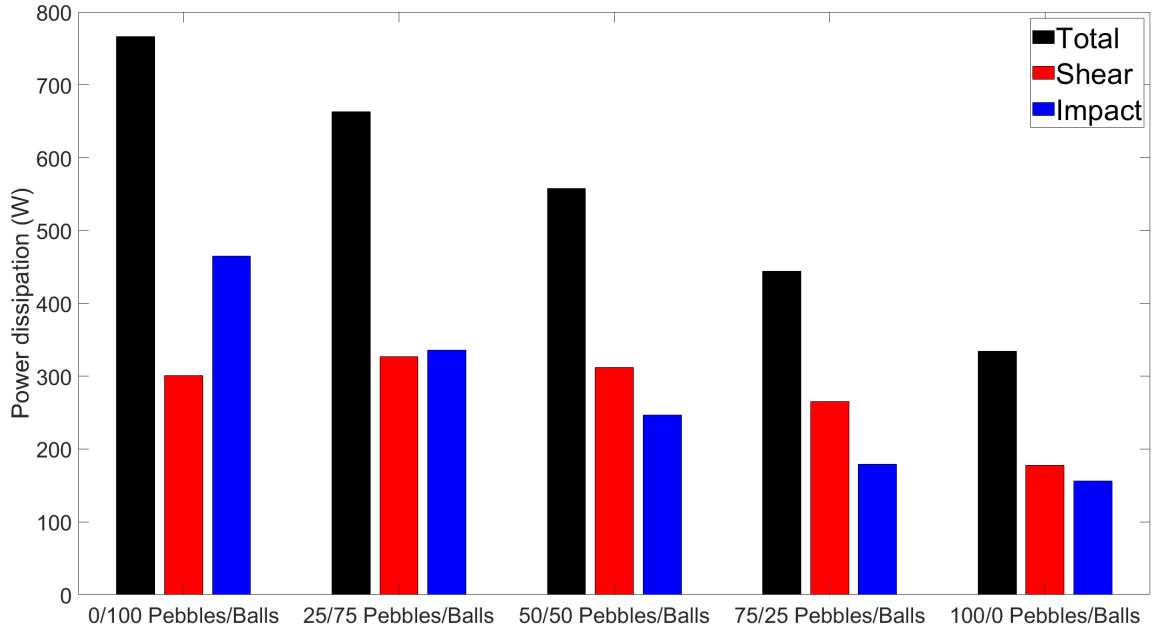

FIG 6 – Regrind ball mill simulations.

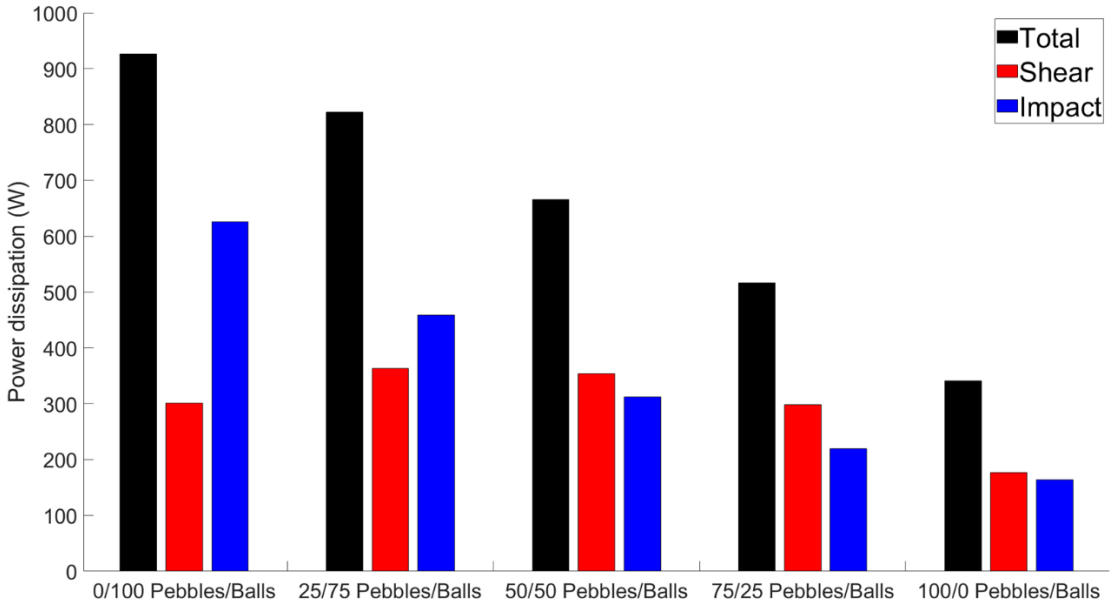

FIG 7 – Secondary ball mill simulations.

It can be deduced from Figures 6 and 7 that changing from ball milling to composite milling resulted in decline in the total power dissipated. This was expected since the bulk density of the charge decreases when steel balls (7850 kg/m^3) are substituted by an equivalent volume of pebbles (3280 kg/m^3 in regrind mill and 2644 kg/m^3 in secondary stage mill).

It is evident from Figures 6 and 7 that, in addition to a decline in total power dissipated, changing from ball milling to composite milling results in a redistribution of the collision power. In Figure 6 the proportion of shear power increased from 39 per cent to 49 per cent on a 25/75 blend, and to 56 per cent on a 50/50 blend. The redistribution of the dissipated power results in the shear power in composite milling being comparable to (or slightly more than) that from ball milling.

The data presented in Figures 6 and 7 suggest that when a fraction of the steel balls load is replaced by an equivalent volume of pebbles, there is a change in the balance of grinding mechanisms, with increasing relative contribution of attrition.

The amount of fines generated by shear events in ball milling and composite milling can be expected to be similar if the ore particles are sufficiently broken by attrition, and if the following hold:

- The shear energies dissipated in ball milling and composite milling are within the same collision energy level.
- The spatial location and area of regions of high shear energy dissipation in ball milling and composite milling are similar, and the energies dissipated in these regions are similar.

Collision energy spectra plots and spatial maps of collision energies are useful for exploring if these conditions hold.

Pilot-scale mill (1.2 m diameter) simulations

A 1.2 m diameter mill was simulated in DEM to investigate the effect of mill diameter, speed and filling level. Figures 8–10 shows the distribution of collision power from the simulations. For these simulations the size distribution of steel balls and pebbles was the same, this was done to ensure that the effect of size of pebbles on the distribution of power was eliminated. It was important to do this in order to show that the redistribution of power in composite milling is mainly a result of pebble shape, especially because in real applications the size distribution of pebbles will be variable.

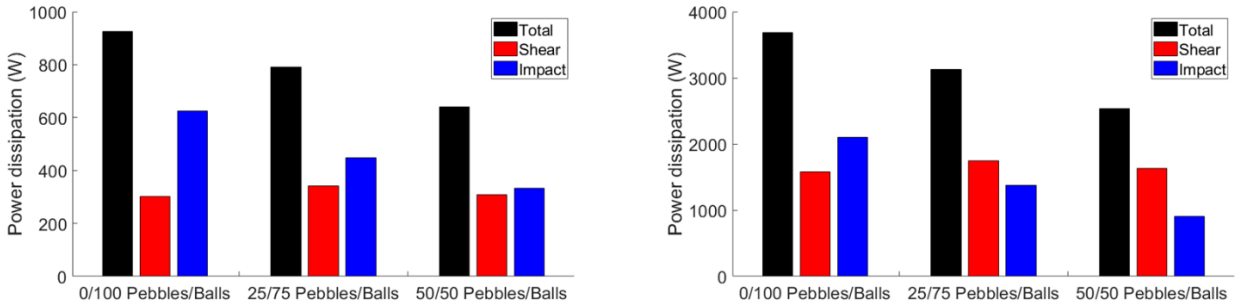

FIG 8 – Effect of mill diameter using a 33 per cent fill level and a speed of 75 per cent *Nc*. Left: 0.6 m diameter mill, Right: 1.2 m diameter mill.

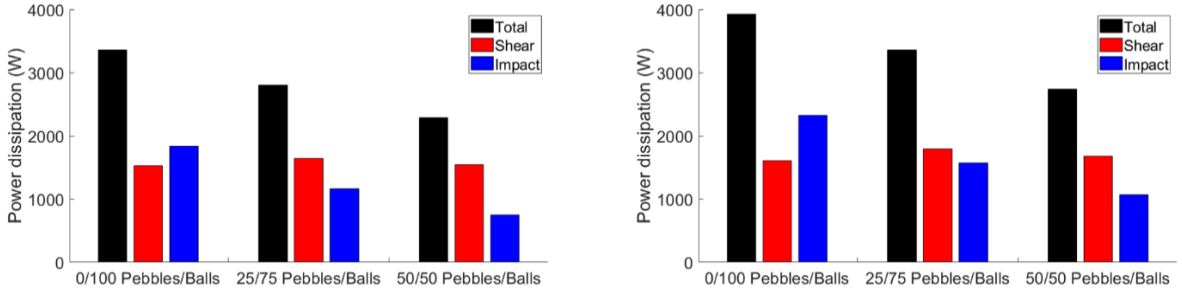

FIG 9 – Effect of mill speed using a 1.2 m diameter mill filled up 33 per cent level. Left: 68 per cent *Nc*, Right: 83 per cent *Nc*.

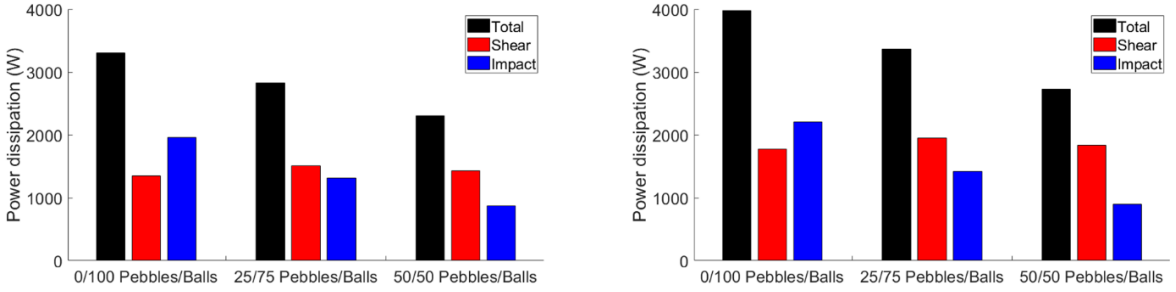

FIG 10 – Effect of mill fill level using a 1.2 m diameter mill operated at 75 per cent *Nc*. Left: 28 per cent fill, Right: 40 per cent fill.

Figure 8 shows a notable difference in the distribution of collision power in the two mills simulated. Comparing the ball milling cases, in the 0.6 m diameter mill the shear component is 32 per cent, whereas in the 1.2 m diameter mill it is 43 per cent. A similar mill size effect has been reported in Weerasekara *et al* (2016).

As expected, Figure 9 shows that the proportion of shear is lower for the high speed, and Figure 10 shows that it is higher for the high fill level. Comparing 25/75 mixture cases, the proportion of shear for the mill rotating at 68 per cent *Nc* is 59 per cent, whereas at 83 per cent *Nc* it is 53 per cent. Comparing the 50/50 mixture cases, the proportion of shear for 28 per cent filling level is 62 per cent, whereas at 40 per cent fill level it is 67 per cent.

Figures 8–10 show that the redistribution of the collision power when changing from ball milling to composite milling was evident in both mills, across all speeds and filling level, and independent of media size distribution. For an example, in Figure 9 (left) the proportion of shear increased from 46 per cent to 59 per cent in 25/75 mixture, and to 67 per cent on 50/50 mixture.

Ball milling versus composite milling – energy spectra

The data presented in Figures 4–10 show the total power resulting from all collision events (ball-ball, ball-pebble, ball-liner and pebble-liner) in the normal and tangential directions. It is also important to compare the probability distribution of power and collision frequencies in all possible collision energy

levels. Figures 11–12 show the energy spectra plots for shear events (truncated at 1 × 10^{-4} J), which are of interest in this paper.

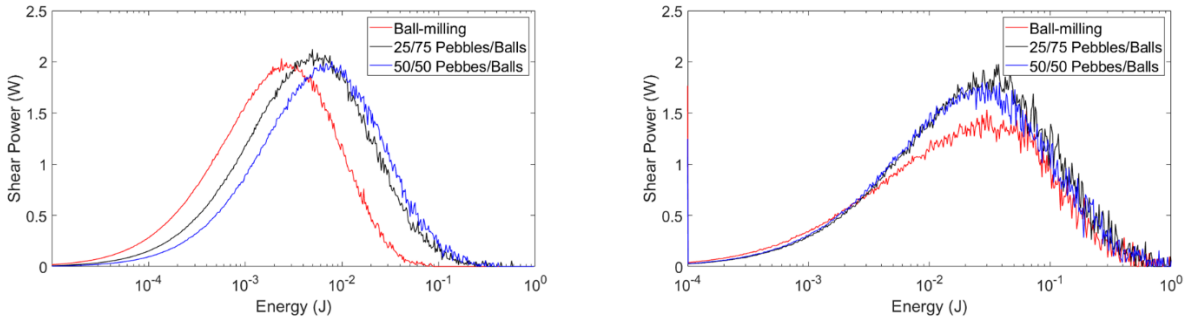

FIG 11 – Shear power dissipation. Left: Regrind ball mill, right: Secondary ball mill.

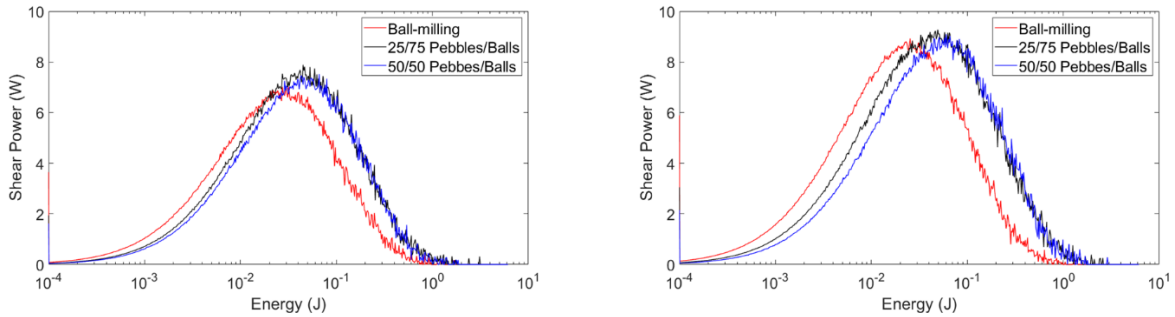

FIG 12 – Shear power dissipation (1.2 m diameter mil, effect of fill level). Left: 28 per cent, Right: 40 per cent.

Figure 11 left shows that for simulated charge filling, mill speed and media size distributions, in composite milling the energy spectra shift to the right. The energy spectra reveal that the total shear power (shown in Figure 6) in composite milling (25/75 and 50/50 mixtures) is comparable to that in ball milling because of higher energy shearing events.

Figure 11 right shows that for the simulated charge filling, mill speed and media size distributions, in composite milling the energy spectra shifts upwards. The energy spectra reveal that the shearing events in ball milling and composite milling (25/75 and 50/50 mixtures) are similar in energy intensity.

Figure 12 show that for the simulated charge filling, mill speed and media size distributions, in composite milling the energy spectra shift slightly upwards and to the right. The energy spectra reveal that the total shear power (shown in Figure 10) in composite milling (25/75 and 50/50 mixtures) is comparable to that in ball milling because of higher energy shearing events.

As mentioned earlier, introducing non-spherical media changes the local contact interactions from predominantly rolling to sliding. This information can be deduced from a collision frequency plot. Figures 13 and 14 show the collision frequency plots corresponding to Figures 11 and 12.

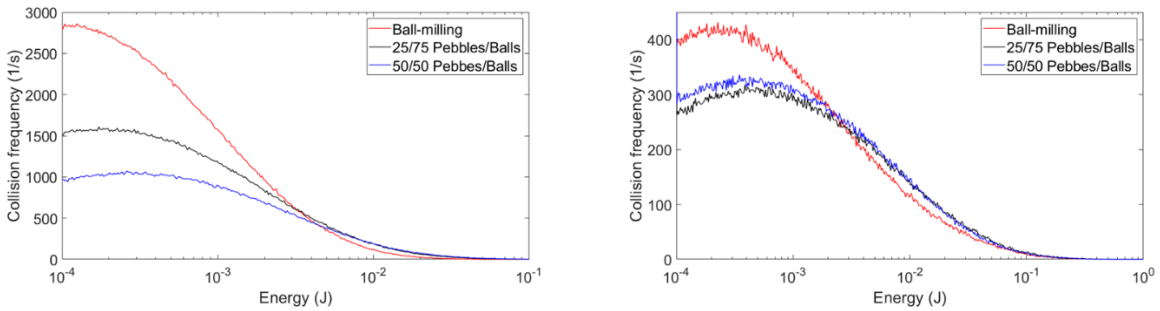

FIG 13 – Collision frequency. Left: regrind ball mill, right: Secondary ball mill.

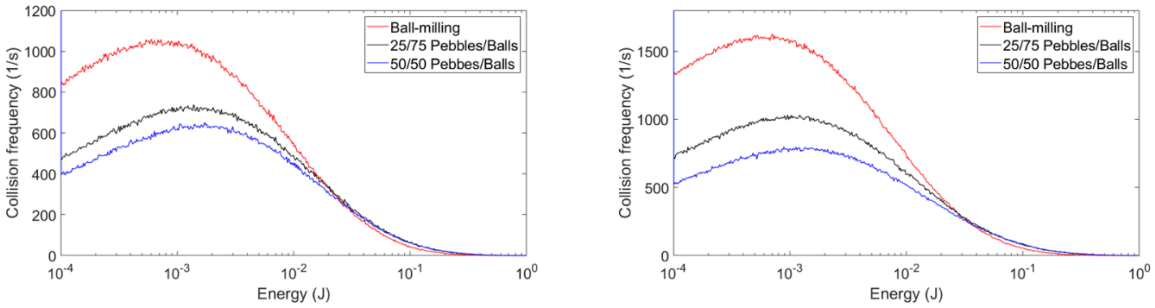

FIG 14 – Collision frequency (1.2 m diameter mil, effect of fill level). Left: 28 per cent, Right: 40 per cent.

It is evident in Figures 13 and 14 that on the higher end of the energy spectra (>10^{-2} J), the frequency of collisions in composite milling are slightly higher than in ball milling. However, on the lower energy end the frequency of collisions in composite milling are significantly less. One can expect rolling to be a low energy shearing event compared to sliding. Therefore the high frequency of low energy collisions in ball milling can be attributed to the fact spherical media roll with ease, but dissipates less energy in the tangential direction.

Ball milling versus composite milling – spatial maps of collision energy

Spatial distribution maps can be used to locate the regions where the energy dissipated is high ('hot-spots'), and by inference the regions where the probability of ore particle breakage is high (Ndimande *et al,* 2019; Nordell and Potapov, 2015; Powell and McBride, 2004). Figure 15 shows the spatial distribution of cumulative shear energy dissipated in collisions over a period of 10 seconds after the simulation has reached steady state, and the average volume fraction. The spatial maps shown are for the 1.2 m diameter mill filled up to 40 per cent level and rotating at 75 per cent *Nc*. Similar trends have been observed from maps of all the other simulations described in this paper.

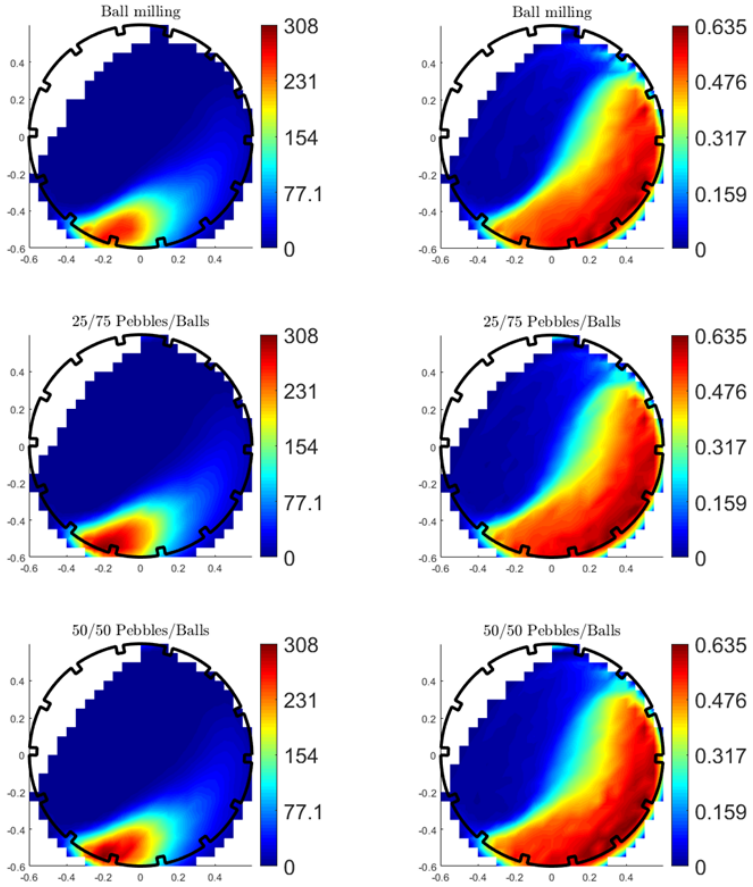

FIG 15 – Spatial distribution maps. Left: Cumulative shear energy dissipation, Right: Volume fraction.

High shear energy dissipation occurs in regions where the pressure and shear rates are high. The pressure and shear rates can be expected to be high starting from the bulk toe region, and moving inwards into bulk of the charge. In this region there is high turbulence, the cataracting streams and the cascading streams converge and change flow direction. The pressure is also high in this region due to the weight above the charge. The location of the 'hot-spots' in Figure 15 are in agreement with the description given here.

From a qualitative standpoint, it appears that the area of the 'hot-spots' (the red, yellow, green and light blue hues) are comparable. The cumulative shear energies dissipated in the hot-spots are also comparable (with a slight increase as the volume of pebbles increases). There is no significant difference in the volume fraction maps of composite milling and ball milling. This implies that the irregular shapes of pebbles may not compromise the probability of capture of ore particles between the colliding media in composite milling.

If the collision energies covered by the energy spectra shown in Figures 11–14 exceed the threshold required to cause catastrophic (body) breakage of the ore particles captured, the maps shown in Figure 15 suggest that one can at least expect the size distribution of the progenies produced from attrition when using 25/75 and 50/50 mixtures will be similar to that from ball milling.

The effect of the reduction in impact energy (refer to Figures 6–10) on the overall fines production depends on the contribution of impact breakage. Literature does not provide a clear weighting of attrition and impact breakage on the overall fines production from a secondary stage or regrind ball mill. However, intuitively one can imagine that if the feed material has a considerable mass of coarse and hard particles, the reduction in impact energy can be detrimental to fines production.

If only the shear power was important, then a ball mill charged with only spherical steel balls and a ball mill charged with a 50/50 mixture will produce the same amount of fines per unit time. The experimental data reported in Nkwanyana and Loveday (2018, 2017) showed that this is not the case, a loss in the production of fines was incurred when a 50/50 mixture was used. Therefore, there is an unknown weighted contribution of shear and impact events on the production rate of fines, but in this paper it is assumed that the shear contribution dominates. At high pebble volumes the effect of reduction in impact energy becomes evident.

CONCLUSIONS

- There is a complex interrelationship between grinding medium size, shape and material and the distribution of the energy dissipated in collisions. The interrelationship results in a redistribution of collision energy (shear: impact) when a portion of spherical steel balls is replaced by irregular shaped rounded pebbles in a ball mill.
- The redistribution was evident on 0.6 m and 1.2 m diameter mills, at 68 per cent, 75 per cent and 83 per cent of critical speed, and at 28 per cent, 33 per cent and 40 per cent filling.
- There is an unknown weighted contribution of shear and impact on the production rate of fines in a ball mill processing fine feeds (F_{80} <1 mm). In this paper it was assumed that the shear contribution dominates.
- Based on the shear power dissipation it can be postulated that attrition grinding in ball milling and composite milling (25/75 and 50/50) would yield progenies of similar size distribution.
- The shear power in a mill loaded with steel balls only and in mill loaded with a 25/75 mixture are comparable, this is a probable reason for the comparable production rate of fines (-75 µm material) reported in Nkwanyana and Loveday (2018, 2017).

ABSTRACT

The gravity-induced stirred mill such as the TowerMill is an energy-efficient grinding solution used in secondary, tertiary, and regrinding duties in the mineral processing concentrator. The interest in this technology is emerging, with more than 300 mills installed globally in various grinding duties and commodities for the last 30 years. Although the technology is matured, there are still opportunities for improvement and the development of new knowledge to improve its circuit energy efficiency and reduce water consumption. Recent studies show that a combination of stress intensity, ore hardness, slurry density, and mill feed configuration can be used to evaluate the performance of the grinding circuit. A recent pilot-scale TowerMill test work at various stress intensities shows that a lower operating work index and size-specific energy were achieved at higher agitator tip speed and using medium size grinding media. These outcomes were confirmed through several site trials. A smaller 17 mm grinding media has reduced the operating work index and size-specific energy by 18 per cent and 11 per cent, respectively, compared to the 20 mm in a magnetite concentrator. Moreover, the conversion from top feed to bottom feed configuration has reduced the operating work index and size-specific energy by 13 per cent and 37 per cent, respectively. The circulating load was reduced by 34–38 per cent, leading to a reduction in the dilution water consumption in the hydrocyclone feed sump by 20 per cent. A variable frequency drive offers flexibility to change the stress intensities on the TowerMill, where a 35 per cent reduction in specific energy was achieved when the ore became soft. This paper explores the potential design and operating strategies that can be implemented to enhance the energy efficiency, reduce water consumption and reduce CO_2 emissions in the circuit and finally evaluate its impact on the total cost of ownership.

INTRODUCTION

The mining industry has been facing challenges such as depleting orebody grades, increase in hardness as the mine goes deeper, and finely disseminating valuable minerals in the orebodies. All these challenges have led to the building of large energy and water-intensive concentrator to meet the targeted concentrate grade and productivity for a profitable operation. These concentrators were equipped with large autogenous/semi-autogenous grinding mills and ball mills to grind and liberate the valuable minerals from the gangue. These comminution devices consume 50–70 per cent of the energy in the concentrator that making grinding an energy-intensive process. On top of these challenges, our industry is also facing increasing pressure to reduce carbon emissions to secure a global net-zero by 2050 and keep a maximum of 1.5°C of warming within reach.

Energy-efficient equipment such as the stirred mills and high-pressure grinding rolls (HPGR) have been introduced to the comminution circuit to address the above-mentioned challenges specifically to reduce specific energy consumption (the kWh/t) and water consumption. This paper will focus on the application of the stirred mill in the circuit specifically the TowerMill – a gravity-induced stirred mill. The TowerMill was developed in Japan in the 1950s for fine grinding duty. In the 1980s, this technology was introduced in the mineral processing concentrator for rougher concentrate regrind duty to improve the concentrate grade. The ability of the TowerMill to grind efficiently down to 13–15 µm at a lower specific energy consumption has attracted many concentrators to install this technology in the regrind duty. Over the last 15 years, the TowerMill technology has been introduced to the coarse grinding application by partially replacing the secondary and tertiary ball mill duties. The ability of the TowerMill to receive feed up to 6 mm (100 per cent passing) has attracted applications that partially replace the ball mills. Recently, the Eirich TowerMill has been chosen for

a coarse grinding duty of soft hematite ore (F100 = 6 mm) to produce a pellet feed with Blaine number of 1800–2000 cm^2/g.

The technology is mature and has been well accepted in the industry but, with the new challenges, there are still opportunities to further improve in terms of equipment, circuit design, and operations. These improvements will reduce the energy and water consumption in the circuit hence reducing the carbon emission as well. This paper will present some new knowledge that has been developed through laboratory experiments and site trials that reduces energy and water consumption.

GRINDING DUTIES OF TOWERMILL IN THE CONCENTRATORS

The TowerMill has been used in mineral processing concentrators for the last 40 years in various grinding duties and commodities such as copper-gold, silver-lead-zinc, hematite, magnetite, and PGMs. Its grinding duties include secondary, tertiary, and regrinding of concentrate and tailings. Its ability to receive feed up to 6 mm (top size) and produce a circuit product down to 13 µm has enabled this technology for a wide range of grinding duties in the mineral processing concentrators. This section will discuss the application of TowerMill in secondary and tertiary grinding duties.

Secondary grinding duty

The TowerMill has been installed for secondary grinding duty receiving the feed from the autogenous or semi-autogenous mill replacing the ball mill. Figure 1 shows the simplified comminution circuit flow sheet of a magnetite concentrator in West Asia – one of the lines out of 14 lines. The primary grinding was carried out in an autogenous mill and the rougher magnetic separator (RMS) concentrate was ground in a TowerMill down to 35 µm and followed by a cleaner magnetic separator (CMS) to produce the final concentrate. One of the advantages of this circuit is the application of an autogenous mill that eliminates the use of grinding media in the primary grinding stage and energy-efficient TowerMill in the secondary grinding duty. Typically the secondary grinding duty is being carried out in a ball mill. A comparison in terms of specific energy consumption, dilution water addition to the circuit (that can be translated to water consumption for the secondary grinding duty), and CO_2 emission were compared for the existing TowerMill circuit and equivalent ball mill circuit. The CO_2 emission was calculated based on the CO_2 emissions for electricity generation and grinding media manufacturing. Morrell (2022) mentioned that the CO_2 emission for electricity generation and grinding media manufacturing were 556 g/kWh and 2.3 kg per kg of steel ball consumed. The specific energy consumption for the ball mill was determined through the Levin Test. The circulating load for the ball mill circuit and TowerMill circuit were 380 per cent and 270 per cent respectively. Table 1 shows the specific energy consumption, dilution water requirement, and CO_2 emission for the existing TowerMill circuit and the simulated ball mill circuit. The specific energy consumption, dilution water requirement, and CO_2 emission for the TowerMill circuit are lower compared to the ball mill circuit. The grinding efficiency through attrition in the TowerMill has contributed to the lower specific energy and grinding media consumption hence reducing the CO_2 emission. Moreover, the lower circulating load helps to reduce the dilution water requirement. The hydrocyclone feed slurry density is maintained below 50 per cent (w/w). In general, the application of TowerMill technology in the secondary grinding duty has more benefits compared to the ball mill in the secondary grinding duty in a magnetite concentrator.

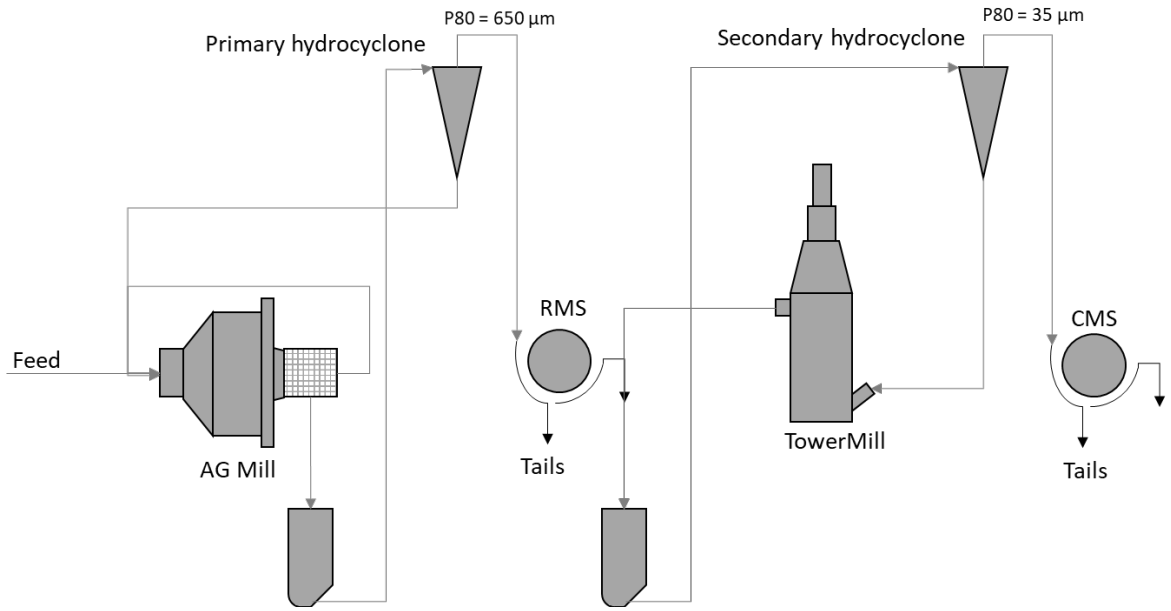

FIG 1 – Simplified comminution circuit of a magnetite concentrator.

TABLE 1

Comparison between the ball mill and TowerMill circuit in the secondary grinding duty in a magnetite concentrator.

Circuit	Ball Mill	TowerMill	% reduction
F80 (µm)	460	460	-
P80 (µm)	34	34	-
Throughput (t/h)	133	133	
No of Mills	1	1	
Power requirement in the mill (kW)	2558	1968	
Hydrocyclone feed pump power (kW)	211	166	
Total power requirement in the circuit	2783	2050	
Installed power in the mill (kW)	2984	2050	
Specific energy consumption (kWh/t) – Mill only	21.3	16.4	23.1
Specific energy consumption (kWh/t) – Circuit	23.2	17.8	23.3
Dilution water requirement (m^3/h)	360	308	12.0
CO_2 emission per tonne of ore ground (kg/t-of ground ore)	15.3	10.7	30.0

Tertiary grinding duty

A similar analysis was carried out to compare the ball mill and TowerMill in a tertiary grinding duty in a Cu-Au concentrator where the front-end grinding circuit was a semi-autogenous-ball mill-pebble crusher (SABC). The circuit product of SABC circuit product ranged between 150–180 µm. The ore is considerably hard with a Bond ball mill work index of 18 kWh/t. The site decided to reduce the rougher flotation feed to 85 µm to enhance the liberation and recovery. Two grinding technologies were compared ie ball mill and TowerMill during the study phase. Finally, the TowerMill was chosen due to its lower specific energy consumption and minimal space requirement as space was limited for this brownfield expansion. After the installation, the TowerMill circuit performance was audited and the results are shown in Table 2. The same data (F80 and P80) was used along with the Bond Ball Mill Work Index to determine the specific energy requirement for a tertiary ball mill circuit. Table 2 summarises the comparison data between the existing tertiary TowerMill circuit and the simulated ball mill circuit. In general, the TowerMill circuit exhibits lower specific energy consumption, dilution

water requirement, and CO_2 emission. Similar to the abovementioned secondary grind circuit, the TowerMill circuit exhibits superiority compared to the ball mill circuit in the tertiary grinding circuit.

TABLE 2

Comparison between the ball mill and TowerMill circuit in the tertiary grinding duty in a Cu-Au concentrator.

Circuit	Ball Mill	TowerMill	% reduction
F80 (μm)	155	155	-
P80 (μm)	85	85	-
Circuit feed rate (t/h)	335	335	
Specific energy consumption (kWh/t)	5.07	3.15	37.8
Power (kW) – Mill	1697	1055	
Power (kW) – Pump	212	166	
Power (kW) – Total	1909	1221	
Installed Power (kW)	1865	1120	
No. of mill	1	1	
Dilution water requirement (m^3/h)	330	178	46.1
CO_2 emission per tonne of ore ground (kg/t of ground ore)	3.63	2.19	39.6

TOWERMILL CIRCUIT PRODUCES A NARROW PRODUCT SIZE DISTRIBUTION

The TowerMill circuit produces a narrow product size distribution. Figure 2 shows the particle size distribution of the secondary grinding TowerMill circuit feed and the product in a magnetite concentrator (Figure 1). The circuit product exhibits narrow product size distribution with an excellent top particle size reduction for magnetite particle liberations. Both particle size distributions were fitted to the Rosin-Rammler model to determine their slopes. The circuit feed and product size distribution slopes were 0.75 and 1.02 respectively. These numbers indicate that the TowerMill circuit produces a sharper product size distribution which aids mineral recovery and dewatering processes. The slurry zone on top of the grinding zone in the TowerMill shell acts as a classification zone – especially in coarse grinding applications. The coarse particles that enter the slurry build-up zone will be returned to the grinding zone, while the slurry current will push the fines out from the mill. The slurry build-up acts as an internal classifier. In this case, those particles that reached the targeted grind size will be classified immediately thus reducing the over-grinding in the mill grinding chamber hence reducing the circulating load in the hydrocyclone. The combination of internal classifications in the mill and hydrocyclone produces a narrower circuit product size distribution. This effect is common in TowerMill circuits for all grinding duties.

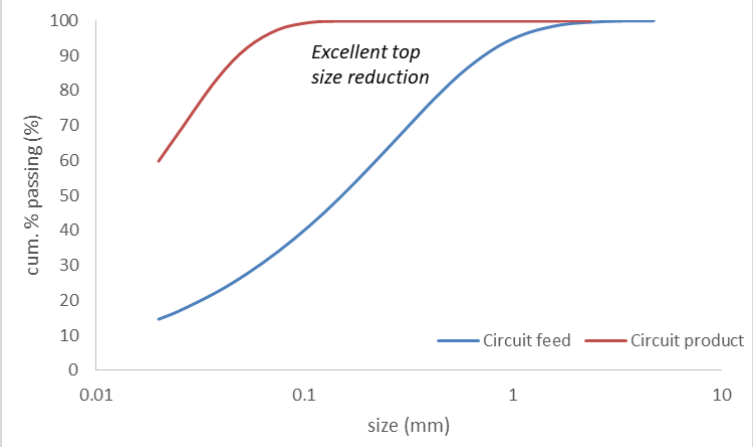

FIG 2 – Particle size distribution of TowerMill circuit feed and product.

TOWERMILL DESIGN, OPERATING VARIABLES, AND STRESS INTENSITY CONCEPT

Despite the maturity of the technology and the advantages mentioned, there is still opportunities for improvement to operate the mill more efficiently and maximise its capability. This section will evaluate the design and operating variables that affect the grinding efficiency and later relate it to the stress intensity concept. The TowerMill model available ranged from ETM 20 (15 kW) to ETM 2000EX (1865 kW). The design concept of the TowerMill includes gap (distance between mill shell and the tip of the screw), agitator screw design, and agitator screw tip speed (if the mill is installed with a DOL main drive motor), mill feed configuration, and the application of the coarse classifier. The operating variables include specific energy consumption, grinding media size, grinding media density, % solids, and tip speed (if the main drive motor is operated with a variable frequency drive). Table 3 shows the summary of the design and operating variables.

TABLE 3

Summary of design and operating variables.

Variables		**Description**
Design	Application of coarse classifier	The coarse classifier is recommended for coarse grinding application when the particle size is above 1–1.5 mm to classify and recycle the coarse particle to the high grinding efficiency region at the bottom of the mill. Typically, the coarse classifier is installed at the mill discharge launder.
	Mill feed configuration	Top feed → low reduction ratio regrinding duty Bottom feed → large reduction ratio grinding duty – secondary, tertiary, and regrind
	Agitator screw tip speed (for DOL main drive motor)	Typical screw agitator speed ranged from 3.5–4.0 m/s
Operating	Specific energy consumption	This is the main operating variable as a function of motor power draw and circuit feed rate that determines the fineness the of grind.
	Grinding media size	12.7–25 mm
	Grinding media density	Typically, the steel Hi-Cr grinding media with a density of 7800 kg/m^3 is used but recently there are the application of ceramic media in the TowerMill to eliminate the iron contamination. The ceramic media density ranged from 3600–6000 kg/m^3.
	Mill content % solids (w/w)	50–74% depending on the specific gravity of the feed.
	Agitator screw tip speed (if the main drive motor is operated with a variable frequency drive)	The agitator tip speed can be an operating variable if a variable frequency drive is installed to the main drive motor. It is not recommended to operate below 2.0 m/s as it affects the grinding efficiency.
	Amount of grinding media in the mill	The amount of grinding media inside the mill affects the power draw.

Design variables

Two design variables that are useful during the circuit design stage will be discussed in this section ie mill feed configuration and application of coarse classifier for secondary grinding duty. Mill feed

configurations are an important design variable for the TowerMill. The TowerMill can be fed either from the top or bottom. The choice of top or bottom feed configuration depends on the feed size distribution and reduction ratio. The bottom-feed configuration is preferred for a board feed size distribution and requires a large reduction ratio such as a particle size distribution shown in Figure 2. Meanwhile, the top feed configuration is preferred for fine feed with narrow particle size distribution and requires a low reduction ratio grinding duty. EIRICH TowerMill is designed with both feed ports – top and bottom, that offer flexibility for the circuit design. Table 4 shows the summary of the mill feed configuration based on the grinding duties that enable circuit modification when the ore changes. The effect of mill feed configuration on grinding efficiency can be tested only at the site using the production scale mill. The authors have experience in conducting site trials comparing the effect of top and bottom feed configuration. The results of this study will be discussed in the latter part of this paper.

TABLE 4

Summary of mill feed configuration according to the TowerMill grinding duty.

Mill feed configuration	**Grinding duty**
Top	Tertiary (for fine feed and/or low reduction ratio) Regrind
Bottom	Secondary Tertiary Regrind (flash flotation concentrate + flotation concentrate)

Previously, the TowerMill was designed with a fixed speed (DOL motor) and this was considered a design variable. In the last five to seven years most of the TowerMills are being installed with a variable frequency drive. This upgrade or advancement has offered operational flexibility to the mill, especially when grinding ore with high variability. This upgrade has changed the tip speed from a design variable to an operating variable.

The EIRICH TowerMill is suitable for coarse grinding applications as it can receive feed up to 6 mm (100 per cent passing). A purpose-designed coarse classifier is fitted to the mill discharge stream to classify the coarse particles and return them to the bottom of the mill (high grinding intensity region) to efficiently grind the coarse particles. Figure 3a shows the coarse classifier attached to the ETM 1500 TowerMill and Figure 3b shows the particle size distribution of all three streams of the coarse classifier in one of the coarse grinding hematite applications. The α value (sharpness of cut) of the coarse classifier ranges from 0.6 to 1.5 depending on the operating condition of the mill. Although this is considered a rough classification, it helps to reduce the circulating load in the hydrocyclone by 20–35 per cent. The reduction in the hydrocyclone circulating load helps to reduce the capital expenditure (smaller hydrocyclone cluster and hydrocyclone feed pump) and operating expenditure (smaller slurry pumping energy requirement).

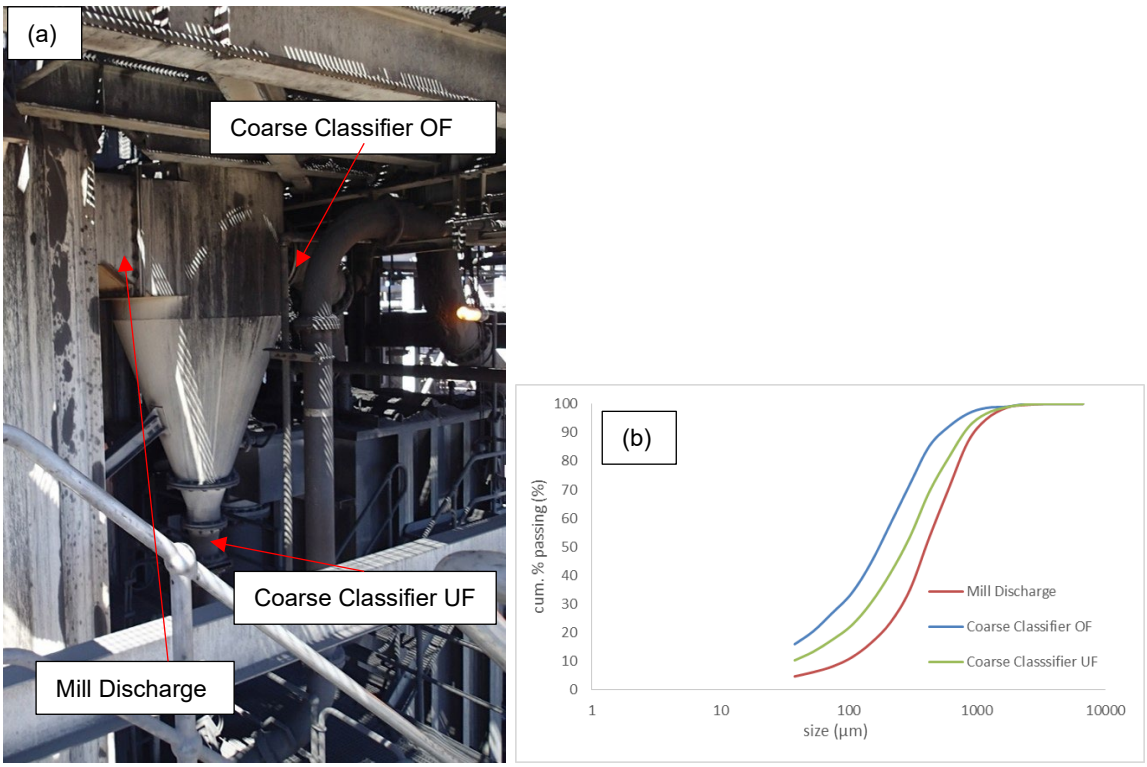

FIG 3 – (a) EIRICH TowerMill Coarse Classifier attached to Mill discharge; (b) Particle size distribution of the coarse classifier streams.

Operating variables

The main operating variables in the EIRICH TowerMill circuit are specific energy consumption, grinding media size, grinding media density, % solids, and screw agitator tip speed (for variable speed main drive motor). The specific energy consumption which is measured in kWh/t is the electrical energy consumed to grind one tonne of material from a designated F80 to a targeted P80. For TowerMill, the power draw is dictated by three main factors, ie the amount of grinding media in the mill, tip speed, and grinding media density. Figure 4 shows the TowerMill power draw as a function of the amount of grinding media in the mill and agitator screw rotational speed. This trial was carried out during ETM 1750 TowerMill commissioning installed for regrind duty at a gold concentrator. In general, as the amount of grinding media and screw rotational speed increases, the mill power draw increases. Table 5 shows the pilot-scale TowerMill power draw when using two different grinding media, ie steel and ceramic. The ceramic media, which has a lower density, draws less power compared to the steel grinding media. Although 98 per cent of the TowerMill applications are using steel media, some concentrators have shifted to using ceramic media in the TowerMill to avoid iron contamination that affects the flotation performances. These results indicate that three main levers can be optimised/manipulated to achieve a certain power draw in the mill.

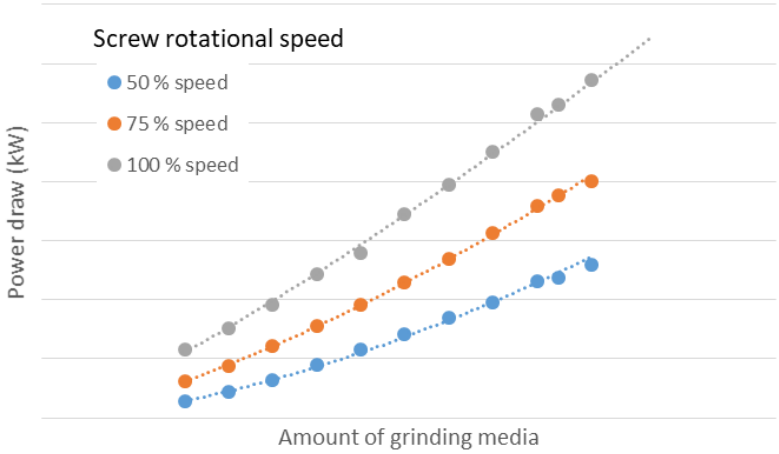

FIG 4 – Effect of grinding media addition and agitator screw rotational speed on power draw for an ETM 1750 EIRICH TowerMill.

TABLE 5

Effect of grinding media density on TowerMill power draw.

Grinding media material	Hi-Cr Steel media	Alumina Ceramic media
Density (t/m^3)	7.8	3.6
Pilot TowerMill Power draw (kW)	1.05	0.44

The effect of grinding media size, screw rotational speed and mill content % solids were tested in a pilot-scale TowerMill. A Cu-Au ore (sampled from a ball mill feed stream) was used for this experimental work. The feed size was 450 µm (at 80 per cent passing). The ore specific gravity was 2.81. Table 6 shows the operating variables range of the pilot-scale TowerMill experiments. The experiments were carried out at three levels. The following section will discuss the piloting results.

TABLE 6

Operating variables range of the pilot-scale mill experiments.

Operating variables	**Range**		
Media size (mm)	12.7	20	25
Solids (% w/w)	50	60	70
Screw tip speed (%)	2.0	2.5	3.0

Effect of screw rotational speed

As mentioned in the previous section, the recent TowerMills are being installed with a variable frequency drive that offers flexibility to adjust the power draw by adjusting screw rotational speed. Three grinding tests were carried out by varying the screw rotational speed at constant % solids and media size. Figure 5 shows the particle size distribution and breakage function at three different screw tip speeds. In general, a higher screw rotational speed results in a higher breakage rate that produces a finer particle size distribution.

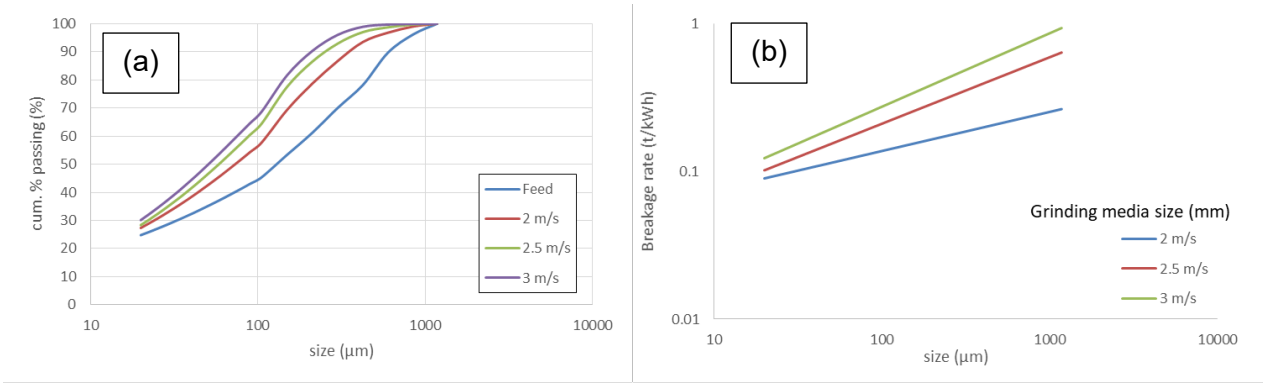

FIG 5 – (a) Particle size distribution and (b) breakage rate at different screw rotational speeds.

Effect of grinding media size

Three grinding media tests were carried out by varying the grinding media size at constant screw rotational speed and mill content % solids. Figure 6 shows the particle size distribution and the breakage rate for three different grinding media sizes. The highest breakage rate was obtained with 15 mm grinding media while the lowest breakage rate was observed with 12.7 mm grinding media. Choosing the appropriate grinding media size is essential for optimum breakage in the mill. The rule of thumb is to choose the grinding media size that can break the top particle size. In this test work, the 12.7 mm grinding media exhibited a lower grinding efficiency to break the coarse particles. Typically smaller grinding media have a higher surface area which leads to higher grinding efficiency but in this case, it has a lesser ability to break the top particle sizes. The 20 mm grinding media has a lesser surface area compared to the 15 mm, and shows lower grinding efficiency comparatively. This test work shows that selection of grinding media size is of utmost importance for a given grinding duty.

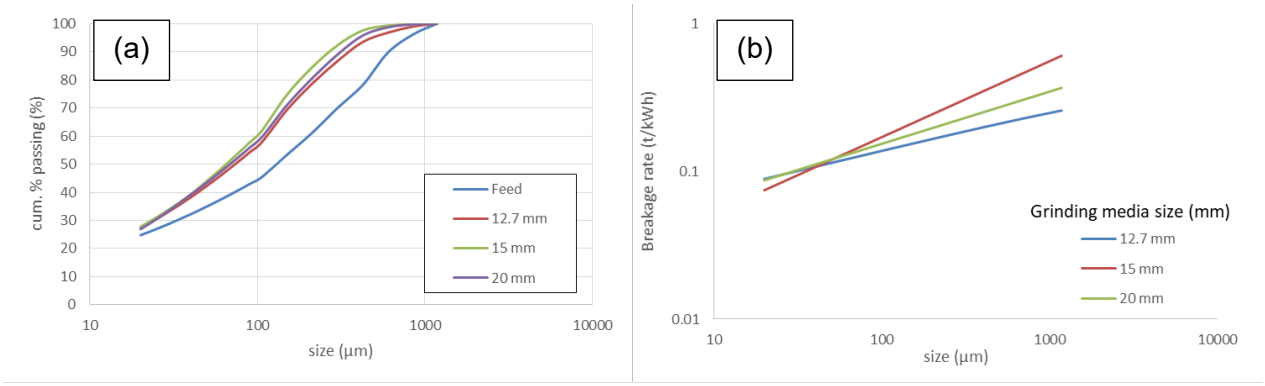

FIG 6 – (a) Particle size distribution and (b) breakage rate at different grinding media size.

Effect of mill content slurry density

The effect of slurry density was tested at three different levels, ie 50 per cent, 60 per cent and 70 per cent. Typically the TowerMill operates comfortably between 50 per cent to 68 per cent solids for ore with a specific gravity of 2.65 to 2.80. Meanwhile, for high specific gravity ore such as magnetite and lead concentrate, the TowerMill mill content % solids ranged from 70 per cent to 80 per cent. Figure 7 shows the particle size distribution and breakage rates at three different levels of mill content slurry density. The breakage rate at 50 per cent and 60 per cent solids were similar; meanwhile, the breakage rate reduced when the per cent solids increased to 70 per cent. This result indicates that the grinding efficiency drops at higher % solids due to the increase in the slurry viscosity. On a separate note, operating the TowerMill below 40 per cent solids will increase the interaction between media to media and media to the liner which will escalate the wear rate of the grinding balls and screw liner. In this case, it is not advisable to operate the mill with a slurry density (mill content) below 40 per cent solids.

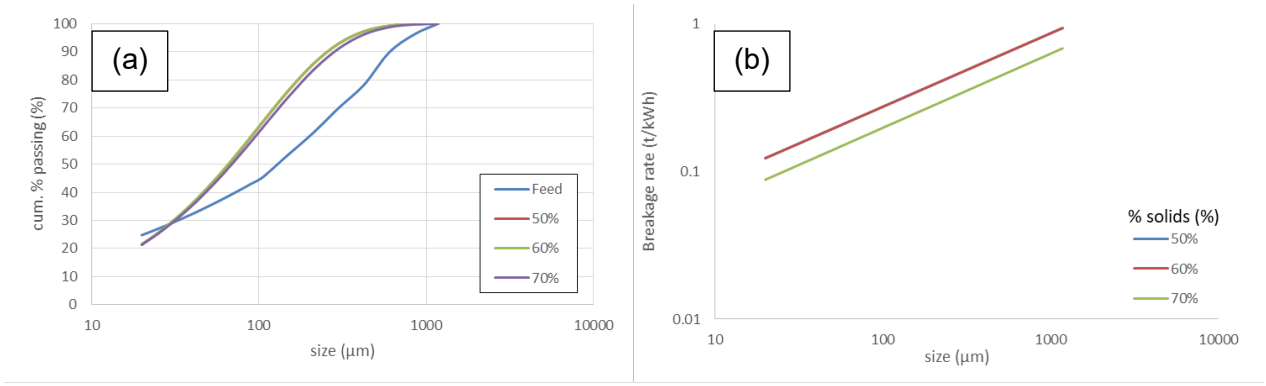

FIG 7 – (a) Particle size distribution; and (b) breakage rate at different mill content slurry density.

The pilot test work indicated that grinding media size, agitator screw rotational speed and mill content slurry density affect grinding efficiency in the TowerMill. In general, a higher screw rotational speed, and an appropriate choice of grinding media according to the feed top size and % solids around 65–68 per cent exhibits optimum grinding efficiency for the TowerMill. There is another concept, ie media stress intensity that co-relates media size, media density and tip speed. It is worth investigating as this analysis will exhibit the optimum media stress intensity to achieve the targeted grind size. The following section will use the test work data and evaluate the optimum media stress intensity required to achieve the targeted grind size.

Media stress intensity to understand the optimum grinding condition

The main particle breakage mode in the TowerMill is predominately attrition. The attrition breakage takes place at the annular region – the gap between the tip of the screw and mill shell. Equation 1 shows the grinding media stress intensity model which is a function of grinding media diameter, density, and tip speed.

$$SI_{GM} = d_{GM}^3 * \rho_{GM} * v_t^2 \quad (1)$$

where:

SI_{GM} stress intensity due to centrifugal force

d_{GM} grinding media diameter

ρ_{GM} density of grinding media

v_t agitator screw tip speed

Figure 8 shows the product particle size (P80) as a function of stress intensity. The results show that there is an optimum stress intensity value to reach the minimum product size. The stress intensity is a measure of pressure acting on the particles by the grinding media. In a typical grinding application, the media size, media density, and tip speed are fixed. For a given feed size and specific energy consumption, the stress intensity controls the product size distribution. For a given specific energy, the stress intensity can be manipulated by varying the media size, media density, and tip speed. In this work, the stress intensity of 0.8 Nm is optimum where a targeted product size of P80 150 µm was achieved. Table 7 shows that a similar stress intensity can be achieved in two different conditions. This analysis clearly shows that the screw rotational speed needs to be changed when the grinding media size is changed in the TowerMill. The recent development by using variable frequency drive type main motor is the way to move forward to achieve optimum grind size.

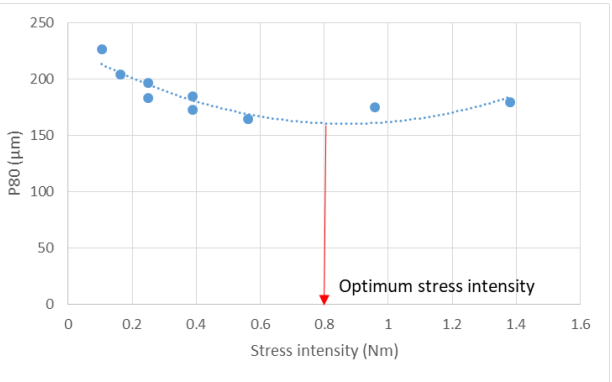

FIG 8 – P80 as a function of stress intensity.

TABLE 7

Grinding media stress intensity.

Media size (mm)	15	20
Media density (kg/m^3)	7800	7800
Tip speed (m/s)	5.5	3.6
SI (Nm)	0.80	0.81

The pilot TowerMill specific energy for the abovementioned two conditions were 14.8 and 12.1 kWh/t, calculated based on an empirical model. The difference in the specific energy was mainly contributed by the screw rotational speed. A basic calculation of carbon emission for a hypothetical feed rate of 100 t/h to reduce the particle size from 450 µm to 100 µm was done based on these two conditions. The CO_2 emissions were 8.23 and 6.73 kg/t of ground ore respectively for the 15 and 20 mm grinding media.

The pilot test work analysis has developed new knowledge in looking at the operating condition of the TowerMill. It is worth incorporating the stress intensity concept together with the operating condition such as grinding media size, and screw tip speed to identify the optimum grinding condition at lower CO_2 emission. The challenge is to scale this concept for the production scale TowerMill where the stress intensity due to gravity plays an important role.

PRODUCTION SCALE TOWERMILL ON-SITE TRIAL

The authors have carried out several trials at the site on the production scale TowerMill such as the ETM 1500 and ETM 1750. The results of such trials have been reported in several technical papers (Palaniandy *et al*, 2017, 2018, 2021). This section will discuss the effect of mill feed configurations, ball size, and screw rotational speed that was carried out in a magnetite concentrator in Western Australia and a gold concentrator in the United States. The details of these trials can be referred to in the abovementioned technical papers. Additionally, the CO_2 emission in each trial after the improvement will be calculated and compared as part of this paper.

Modification of mill feed configuration that improves grinding efficiency

A plant trial was carried out at a magnetite site in Western Australia to compare the top and bottom mill feed configuration. The trial was motivated by the changes in the circuit feed that are coarser than the design particle size as the Derrick Screen in front of the TowerMill circuit was bypassed. Initially, the circuit was designed with a top mill feed configuration. When the Derrick screen was bypassed, the top size (F99) increased from 100 µm to 1180 µm. Based on Nippon Eirich's experience, the authors recommended changing the mill feed configuration from top to bottom feed configuration. Table 8 shows the results of the site trial comparison between the top and bottom feed configuration. The Bond operating work index and the size-specific energy at 35 µm represent the grinding efficiency at coarse and fine particle sizes. Indicators showed a reduction of 30 and 50 per cent respectively. Meanwhile, the circulating load was reduced by 34 per cent. In general, the

modification from the top feed to the bottom has improved the overall grinding efficiency in the mill which requires lesser specific energy to achieve the same targeted grind size.

TABLE 8

Comparison of top and bottom mill feed configuration (Palaniandy *et al*, 2017).

Mill feed configuration	Top	Bottom
Circuit Specific energy (kWh/t)	3.0	2.9
Bond Operating work index (kWh/t)	14.2	9.90
Size specific energy at 35 µm (kWh/t)	55.0	27.6
Circulating load (%)	185	122

Improving grinding efficiency using slightly smaller grinding media

The ETM 1500 installed at the Western Australian magnetite concentrator was using 20 mm grinding media. As part of the process improvement program, one of the mills was loaded with 17 mm grinding media and its performance were compared to another mill with 20 mm grinding media. The specific energy consumption of both mills was similar during the survey. The total surface area of the 17 mm and 20 mm grinding media was 7139 and 6088 m^2 respectively. The 3 mm reduction in the grinding media size has increased the total surface area by 15 per cent. Table 9 shows the performances of the 17 and 20 mm grinding media. In general, the grindability improves by 18 per cent and 11 per cent at coarse and fine particle sizes plus a 33 per cent reduction in the circulating load. The 17 mm grinding was chosen as it can break the top particle sizes and at the same time, the increase in the surface area helps the attrition breakage. Although the smaller grinding media such as 12.7 mm will improve the fines generation through attrition, it will not have the ability to break the top particle sizes. The choice of 17 mm grinding media was a balance for efficiently breaking the top particle sizes and attrition of fine particles generation.

TABLE 9

Comparison of 17 and 20 mm grinding media (Palaniandy *et al*, 2018).

Grinding media size (mm)	20	17
Circuit Specific energy (kWh/t)	2.94	3.00
Bond Operating work index (kWh/t)	30.8	25.2
Size-specific energy at 35 µm (kWh/t)	22.6	20.2
Circulating load (%)	106	71

Reducing specific energy consumption by adjusting screw rotational speed

The ETM 1750 in a gold mine was installed with a variable frequency drive main motor that allows operating the mill at different screw rotational speeds. The targeted grind size was 25 µm. Table 10 shows the operating conditions at two different screw rotational speeds. At 100 per cent speed, the circuit product was finer than the design as the plant was receiving softer ore. This site is experiencing a high ore variability. The second survey was carried out by reducing screw rotational speed to 75 per cent that reducing the specific energy consumption by 36 per cent. As the specific energy reduces, the Bond ball mill work index and the size-specific energy reduce as well indicating improved energy utilisation for grinding to achieve the design product size. The reduction in the specific energy has increased the circulating load by 19 per cent but the value was still below 200 per cent. The ability to adjust the mill power draw by changing the screw speed is beneficial when grinding ore with high variability to achieve the targeted grind size plus optimising the operating expenditure (possible reduction in energy and wear part consumption).

TABLE 10

Comparison of specific energies by adjusting the screw rotational speed.

Screw speed (%)	100	75
Circuit Specific energy (kWh/t)	25.4	16.2
F80 (µm)	99	106
P80 (µm)	22	25
Bond Operating work index (kWh/t)	18.1	12.9
Size-specific energy at 20 µm (kWh/t)	57.2	41

Implementations that reduce water consumption and CO_2 emission

The implementation of process improvements has helped to reduce the dilution water consumption and the CO_2 emission. The reduction in the dilution water is achieved due to the reduction in circulating load and maintaining the hydrocyclone feed slurry density. Based on the process improvement implemented at the magnetite and gold concentrator, the dilution water requirement and CO_2 emission were calculated. Table 11 shows the dilution water requirement at the hydrocyclone feed sump and the CO_2 emission per tonne of ground ore. The implementation of bottom feed configuration and the use of smaller grinding media (17 mm) reduces the dilution water requirement and CO_2 emission.

TABLE 11

Reduction in water consumption and carbon emission after implementation of process improvement.

	Magnetite Concentrator			**Gold concentrator**	
Condition	Base case	Bottom Feed	Smaller media	Base case	Reduce speed
Dilution water addition (m^3/h)	702	523	529	13.9	21.2
CO_2 emission per tonne of ore ground (kg/t-of ground ore)	1.67	1.16	1.37	14.6	11.5

These analyses indicate that a small step-by-step improvement on one unit operations in the whole concentrator helps to reduce water consumption and CO_2 emission. It is important to understand the fundamentals behind the technology that helps to improve the overall process.

REDUCTION IN TOTAL COST OF OWNERSHIP

The improvement in the design and operating strategies will also reduce the overall circuit's total cost of ownership. For example, smaller units of pumps, sumps, hydrocyclone, foundations, and electrical items are required. These items can contribute towards lower capital expenditure hence also reducing operating expenditure through lower energy, water, grinding media, and liner consumption for future circuit design.

A total cost of ownership analysis was carried out using the data from the above-mentioned magnetite concentrator. This analysis includes capital expenditures (equipment prices, foundation, and installation costs) and operating expenditures (power, grinding media, screw liner, and maintenance costs). An internal rate of return and price escalation of 8 per cent and 4 per cent were taken into consideration in this analysis. The operational data was used to select the equipment model as shown in Table 12. In general, the pump, and hydrocyclone cluster became smaller for the optimised condition.

TABLE 12

Equipment model selection for the base case and optimised condition.

Condition	Base case	Optimised
No of 15' hydrocyclone in the cluster	12	10
Hydrocyclone feed pump model	14 × 12	12 × 10

The difference in the capital expenditure is around A$0.4 million but there is a huge difference in terms of operating expenditure. The difference in net present value operating expenditure for fifteen years of operation is approximately A$13 million and offers a shorter payback period of six months. The cost per tonne calculated based on 15 years of productivity is A$1.19 and A$0.87 for the base case and optimised scenarios respectively. This is a significant difference between these two conditions with a 27 per cent difference. This analysis shows that improvement in the design and operation of the TowerMill circuit has a significant contribution to the total cost of ownership of the circuit.

CONCLUSIONS

The EIRICH TowerMill technology has been used in the mineral processing concentrators since the 1980s for regrind duty. For the last 10–15 years, this technology has been used to partially replace the ball mill in secondary and tertiary grinding duties. The TowerMill circuit consumes lesser energy/water and emits less CO_2 compared to the ball mill circuit for all the above-mentioned grinding duties. Although this technology is mature and well accepted in the mining industry, there are opportunities for improvement in terms of design and operating strategies when processing challenging ores. Implementation of new design concepts and optimising operating conditions such as mill feed configurations, application of coarse classifiers in a coarse grinding application, agitator screw rotational speed, media size, and mill content slurry density improved the overall grinding efficiency. The media stress intensity concept helps to evaluate the best combinations of circuit operating conditions to achieve the target efficiently – low energy and water consumption and lower CO_2 emission. The CO_2 emission can be implemented as one of the mill operators' key performance indicators (KPI). This paper has shown the importance of continuous design improvement and operating strategies that reduced the specific energy/water consumption and CO_2 emission by 20–30 per cent. Nippon Eirich is committed to achieving this goal.

ABSTRACT

The question of effective energy utilisation in grinding mills is not new. There are several conflicting arguments about tumbling mills, whether the efficiency is around 1 per cent or maybe 10 per cent, or even much lower. The energy not used is assumed to be lost as heating of the pulp, the grinding mill body, the charge, generation of shock waves and vibrations, etc. Stirred media mills on the other hand are generally considered to have better energy utilisation, but their energy efficiency is still not that clear. To shed some light on this a pilot-scale, wet stirred media mill was investigated over a range of operating conditions.

The wet stirred media mill is a Drais PMH 5 TEX pearl mill fitted with an electric motor at 11 kW. It has been investigated over a range of operating conditions to try to balance the dissemination of the input energy in forms of the net grinding energy, mechanical energy losses, and the heating transferred to the pulp, the mill, the charge, and the cooling water.

It is found that approximately 20–40 per cent of the input energy accounts for the grinding process. Also, that the difference between gross and net input electrical energy is mainly disseminated as heating of the pulp and cooling water. Mechanical energy losses appear to be much smaller than the heating effects. The use of a dispersant seems to mainly influence the heating effect.

INTRODUCTION

The question of effective energy utilisation in grinding mills is not new. There are several conflicting arguments about tumbling mills, whether the efficiency is around 1 per cent or maybe 10 per cent, or even much lower (Wills and Finch, 2016). They cite Lowrinson (1974), who calculated the efficiency as 1 per cent by multiplying the created increase in surface area by the surface tension of the material ground. Fuerstenau and Abuzeid (2002) on the other hand, arrived at an efficiency of 15 per cent for ball mill grinding of quartz.

The energy not used for particle breakage is assumed to be lost as heating of pulp, the grinding mill body and charge as well as elastic deformation of particles and initial creation of micro-cracks (Wills and Finch, 2016).

Stirred media mills are generally considered to have better energy utilisation than ball mills (Shi *et al*, 2009). However, their energy efficiency is still not that clear. To shed some light on this a pilot-scale, wet stirred media mill was investigated over a range of operating conditions.

EXPERIMENTAL

The wet stirred media mill is a Drais PMH 5 TEX pearl mill fitted with an electric motor at 11 kW. It has a horizontal design, a double-walled water-cooled grinding chamber with an inner diameter of 149 mm and a length of 415 mm. A central shaft with discs is used to rotate the grinding charge. The mill is described in more detail in Gao and Forssberg (1992, 1993) and the current experimental set-up in Larsson *et al* (2020).

It has been used in several investigations on grinding of mineral fillers and mineral coatings. Basic parameter studies were presented already in 1992 and 1993 by Gao and Forssberg. The influence of rheology effects were reported for quartzite (He and Forssberg, 2007a) and limestone (He and

Forssberg, 2007b). Recently, the whole mill was simulated in a new approach with the particle finite element method (Larsson *et al,* 2020). During the latter investigation, the idea that it might be possible to also use the mill for a primitive energy balance emerged.

Testing

The test material is a commercial dolomite filler (myanite 0–70) from Björka Mineral AB in Sweden. The solid density is measured to be 2.87 g/cm³ with a helium pycnometer (micromeritics Accupyc II 1340). For every test, a sack with 25 kg dolomite filler was used. While stirring, it was slowly emptied into a 50 L plastic bucket prefilled with the amount of water required for each test. The resulting slurry was kept in suspension with a mechanical stirrer driven by a compressed air motor.

Tests were conducted at three suspension concentrations: 60, 65 and 70 weight% solids. To the feed pulp at 65 and 70 weight% a liquid dispersant, Dispex® AA 4140 from BASF was added. This dispersant is a solution of a sodium salt of an acrylic polymer in water. It was added at 0.5 per cent of the solids mass in a test ie approximately 125 g. For each suspension concentration, two separate tests were run at approximately feed rates 1 and 2 L/min respectively. A test run was started with the preparation of the suspension, it was then pumped (Pass 1) through the mill into another, receiving 50 L bucket until the feed bucket was nearly empty. Thereafter, the receiving bucket became the new feed bucket, and the suspension was pumped back (Pass 2) into the now cleaned first bucket. Samples for particle size measurements were collected in 0.5 L plastic bottles: from the first feed bucket and from the mill discharge pipe close to the end of each pass. Particle size distributions were obtained by wet laser diffraction (Cilas 1064), *cf* Figure 1.

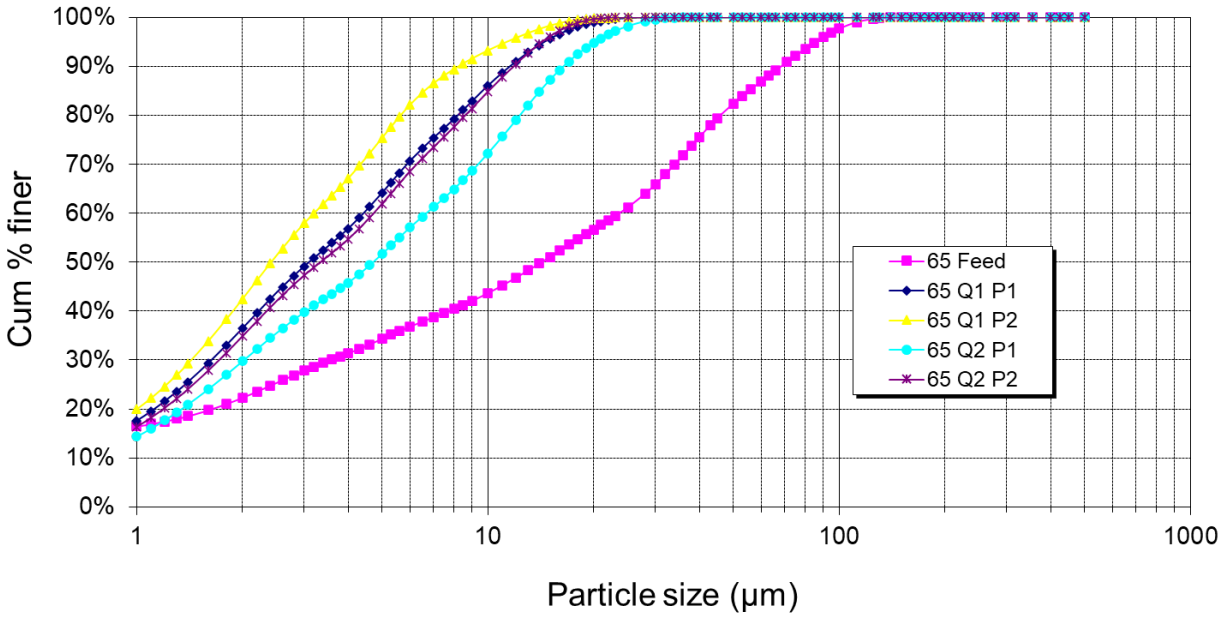

FIG 1 – Particle size distribution for test with 65 weight% solids. Q1 1 lpm, Q2 2 lpm, P1 Pass 1, P2 Pass 2.

Temperatures of pulp and cooling water, as well as the cooling water flow was manually measured at intervals throughout each pass. For temperature, a digital contact thermometer was held in the pulp flow and cooling water flow until a stable reading was obtained. Cooling water flow and pulp flow were estimated by taking the time to fill a 1 L graded beaker. An example of temperature measurements is in Figure 2.

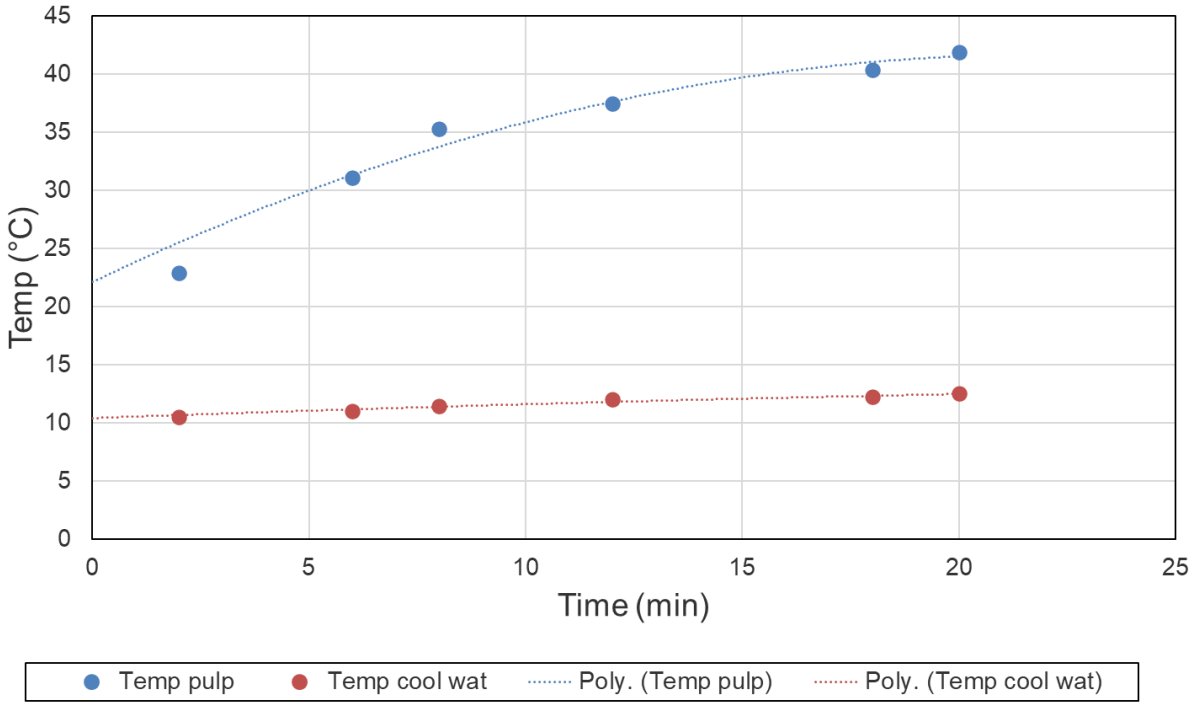

FIG 2 – Temperature curves for test with 65 weight% solids. Dotted lines for second order polynomial fits.

Traditional grinding parameters

The mill is investigated in two ways: firstly, the traditional approach with measurement of supplied electrical energy resulting in a decrease of particle size, and from this, several grinding efficiency indices may be calculated; secondly by comparing the supplied electrical energy to the heating of pulp and cooling water, and then an estimate of energy efficiency can be obtained.

The active power was measured by an energy metre (Micro VIP from ELCONTROL). It was found that the mill idling power with water in the mill was approximately 3 kW, and the working power varying between 4 and 5 kW. Knowing input power, feed rate, dilution ratio, and pulp density, it is possible to calculate the amount of net energy spent per mass unit of solid feed. Here, the mechanical efficiency is taken as the quotient between net and gross power. The size reductions were estimated from the particle size distributions (Figure 1), and then an apparent Bond work index, and grindabilities (kg <size/kWh net energy) could be calculated. An example for a test with 65 weight% solids and 1 L/min feed rate is shown in Table 1.

TABLE 1

Compilation of grinding data for test with 65 weight% solids, feed rate 1 L/min.

Dolomite filler 0–70 µm	Feed	Pass 1	Pass 2
Amount of material [kg]		25.08	25.08
Pulp feed rate [lpm]		1.04	1.05
Pulp wt-% solids		65.08%	65.08%
Dilution ratio		0.54	0.54
Solids flow [kg/s]		0.020	0.020
Gross power [kW]		4.5	4.0
Idling power [kW]		3.1	3.2
Mechanical efficiency [%]		31.1%	20.0%
Net power [kW]		1.4	0.8
Specific net energy in each step [kWs/kg]		71.48	40.46
Specific net energy in each step [kWh/tonne]		19.86	11.24
Cumulative specific net energy [kWh/tonne]	0.00	19.86	31.09
d_{80} [µm]	45.0	8.5	5.6
< 20 µm [%]	56.68	98.97	99.84
< 10 µm [%]	43.71	86.05	93.25

Apparent BWI [kWh/tonne]		10.24	14.12
Average app. BWI [kWh/tonne]		10.24	11.37

Energy parameters

Knowing the gross and net power of the mill in combination with the heating of the pulp and the cooling water allows for doing a rough energy balance for the mill under the following assumptions:

- Net energy comes from the difference between working and idling power, and that the calculations are done per second.
- Temperatures at the end of a run have approximately reached steady state. This is seen in Figure 2.
- Heating of internal parts at the end of a run are at steady state, and then the heat capacity and heating of these parts may be neglected in the calculations.

The results for a test with 65 weight% solids, and pulp flow 1 L/min are presented in Table 2. In most tests, the net energy for the second pass is lower than in the first. This is interpreted as a grinding limit effect that the smaller particle size makes for less efficient grinding. This is also supported by the fact that the heating of the pulp is larger in the first step. To calculate the heating of pulp the specific heats for limestone 0.84 kJ/kg·K and water 4.18 kJ/kg·K are used in combination with the respective flows of solids and water. In the same way, the heating of the cooling water comes from the knowledge of temperature increase and water flow. These three heating values taken together

become the sum of heating, or loss of energy to heating. It is interesting to note that sum of heating is approximately 2/3 of the idling energy.

TABLE 2

Energy values for test with 65 weight% solids, and flow 1 L/min.

Pass	**Gross power (kW)**	**Gross energy (Ws) or (J)**	**Net power (kW)**	**Net energy (J)**	**Idling energy (J)**

P2	5.56	0.093	3.6	1394.45	2034.80		

RESULTS AND DISCUSSION

A summary of all the results is presented in Table 3. In the left part of the table are the traditional grinding efficiencies: grindability at 5 and 10 μm, and the apparent Bond Work Index. Grindability is a fair indicator of overall grinding efficiency since it connects a grinding result fineness with a measured energy input. The Bond Work Index is included for comparison since it is an industry standard, but it is hardly applicable in this low particle size range. In the present case, the net energy is the active energy as measured with an energy metre, and with the idling energy deducted. In this way, it is found that approximately 20–40 per cent of the input gross energy is used for the grinding process, and this is in fair agreement with the data found by Shi *et al* (2009). It does not say, however, that this is the real energy used for breaking the particles since the energy connected to the elastic deformation of particles and creation of micro-cracks cannot be distinguished. Therefore, the net energy and grinding efficiencies presented here are practical limits that can be had in full-scale operations.

The idling energy, the difference between gross and net input electrical energy, is always larger than the calculated heating of the pulp and the cooling water. The difference between them, is energy not measurable in the experimental set-up. However, it may be assumed that this is mainly mechanical energy losses in the transmission.

The table also reveals that most of the grinding takes place during the first pass through the mill, as can be seen from the grindability values. There is no clear effect of the use of a dispersant on the grindability, but the measured heating is lower if a dispersant is added to the pulp. However, this cannot in this experimental set-up be separated from the effect of increasing the solids concentration.

For the two lower solids concentrations, there is a patten that the higher flow rate (Q = 2 L/min) gives a better grinding efficiency. This seems not to be true for the highest solids concentration (70 weight% solids) that corresponds to 44.3–44.9 volume% solids. The grinding efficiency in this case is generally worse, especially at the high flow rate. At the same time, the heating is lower. A likely interpretation is that what is seen is a flow resistance effect, due to the high volumetric solids concentration. A possible explanation is that the charge is mostly rotated as a viscous body inside the mill, without the free movement of grinding bodies. The free movement and rotation of grinding balls is a necessity for attrition grinding. It should also be noted that the measured idling energy is lower at the highest flow rate, and this might indicate an experimental error. This also results in apparent, but not likely, better usage of energy for the highest solids concentration and flow rate.

TABLE 3

Summary of grinding and energy efficiencies.

Grinding				Energy					
Identity	Grindability		App BWI	Gross energy	Net energy	Idling energy	Heating	Dispers.	Used for grind.
	(kg <10 µm/ kWh)	(kg <5 µm/ kWh)	(kWh/ton)	(J)	(J)	(J)	(J)	(% of solids)

The relationships between the different energies are also described in Figure 3 with the example of the runs with 65 weight% solids and flow rate 1 L/min. Here, the gross energies are set as 100 per cent, and the others as part of this. The net energy, defined as the difference between the supplied gross energy and the idling energy, is in this case between 20 and 30 per cent. The idling energy may be split between the energy related to heating of pulp and cooling water, and a difference that is here called Idling-Heating (Idling minus Heating). This energy difference probably mostly contains mechanical losses, but also any heating of the gearbox and motor.

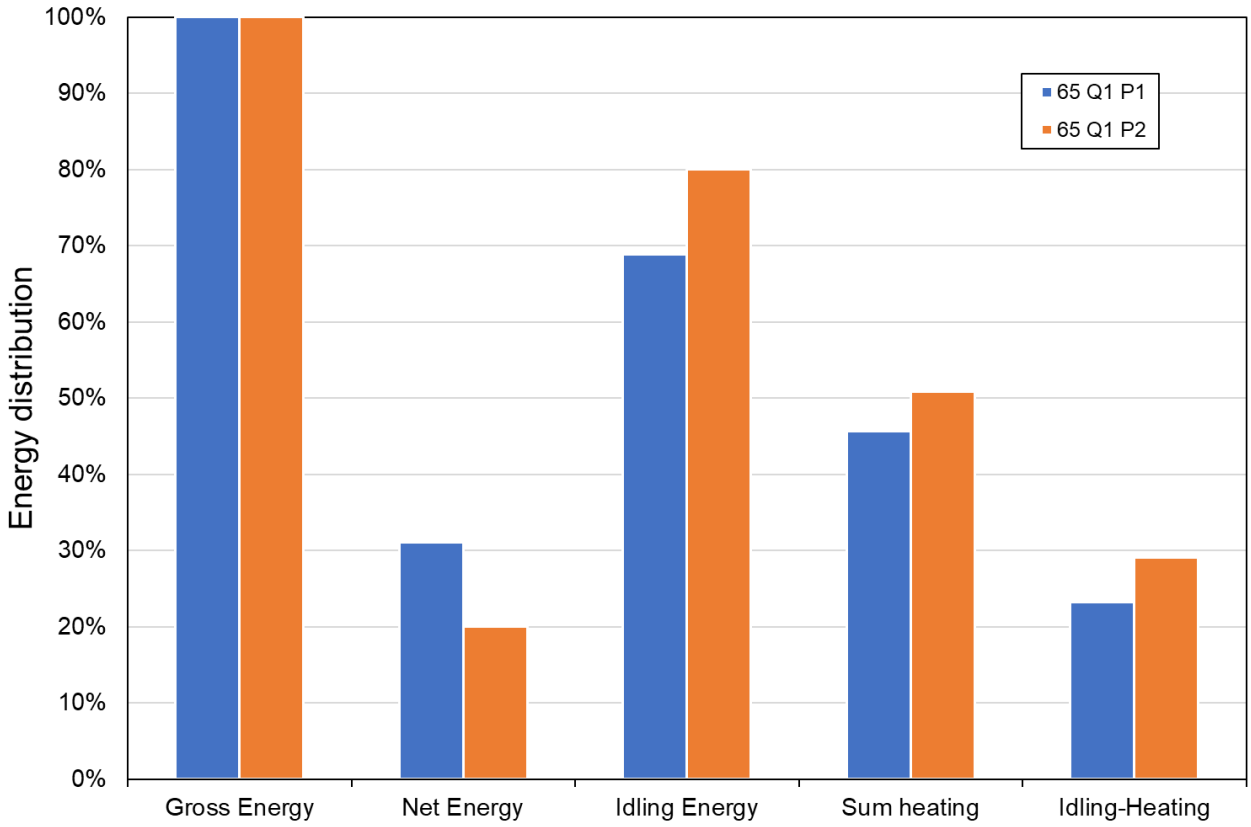

FIG 3 – Energy distributions in test with 65 weight% solids, and pulp flow 1 L/min.

CONCLUSIONS

The actual useful grinding energy is the estimated net energy, and this accounts for 20-40 per cent of the applied electrical energy to the stirred media mill. This is far more than what was estimated by Lowrinson (1974), but slightly higher than found by Fuerstenau and Abouzeid (2002), who worked with ball mill grinding. This is a reasonable difference since stirred media grinding is normally assumed to be more efficient than ball mill grinding.

It is not certain that the net energy is the effective energy for size reduction since it is not known to what extent any elastic effects in the deformation of the solids are accounted for. However, it is the most effective measure from an industrial perspective.

Any estimation of an approximate grinding energy balance should be simple even on an industrial scale:

- Run the mill with no feed to get an estimate of the idling power, and then measure the power draw with normal feed rate. This will work for stirred media mills, but maybe not for tumbling mills since a low feed rate will move the charge centre of gravity outwards.
- Measure the temperature difference between feed pulp and discharge pulp at steady-state operation to calculate the heating energy.

Heating of pulp and cooling water accounts for most of the idling energy, the rest is mechanical losses and heating in motor and gearbox that are not caught by the experimental set-up.

The addition of a dispersant seems not to directly affect the net grinding efficiency but lowers the losses to heating. Thus, a dispersant is indirectly beneficial.

ACKNOWLEDGEMENTS

The work presented here was done within the Vinnova project 2017–05463, ‘Stirred media mill performance and grinding wear prediction’.

ABSTRACT

One of the main factors affecting the suitability of an ore for autogenous grinding is the ore's competency, ie providing enough critical stones for the grinding process. Several experimental test routines exist and are used for assessing the viability of the ore for autogenous grinding. However, very little attention is given to the generation of fatigue in large stones experiencing repeated shocks in the mill. To investigate this, large pebbles sampled from an industrial autogenous grinding mill running hard and soft ores were categorised based on the grinding energy.

From the pebbles, small drill core samples were prepared and went through a series of fatigue cycle tests. Both hard and soft ores showed similar average resistance to failure in compression tests, but the hard ore had a consistent resistance with lower variations. The cores were scanned by XCT before and in-between fatigue tests at the highest reachable resolution, 1.5 µm voxel size. The outcome showed that a higher number of micro-cracks were visible in the soft ore compared to the hard ore. The frequency of micro-crack development in the soft ore may be the reason for its lower specific grinding energy compared to the hard ore.

It is obvious that for realistic conditions in an autogenous grinding mill, stones are pre-weakened by fatigue before they fracture. Therefore, shortcut methods focusing only on running tests on fresh and small samples may operate in unrealistic conditions by ignoring the fatigue phenomenon. This is even more important for ores that are on the borderline to be considered as competent for autogenous milling.

INTRODUCTION

Comminution is the process for liberation and size reduction of ores prior to separation processes. Generally, in mineral processing, grinding is done using rod, ball, autogenous, or semi-autogenous mills. Fully autogenous grinding (AG) is the most cost- and process-efficient grinding, benefiting from eliminating steel grinding media. It is also a superior choice for downstream processes such as flotation, since some sulfide minerals are sensitive to the reducing conditions caused by iron chipped away from the steel media.

The dominant loadings on particles in autogenous mills are impact and attrition. Successful impact of large stones on particles directly relates to an ore's competency and hardness. On the other hand, fines generation in the mill is often related to abrasion resistance of the ore. During mill tumbling, the large stones self-break after some cycles and generate smaller and sometimes critical stones. The motion of the charge and sliding of the particles inside the mill leads to abrasion breakage. This is known for quite some time and applied also for developing empirical and mathematical models for AG mills (Stanley, 1974).

The general idea of designed tests for autogenous grinding originated from how the breakage may occur inside the mill. This is principally divided into impact and attrition tests also known as low and high energy breakage (grinding) tests. Many small-scale test methods were developed and used over the years for AG milling design and estimating the ore response to AG grinding. These include, for example, the Macpherson test (Macpherson, 1977), Bond work indices (Barratt and Allan, 1986), the Drop Weight Test (Lynch, 2015), the SAG Power Index (Starkey and Dobby, 1996), the SAGDesign test (Starkey, Hindstrom and Nadasdy, 2006), the SAG Variability Test, Advanced

Media Competency Testing (Mcken and Williams, 2006), the Hardness Index Tester (Bergeron *et al*, 2017) and a couple of other instrumented tests based on similar principles.

A large number of small-scale test methods ignore realistic mill conditions corresponding to the generation of fatigue in stones during grinding cycles. The current study presents an experimental procedure and results from fatigue tests on two samples, corresponding to two ores described as soft and hard ores. The generation and growth of micro-cracks during fatigue cycles contribute to weakening the stones prior to breakage, therefore, X-ray computed tomography (XCT) scanning with the highest resolution was used to observe these phenomena (Parapari *et al*, 2020).

EXPERIMENTAL WORK

The experimental part is focused on investigating the generation of fatigue in large stones (coarse fraction of the AG mill feed) that happens under realistic mill conditions. Fatigue, the accumulated stress in stones, makes them more prone to fracture. It is believed that the generation of micro-cracks (in size of microns) and their growth during loading cycles are the main contributors to this phenomenon. Therefore, XCT scanning at best resolution (1–2 µm) may potentially reveal the frequency of micro-cracks in the micron range. As high resolution XCT scanning works best on extremely small samples, drill cores with dimension of ϕ4.5 × 7.0 mm were produced. To perform loading on such a small drill core, a special sample holder was designed and manufactured. Loading on the samples was done at the Geological Survey of Finland (GTK) and followed by XCT scanning at their facilities.

Samples and sample preparation

The samples for the experimental work were received from Boliden Mineral AB. The samples named soft and hard ores were the <100 mm fractions of the ores. The specific grinding energy required for the soft and hard ore was 17 and 9 kWh/t respectively in an autogenous grinding circuit in the plant. To evaluate the fatigue of large stones in AG grinding, a coarse fraction from both ore types was selected for preparing small drill cores. The samples were washed and cut into 2 cm slices (Figure 1), drilled using a diamond bit, and trimmed to obtain ϕ4.5 × 7.0 mm drill cores.

FIG 1 – Sliced large stones for preparation of small drill cores.

Instrumental set-up for failure and fatigue tests

To generate fatigue in the cores, a special sample holder for conducting the Brazilian loading test (Bieniawski and Hawkes, 1978) was designed and manufactured at the workshop of Luleå University of Technology. The sample holder outer dimension was set to match the dimensions of the loading machine (Figure 2) and the inner gap matched the cores of diameter 4–8 mm.

The Deben CT5999 Tec unit at GTK was used for the compression tests. The device can deliver up to 5000 N loading. For the experiments, a 0.1 mm/min displacement rate was selected as the ore material is brittle and generally has very low elastic behaviour.

FIG 2 – Deben CT5000 TEC unit at GTK used for compression tests. The Brazilian loading test apparatus is on top of the loading cell.

Failure tests

Before starting the fatigue tests, it is important to know the range of resistance that the ores may have to avoid breaking the cores too early. Therefore, to find the range of failure points for both ores, ten failure tests were performed on each ore type. The test procedure for all the test runs was identical.

In general, both ore types had similar average failure points of around 433–435 N (Table 1). However, the soft ore showed larger variability (Standard deviation 114 compared to 73) and is often accompanied by initial breakage (or chipping) before breakage. The minimum and maximum resistances for the hard ore were 303 N and 570 N and for the soft ore were 284 N and 673 N. In general, the hard ore showed more consistent resistance to compression load.

TABLE 1

Failure points for hard and soft ores and the average values.

Sample	Hard ore	Soft ore
	Failure load [N]	Failure load [N]
1	303	542
2	410	673
3	570	485
4	366	323
5	501	409
6	459	431
7	438	284
8	447	338
9	395	402
10	464	445
Average	435	433
Standard deviation	73	114

Fatigue tests

To ensure that the samples will not break prematurely during fatigue test experiments, a safe loading force, 200 N, and 0.1 mm/min displacement rate was used for the first cycle of fatigue tests. For the

second stage of fatigue tests, the load was increased to 300 N with a 0.1 mm/min displacement rate. Each fatigue stage consists of ten loadings and ten releases of the force at a 0.1 mm/min displacement rate (Table 2). During running the first and second fatigue stages none of the cores broke. The cores were saved for XCT analysis and new cores were selected for higher load tests. For the new cores, the fatigue test run was ten cycles of 400 N loading at 0.1 mm/min displacement rate. Therefore, the first set of samples went through the first two stages of fatigue runs (in Table 3, A1 and B1 samples) and the second set of samples underwent only the third stage of fatigue runs (Table 3, A2 and B2 samples).

TABLE 2

Fatigue test stages on each ore type core.

Stage	Sample state	Fatigue test condition
0	no fatigue	No cyclic load
1	1st fatigue run	10 cycles at 200 N
2	2nd fatigue run	10 cycles at 300 N
3	3rd fatigue run	10 cycles at 400 N

TABLE 3

XCT scans on samples using the microfocus tube.

Scan	Core	Ore type	Fatigue state
1	A1	Hard	No fatigue
2	A1	Hard	10 cycles at 200 N
3	A1	Hard	10 cycles at 200 N and 10 cycles at 300 N
4	A2	Hard	10 cycles at 400 N
5	B1	Soft	No fatigue
6	B1	Soft	10 cycles at 200 N
7	B1	Soft	10 cycles at 200 N and 10 cycles at 300 N
8	B2	Soft	10 cycles at 400 N

At 400 N loading, the hard ore remained completely intact once in three different core repetitions. Other tests had some chipping and failure before the end of the ten cycles. At the same load, the soft ore broke all the time before the end of the cycles. In one of the test runs, the sample (B2) broke without catastrophic failure.

XCT Scanning

In total, eight XCT scans were conducted on the samples according to Table 3. The samples were scanned using the 180 kV microfocus tube in focus mode 2 with an accelerating voltage of 100 kV and a tube current of 260 µA, for a total tube power of 26 W. No beam filter was used. There were 2700 angle steps, and at each angle, the camera first waited for a single exposure time and then took an average of over three exposures. The single exposure time was 2000 ms for a total imaging time of 6 hours per sample. The voxel resolution was 1.53 µm in the final images.

RESULTS AND DISCUSSIONS

The reconstructed volume from the XCT images has shown many micro-cracks in both the hard and soft ore samples even before the fatigue tests. The micro-cracks in XCT slices are visible as dark spots or hair shapes depending on the orientation of the cracks in the images (Figures 3 and 4).

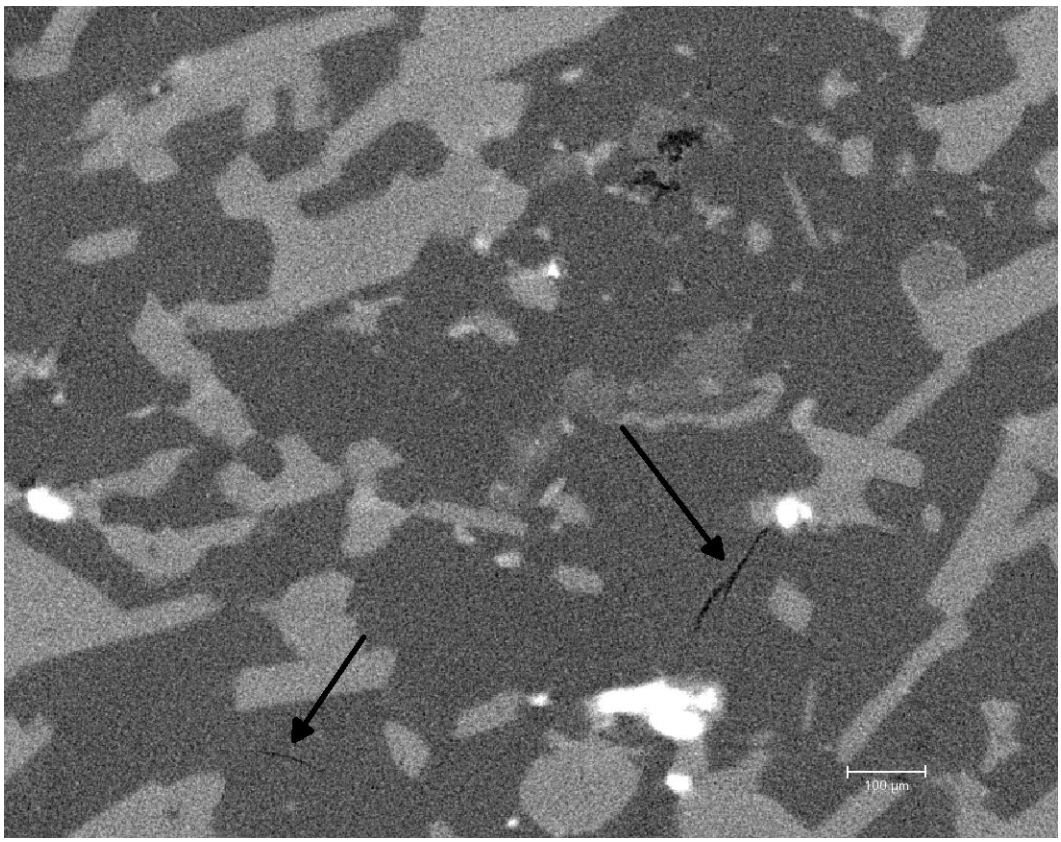

FIG 3 – A slice image of reconstructed volume of drill core A1, hard ore, after the second stage (10 × 200 N and 10 × 300 N cycles) fatigue loading. Dark spots and hair shapes are micro-cracks with different orientations.

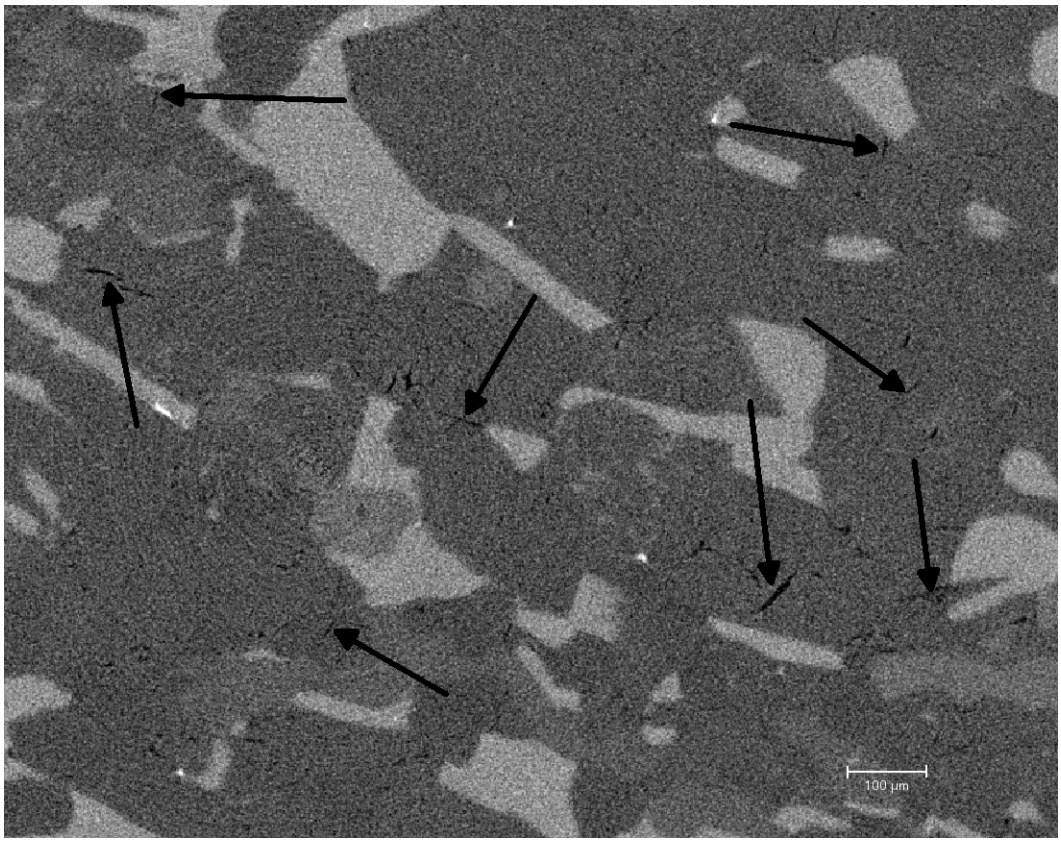

FIG 4 – A slice image of reconstructed volume of drill core B1, soft ore, after the second stage (10 × 200 N and 10 × 300 N cycles) fatigue loading. Dark spots and hair shapes are micro-cracks with different orientations.

After the first stage of the fatigue tests on both samples, the number of micro-cracks in the soft ore increased, however, no apparent increase of micro-cracks was visible in the hard ore. A similar pattern was seen after the second stage of fatigue tests.

The fatigue test at 400 N loading on hard ore (A2) did not result in any fractures visible in the XCT images. But in the process of investigating the images, holes and void volumes were found accumulated in some regions of the samples. Theoretically, they are weak spots for growing cracks, but apparently the 400 N loading cycles were not enough to generate fracture. The soft ore (B2) partially fractured during the 400 N loading cycle tests, but the sample as a whole stayed together and resisted the ten cycles.

In the soft ore, the progressive increase of micro-cracks after each fatigue test and eventually fracturing in the higher load indicate that the critical stones are likely consumed faster compared to the hard ore. This is also reflected in the specific grinding energy of each ore type where they correlate well with the frequency of micro-cracks observed in each ore. To further investigate this, conducting single breakage tests on intact and fatigue-induced samples may give some insights on the magnitude of the pre-weakening effect of fatigue.

In term of crack size, the soft ore has longer visible cracks. It is worthwhile to note that, to view the true size and length of micro-cracks, it is best to be observed under loading when cracks are opened due to tensile stress. However, for such a small sample with loading apparatus close to the objective, this was not achievable.

The XCT scanning of the ore at this resolution (1.53 µm) is providing a lot of details about micro-structure of the rock including cracks. However, this comes with limitation on the sample size and quality of the images. The sample must be in a size of a few millimetres and the results often accompanied by artifacts and irregularities in illumination of image slices. The later makes it difficult to extract volume information digitally. Therefore, the data evaluation in this case was only done qualitatively by comparing two distinctive ores namely the soft and hard ores.

CONCLUSIONS

Two samples corresponding to soft and hard ore according to grinding energy were used to evaluate their behaviour in response to fatigue. Both samples showed relatively similar average resistance to failure in Brazilian compression tests, however, the hard ore had a consistent resistance with lower variations. The soft ore often displayed initial chipping before reaching failure. XCT scans of the cores after each stage of fatigue cycles showed that more micro-cracks were visible in the soft ore compared to the hard ore. The frequency of micro-cracks development in the soft ore may be the reason that it requires lower grinding energy compared to the hard ore.

It is obvious that for realistic conditions in an AG mill, stones are pre-weakened by fatigue before fracture. Therefore, the shortcut methods focusing only on running tests on fresh and small samples may operate under unrealistic conditions by ignoring fatigue. This is even more important for ores that are on the borderline to be considered as competent for AG milling.

ACKNOWLEDGEMENTS

The work presented here was done within the Vinnova project 2019–05194, ‘AG-Test; Small scale tests for autogenous grinding scale-up’. X-ray tomography analysis was funded by the Academy of Finland through the RAMI infrastructure project (293109). Assistance in providing the samples by Boliden Mineral AB is appreciated.

ABSTRACT

It is understood that rocks do not instantaneously transport along a grinding mill and are consequently not perfectly mixed, but this is conveniently overlooked in mill modelling. A lack of understanding of the transport phenomenon and the difficulty of modelling realistic transport in a complex tumbling system, contribute to this.

Visual observation of segregation in AG and SAG mills and measured lag time of mill response to changes in feed provide evidence of the influence of axial transport within mills. Incorporating this lag in dynamic models should underpin dynamic simulation of milling circuits for design and for model-based control. Limitations and errors in predicting the influence of increased power via mill length versus diameter, inability to predict pebble production, and a lack of the differential in residence time across rock sizes and competences, all contribute to inadequate design prediction that can be especially acute for large Autogenous mills. Examples of dramatically under – and over-loaded pebble regrind circuits and the inability to predict pebble load in AG milling discouraging the application of this energy-efficient option, point to the need for predictive modelling of breakage by competence linked to transport through and out of mills.

Incorporating progress in granular flow and mixing, coupled to computational advances enable models to be based on complex breakage and transport models at high spatial resolution. This allows mechanistic models to simulate thousands of times faster than real time, opening the door to more accurate mill design, including dynamics in process simulation and to live simulation for process control – all with advanced mechanistic models. The value of grasping this opportunity is not easily refuted.

INTRODUCTION

It is understood that rocks do not instantaneously transport along a grinding mill and thus the contents are not necessarily perfectly mixed, but this is omitted from mill modelling. A lack of understanding of the transport phenomenon and the difficulty of modelling realistic transport in a complex tumbling system with a wide size range of rocks, contribute to this. The discussion focuses on industrial SAG and AG mills with a wide range of rock size distribution and considerable length, that are most affected by axial transport effects.

As a workhorse for size reduction in the minerals industry for over 100 years, the understanding of the grinding action in the tumbling mill is remarkably poor. Underlying this is the challenge that as simple as it appears in principle, the grinding action in a mill is a genuinely complex problem. The lifting and cascading or cataracting of a mixture of steel balls and rocks was first described in simple mathematical terms by White (1905) and then Davis (1919). Greater insight was provided by Powell and Nurick (1996a, 1996b, 1996c) through filming the internals of a model mill with X-ray cameras to elucidate the motion of grinding balls. This was refined and extended in the work of Govender, Powell and McBride (2004) which provided more quantitative measurement of the charge motion,

leading to a more formal description of the structure of the charge described by Powell and McBride (2004). The description is illustrated in Figure 1.

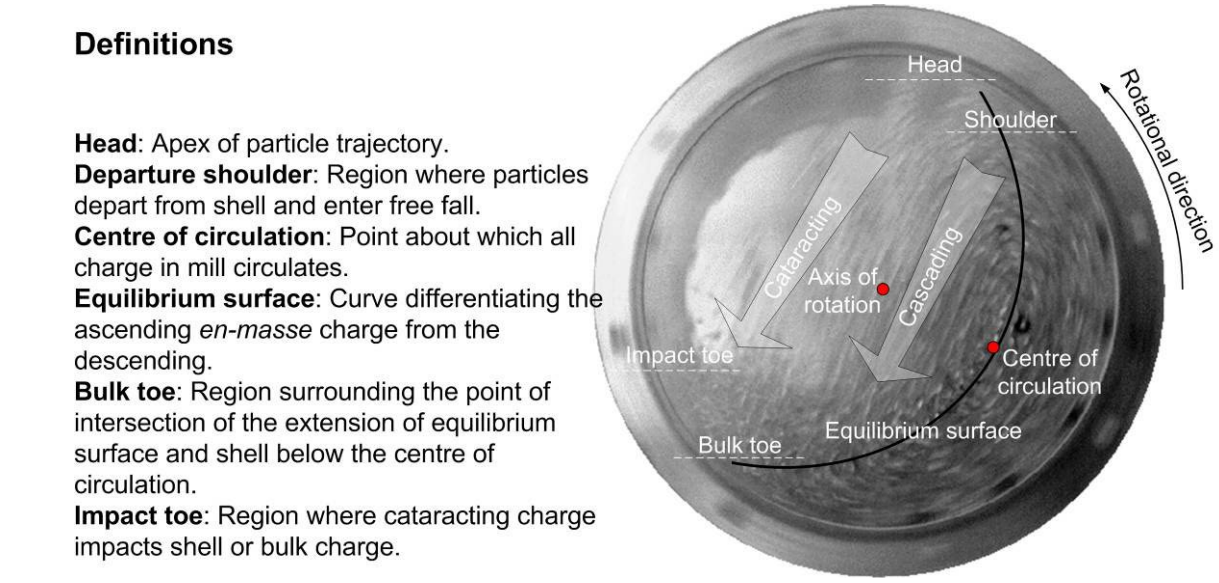

FIG 1 – Description of the charge rotation motion in a tumbling mill (Powell and McBride, 2004).

Although useful, the vertical slice view of charge motion does not provide input to the axial transport phenomenon. Powell measured axial motion of balls (Powell and Nurick, 1996b), but this was presented as qualitative data due to issues of location accuracy of the tracked particle. The work of Govender (Govender, Powell and McBride, 2004) developed improved particle tracking methods that allowed this axial motion to be tracked over many revolutions of the mill, such as that in Figure 2. This shows a strong and quantifiable drifting of a particle over time, which is clear evidence of axial transport and mixing. The particle can take 1 to 3 minutes to travel the length of the mill operated in batch mode. Superimposed upon this will be the average flux of particles being transported along a continuously fed and discharging production mill.

Insights into transport in mills have been gained from radioactive and conductivity tracer studies (Faria, Rajamani and Tavares, 2019; Fuerstenau, Abouzeid and Swaroop, 1986; Gardner, Verggese and Rogers, 1978; Hassanzadeh, 2017; Kelsall, Reid and Restarick, 1970; Makokha, Moys and Bwalya, 2011; Rogers, Bell and Hukki, 1982; Vinnett *et al,* 2018; Weller *et al*, 2000; Yianatos *et al,* 2005). However, very often these studies are either limited to studying either the fluid or very fine particles (Faria, Rajamani and Tavares, 2019; Makokha, Moys and Bwalya, 2011; Hassanzadeh, 2017). Although allowing to confirm the common assumption in assumption of the similar behaviour of those very fine particles to that of the fluid, they offer no insights on the behaviour of coarser particles, which are critical in Autogenous and Semi-Autogenous mills. Only very few studies have been conducted with relatively coarse particles that act as grinding media, in particular in Autogenous and Semi-Autogenous mills (Vinnett *et al,* 2018). Unfortunately, analysis of data has been often only limited to fitting theoretical residence time distribution models for population balance model formulations. Yet, Vinnett *et al* (2018) demonstrated that coarser particles presented twice the residence time of fines, thus demonstrating the important differences in their transport in the mill.

The present work analyses critically transport of coarse particles in mills, with emphasis to AG and SAG mills, analysing practical observations in industrial mills, principles of a modelling approach that can potentially describe it mechanistically and finalising by analysing implications of incorporating transport in dynamic and mechanistic models.

PRACTICAL OBSERVATIONS

One of the strongest motivations for incorporation of transport in mills can be provided by the simple path of observation. It is usual to crash stop a mill in order to conduct accurate measures of mill filling. The concurrent stopping of ore feed, inlet water, recycle streams (crushed pebbles and sometime cyclone underflow) and switching off the mill power provide a snapshot of the mill internals. The high inertial force of the mill contents ensure the mill rapidly decelerates to a stop in less than one rotation, thus not allowing any significant flow along the mill. A few examples are shown to illustrate how significant the transport and segregation is in mills. The images in Figure 3 provide clear visual evidence of segregation by size and ball fraction along a SAG mill. The fraction of balls increases along the length of the mill while the mid-size rocks are sparse and there are fewer large rocks.

FIG 3 – Segregation from feed to discharge end of a 32 ft diameter, 16 ft long SAG mill (left: feed end; right: discharge end).

The segregation in a SAG mill treating a relatively soft ore is well illustrated in Figure 4, with almost no rock visible at the discharge end.

FIG 4 – SAG mill 21 per cent filling, 11 per cent balls.

A large autogenous mill provides an extreme case shown in Figure 5. This 22 MW, 38 ft diameter mill provides an illuminating study of the transport of the large rocks along the length of the mill, crowding near the discharge. Understating the transport time along with the breakage abrasion rate of the large rocks becomes central to predicting the overall performance of this mill.

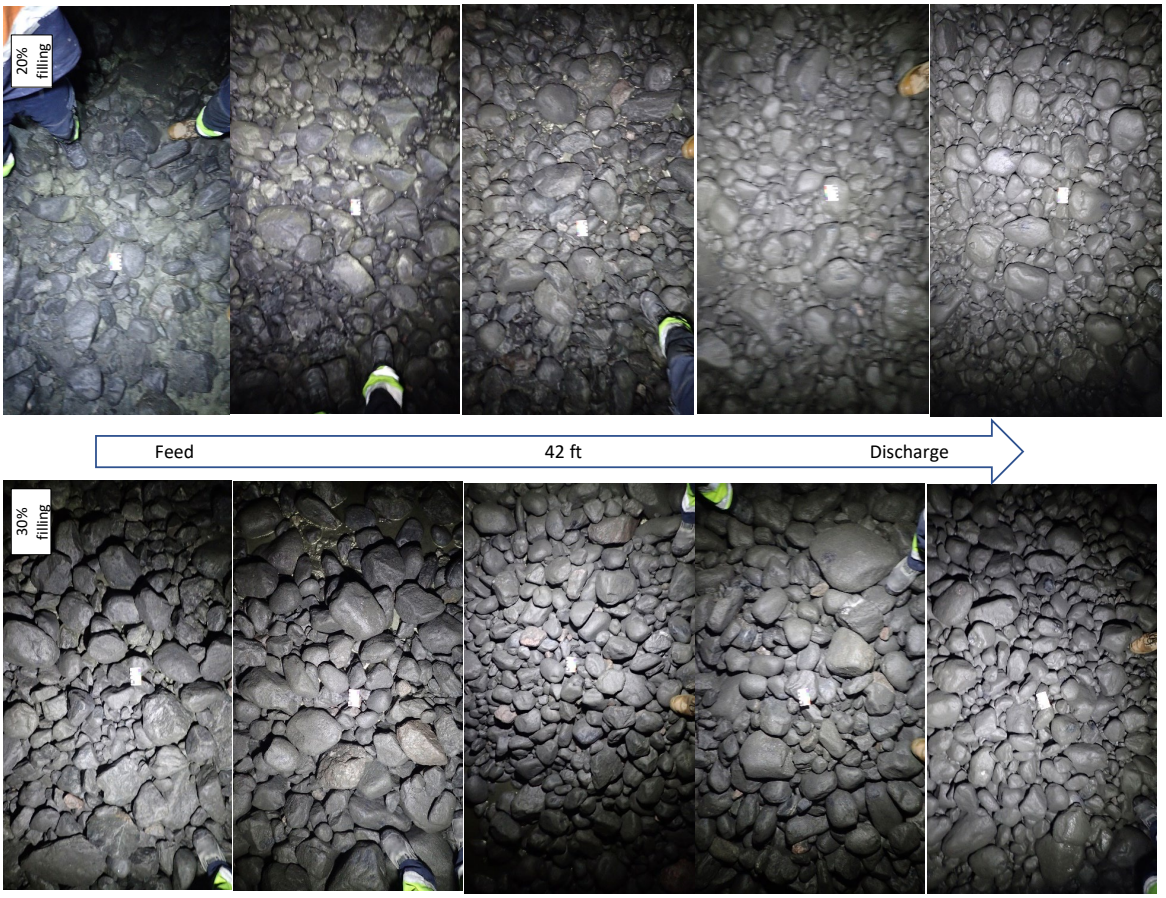

FIG 5 – Survival of large rocks in the Aitik Boliden 42 ft long (12 m internal length) AG mill.

Although indirect, the influence of transport on mill operation is also demonstrated quite differently through the dynamic lag in mill response. The method of developing grindcurves, as evolved by Powell and Mainza (2006), implemented by Powell, van der Westhuizen and Mainza (2009), and extended by Powell, Perkins and Mainza (2011), provides excellent data on control lag. The method of incrementally increasing feedrate in small steps over an extended period prevents pulsing of the mill contents. When applied, this results in a distinct signature of the lag between a control change and mill response, such as in Figure 6.

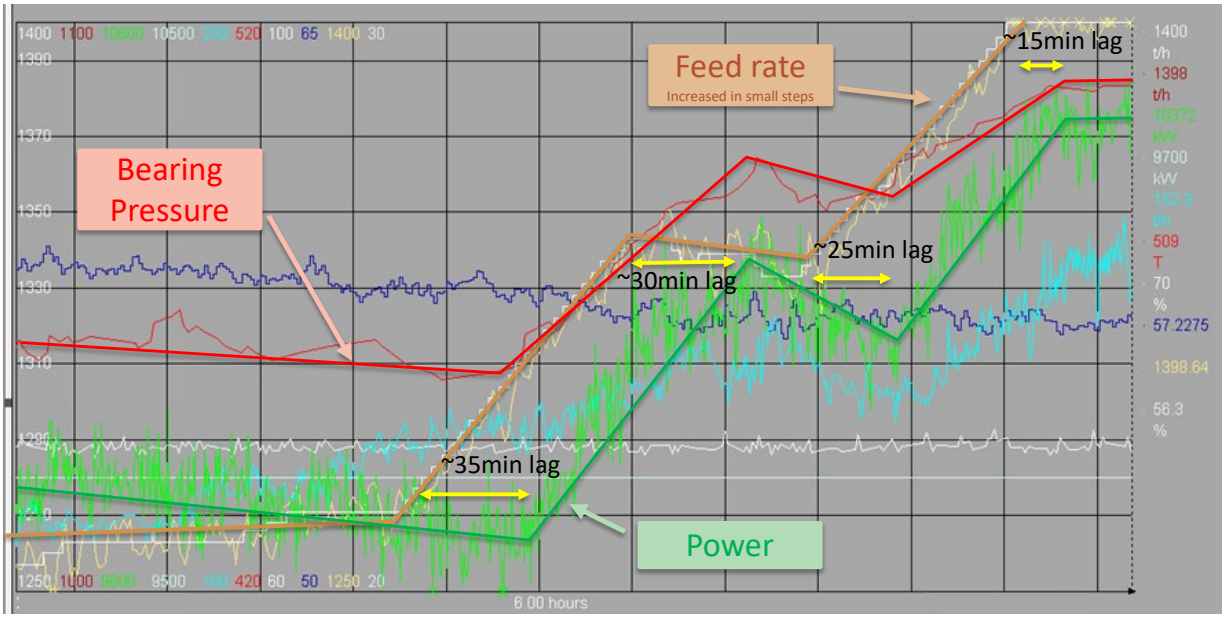

FIG 6 – Response lag time measured in a SAG mill.

For this 12 MW mill, the mill filling is indicated by bearing pressure. The gradual 2 t/h per 2 minute rate of increase in mill feed shows no effect on the mill load and power for 35 minutes at the start of the test, noting that the mill had been gradually losing load and power prior to this feed increase. The feedrate is then held relatively stable for an hour, yet the mill continues to increase in filling for another 30 minutes. The subsequent reduction in filling and power indicate that the discharge has overtaken the new stable feedrate. A further gradual step-wise increase in feedrate turns the mill filling in 25 minutes. The final stabilisation of feedrate brings the mill into a stable operation for the last data point.

The consistent measurement of these lags in mill response point towards the discharge end of the mill being ignorant to the change in feed. The classification of the discharge for the earlier feed remains consistent and the discharge rate is maintained to match the increasing feedrate, as the content at the discharge end has had a longer residence time, consistent with the original feedrate. Gradually the coarser product associated with the higher feedrate reaches the discharge end and begins to build-up and affect the internal transport, leading to the strong ramp-up in mill filling.

No perfectly mixed model or steady state model can predict such behaviour. The so-called model-based control systems rely on extreme step tests for calibration. Large changes do pulse the mill contents and force a rapid, and easily measured, response. However, such a calibration method is inappropriate for a granular system with significant transport time in the system. It is the position of the authors, that this forces calibration leads to over-reactive control systems. Rather than a control that dampens out perturbances these approaches can amplify disturbances through over-control. It is not uncommon to observe cyclic mill operation, with swings in power of up to 10 per cent with a consistent period in the region of an hour. These are control-induced, as easily proven by overriding any control system or operator input and leaving the mill to stabilise, a practice successfully applied by the authors on mills around the world.

Incorporating this lag in dynamic models should underpin dynamic simulation of milling circuits for design and for model-based control. If there is not a realistic, size dependent transport term in a mill model, especially significant for SAG/AG mills, then it cannot be mechanistic or dynamic – highlighting falsely claimed dynamic models in process control.

The analysis of Powell, Morrell and Latchireddi (2001) highlighted the influence of mill aspect ratio (ratio of diameter to length) on grinding performance. As a consequence of longer residence time, which is an outcome of granular flow and transport, the longer mills produce a finer product. A long mill cannot be forced to produce a coarse product and thus design engineers had fallen into the trap of an imbalance between SAG and ball mill power when specifying longer SAG mills.

The work of Mwansa and Powell (2004) and Powell, Mwansa and Condori (2006) provided further impetus to understand transport. In this study, the contents of a small production SAG mill (3.5 m diameter by 4.7 m long) was emptied out as four separate slices, including careful pre-draining of the slurry. The particle size distribution of the feed and content from the four slices along the mill are shown in Figure 7 and the corresponding data for the size passing 80 per cent of the material is given in Figure 8. There is segregation of the material in the mill with the content at the feed end exhibiting more coarse particles. The material was shown to become progressively finer from the feed end to the discharge end of the mill. This agrees with observations made by Hogg and Rogovin (1982) from their segregation studies in an overflow laboratory mill. The unique feature with the high steel load SAG mills, or RoM ball mills are they are sometime referred to, is that the content is depleted of particles in a certain size range represented by the portion where the particle size distribution is constant. Mwansa and Powell (2004) carried out ore breakage characterisation tests on the feed and material from each of the four slices and analysis from the Drop Weight and Bond ball tests indicated the rocks near the discharge end were significantly more competent than that at the feed end. The feed material has a wide distribution of competence, particularly in the UG2 ore in this trial. Since material that is not competent grinds down easily, the fraction of competent rocks increases progressively from the feed end to the discharge end. The Bond work index increased from 15.2 kWh/t for the feed sample to 18.2 kWh/t for the material in the slice just before the discharge (Figure 9), demonstrating that this increase in competence appeared over the whole size spectrum of particles in the mill. Shoji, Hogg and Austin indicated that there is less segregation at high ball load and high filling operations. This would imply that the segregation observed in high steel

ball load SAGs like the example given in this study is less than what would be encountered in conventional SAG mills and AG mills.

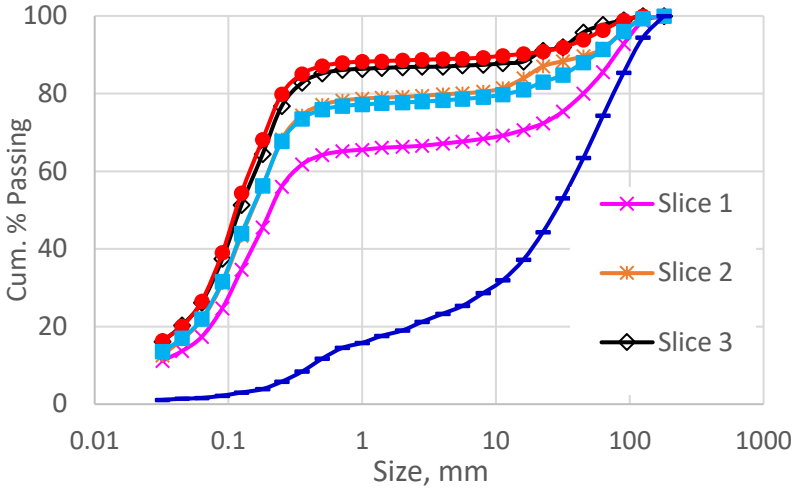

FIG 7 – Particle size distributions for the feed and mill content slices.

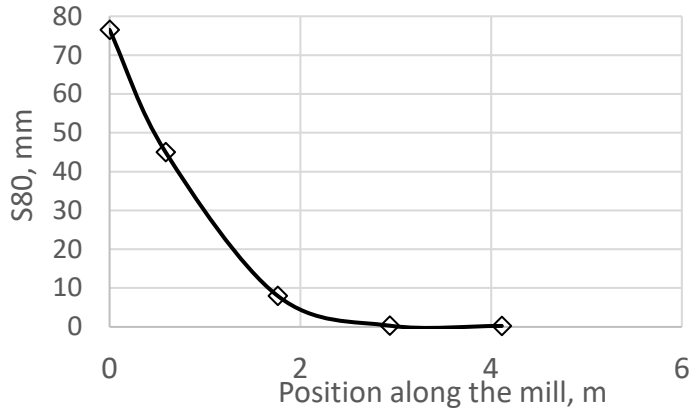

FIG 8 – The 80 per cent passing size of the feed and mill content slices.

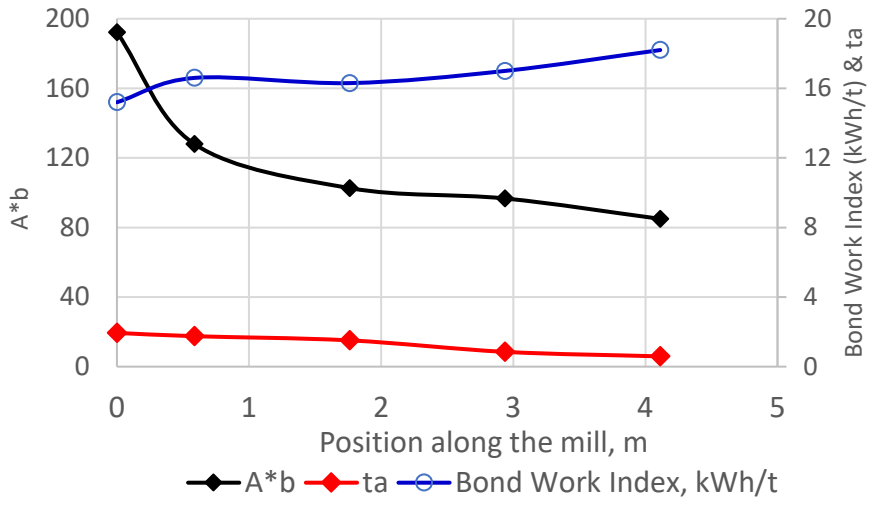

FIG 9 – Ore competence measurements obtained for the feed and mill content slices.

In one hand, these results are consistent with recent approaches that describe breakage in mills mechanistically, since more brittle rocks are preferentially broken (Tavares and Carvalho, 2009; Carvalho and Tavares, 2011), with more competent particles being able to survive and, as such, being transported axially towards the discharge of the mill. On the other hand, results such as these demonstrate the need for understanding and modelling rock segregation in mills, which is not achievable as a single parameter. The combination of the transport rate by size and the competence of the rocks (their survivability) determined the outcome. This led to the initiation of an extended study of transport in tumbling mills and drums led principally by Govender, such as in the work of Tupper *et al* (2016).

An inability to predict pebble production rate is directly related to the assumption of equal residence time for all particle classes – size and competence. This issue becomes acute in modelling large autogenous mills, in terms of predicting the hold-up of competent grinding media and what fraction should be withdrawn for crushing. Uncertainty in pebble discharge has been an ongoing stumbling block in designing SAG circuits with recycle crushing, with evidence of circuits globally that have excess or inadequate recycle crusher capacity.

The science of granular flow dynamics in mixing and segregation is well advanced in other fields, such as pharmaceuticals. Incorporating this progress in understanding mixing, transport and diffusion along mills, coupled to computational advances enable models to be based on complex breakage and transport models at high spatial resolution. This allows mechanistic models to simulate thousands of times faster than real time, opening the door to more accurate mill design, including dynamics in process simulation and to live simulation for process control – all with advanced mechanistic models. The value of grasping this opportunity drives the work of the authors in understanding and applying transport phenomena in mill modelling.

GRANULAR FLOW DYNAMICS

The granular (rocks and balls) porous network through which slurry is transported in a tumbling mill is arguably the primary driver for any pressure-driven slurry transport model. The standard Ergun equation (1952) is well known to describe flow-through a static bed, while the dynamic Ergun equation (Tupper *et al,* 2016) accounts for the granular velocity and includes a Reynolds dependent permeability. In the interest of mathematical tractability, most of these models assume a uniform porosity and granular concentration throughout the drum when effecting a solution. However, rotating drum flows are well known to exhibit radial (Powell and Nurick, 1996b, 1996c; Sherritt *et al,* 2003) and axial (Hajra and Khakhar, 2005; Khakhar *et al,* 1997) granular mixing.

There are numerous studies of segregation in rotating drums and mills but most of these are confined to radial segregation (Rogers and Clements, 1971; Donald and Roseman, 1962; Cleary, 1998) ranging from computational modelling to residence time studies. According to Savage and Lun (1988), radial mixing in rotating drums is governed by two basic mechanisms: Kinetic Sieving (or percolation) and Squeeze expulsion. Shearing layers give rise to voids (sieve-like holes) that are neither fixed in size nor location, ie they are randomly seeded. The appearance rate and structure of the sieves are reported by Gray (2018) to be directly dependent on the shear rate encountered by the granular layer making up the sieve. Gravity pulls particles from the upper layer towards the sieve and the voids regulate whether they go through, with the probability being higher for smaller particles. Contact force imbalances quickly develop to balance the mass differential, resulting in particles being squeezed out to restore the mass balance. For slowly rotating drums, the net effect results in larger particles rising towards the surface of the bed while smaller particles are driven towards the centre of circulation of the bed (De Klerk, Govender and Mainza, 2019). Consistent with basal friction rheological theories on granular flow (Andreotti, Forterre and Pouliquen, 2013), smaller particles have a relatively higher number of contacts than an equivalent volume of larger particles. Accordingly, smaller particles experience a greater flow resistance than their larger counterparts. Lower (respectively, higher) flow resistance reduces (respectively, increases) the probability of larger (respectively, smaller) particles being ‘captured’ by the sieves before reaching the toe region of the bed, thereby reinforcing the radial segregation effect that is commonly referred to as the Brazil Nut Effect (BNE). Interestingly, and somewhat counter-intuitively, above a certain drum speed the segregation pattern can completely reverse (Hong, Quinn and Luding, 2001). Such complex granular flows are commonly found in industry.

Initial reports of segregation in mills were by Oyuma in 1939 who developed a theory to explain axial segregation in terms of surface flow and successfully modified an effective diffusion equation which accounted for reverse effects. In addition to radial segregation, experimental evidence of axial banding is also reported in the literature, such as that of Hill, Caprihan and Kakalios (1997). Most of the experiments for axial segregation involve obtaining particle residence time data and examples of these are the studies by Khakhar *et al* (1997) and Kelsall (1969). The results from residence time studies performed by Khakhar *et al* (1997) using irradiated feed material of varying sizes and by Kelsall using non-breakable (alumina) tracers yielded inconclusive results. They alluded to the coarseness of the tracers as the reason for inconclusive results. Various theoretical models such as Gupta, Khakhar and Bhatia (1991), and computational simulations (Matuttis, Luding and Herrmann, 2000; Newey *et al,* 2004; Rapaport, 2007; Taberlet, Losert and Richard, 2004) have subsequently emerged to explain the time-dependent banding phenomenon. Axial dispersion models comprising convection and diffusion to describe transport in mills have been used in several studies indicating that transport in mills arise from the convective component defined by an axial velocity and a diffusion term defined by a concentration gradient with an appropriate diffusion coefficient. The most practical of the various theories is the axial diffusion model of Zik *et al* (1994) for binary mixtures that was recently extended by Ahmed, Govender and Mainza (2021) to describe the time evolution of ternary and quaternary mixtures while also proposing a general result for any number of particle species. These works argue that spontaneous, localised fluctuations in concentration seed alternating bands along the length of the drum. Figure 10 illustrates three adjacent bands in a batch operation. Consistent with the basal friction theories on granular flow, the relatively higher slices (two outer bands) are richer in high friction particles (less mobile with relatively higher flow resistance) than the lower central slice that is dominated by low friction particles (more mobile with relatively lower flow resistance). The height difference between adjacent bands sets up a natural gravity slope that drives particles down the local axial gradient. Clearly the more mobile (low friction) species flow more readily down the gravity slope than their less mobile counterparts (high friction species), resulting in the depletion of low friction species from the higher bands that accumulates in the central lower band. The slope region also becomes richer in low friction species. Friction-limited mobility acts like a positive feedback mechanism that reinforces the depletion of low friction species from the outer higher bands while simultaneously replenishing the central lower band with low friction species. Accordingly, the alternating banding pattern is reinforced.

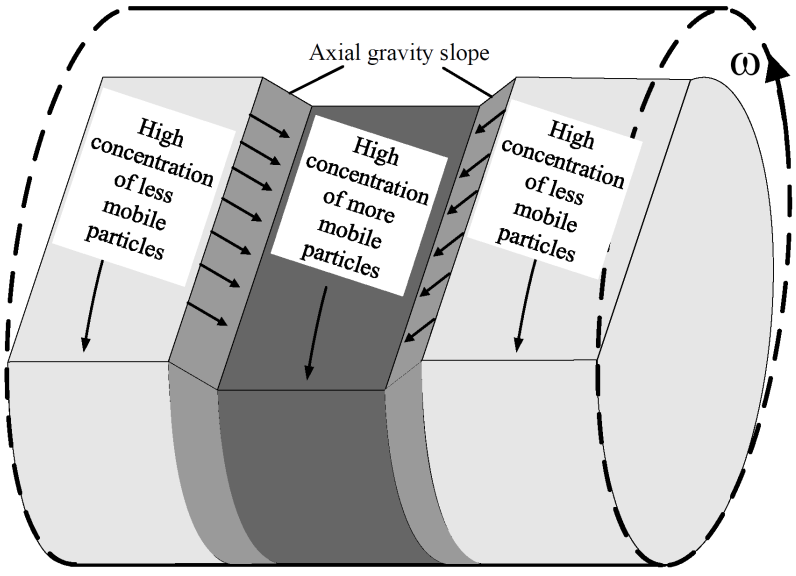

FIG 10 – Development of banding through granular flow.

The governing differential equations of axial segregation is derived from a material balance between flux down the gravity slope and a corresponding back flux occurring deep within the granular bed. Ahmed, Govender and Mainza (2021) showed this derivation for two, three, four frictional species, and illustrated the resulting banding patterns that result in the long-time limit. The result for n-species was also derived. Equation (1) illustrates the governing partial differential for *j*th species in a *n*-species mixture.

$$\frac{\partial C_j}{\partial t} = D\frac{\partial}{\partial z}\left[\left|C_j\right|\sum_{n=1}^{n-1} C_j\left(\mu_j - \mu_m\right) + \left|C_j\left(\mu_m - \mu_j\right)\right|\frac{\partial C_j}{\partial z}\right] \quad (1)$$

Where μ_j is the friction coefficient associated with the *j*th species, μm is the highest friction coefficient of the *n*-species mixture and C_j is the time dependent concentration of the *j*th species along the drum axis. *D* denotes a diffusion coefficient such that model resembles a non-linear diffusion equation for relative concentrations along the axial direction of the mill, which is given by:

$$D = \frac{P_0^3}{3\eta(\rho g)^2}\left[1 + y_x^2\right]\left[\frac{y_{C_j}}{y_x}\right] \quad (2)$$

The diffusion coefficient is physically driven by the lithostatic pressure P_0, viscosity η, material density ρ, acceleration due to gravity g, spatial gradient $y_x = \frac{\partial y}{\partial x}$, and a coupling gradient $y_{C_j} = \frac{\partial y}{C_j}$. The present work does not explore the physical dependencies of the diffusion coefficient and solves the diffusion problem for n-species along the drum length.

Incorporation of this theory into the modelling of transport in tumbling mills presents a pathway to enabling size-dependent segregation to be integrated into mill modelling.

INITIAL MEASURES AND MODELLING

A simplified Surface cascade model based off the theory of Ahmed, Govender and Mainza (2021) leads to some interesting and scalable transport phenomena. With granular friction being lower for larger rocks, based on their ability to flow across a surface, and diverge along the mill due to random collisions.

The work on pilot tracer tests conducted by Powell *et al* (2022) provides novel data upon which to base the development of a model of rock transport in a continuously operating mill. In analysing this data, it was found that the measured transport rates and distribution along the mill in the tests conducted for in-mill segregation demonstrated the dominance of the surface cascading flow phenomena.

The conceptual model is built off four subprocesses (as this stage), namely:

- Advection – bulk flow along the mill. This corresponds to the transport rate of the finer material, taken as 1–10 mm in the first implementation. This can be calculated based on superficial residence and thus transport rate of the measured mass of this size range in the mill load. When estimating this, it aligned with the water flow velocity, providing a pointer to calibrating this in future modelling.
- Bulk diffusion. This is classic diffusion within the granular, stirred media, with particles shifting into available spaces that are formed during the mixing process. It is inferred from the experimental data to be a low rate.
- Cascade diffusion created by the flow of particles down the cascading surface of the descending charge. This is strongly size-dependent, with larger particles having a larger cascade angle and thus displacement, plus the fraction exposed to cascade is greater for larger particles.
- Discharge grate. This hinders discharge of particles, allowing zero above grate size and increasing to a maximum for small particles below about 10 per cent of grate aperture. The hinderance to flow forces particles to crowd and then backflow through diffusion.

The outcome of the cascade concept is illustrated in Figure 11. The model predicts that for a 6 ft (1.7 m) diameter by 1.4 m long pilot mill the maximum transport velocity ranges from 0.016 to 0.025 m/s from 1 to 150 mm particles, a difference of about 50 per cent. For a large 13 m diameter by 12 m long mill the range is reduced to less than 20 per cent. Notably, the model predicts a maximum velocity of about ten-fold for the large mill compared to the pilot mill, related to the long cascading region for this large diameter. Additionally, the maximum velocity is predicted to be more than 10 per cent higher for lower fillings due to the increase exposure of the rocks to the surface cascade zone.

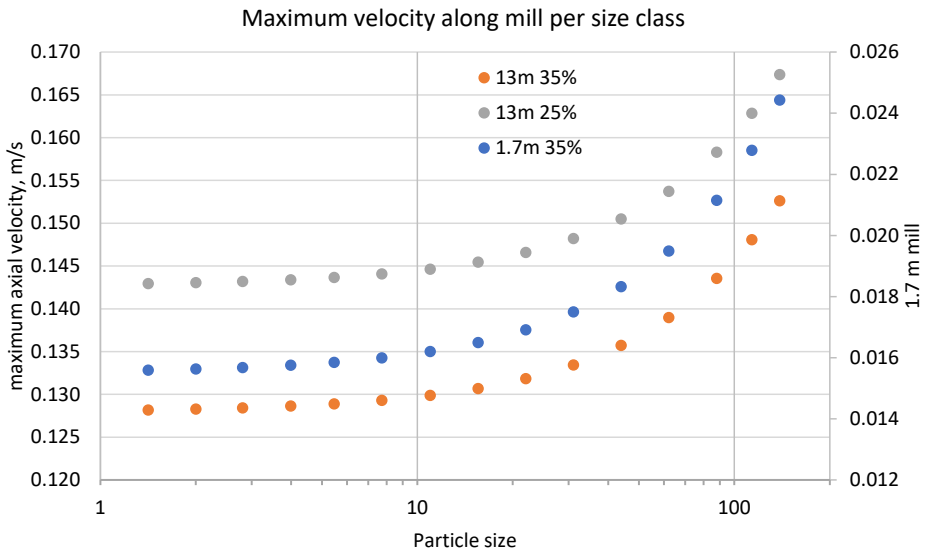

FIG 11 – Differential transport speed by particle size predicted through a conceptual surface cascade model.

This concept cascade model has not been validated and is still a work in progress, but serves to illustrate the effects that can be predicted and then incorporated in models that allow for transport.

For a model to incorporate such transport and diffusion effects, it intrinsically has to be dynamic. The approach taken is that of a discretised time model with conceptual 'slices' along the mill that provide sufficient resolution to capture the transport effects.

IMPLICATIONS OF INCORPORATING TRANSPORT IN MILL MODELLING

Besides breakage rates, breakage distribution and internal classification, transport is another subprocess that is required in a realistic tumbling mill model. However, simplifying assumptions in regard to how particles move axially through the mill by assuming, for instance, that either the entire mill contents or significant parts of it are perfectly mixed have led to challenges in decoupling some of these subprocesses.

Incorporation of size-dependent transport allows the observed accumulation of larger and more competent rocks at the discharge – thereby changing residence time and product size distribution in the modelled mill. Cumulation of larger rocks at the discharge will allow a higher than expected discharge rate, due to their high concentration at the discharge grate.

Indeed, the current SAG models, such as the variable rates model of the JKMRC (Napier-Munn, 1996) suffer from an anomaly for the coarse breakage. The well-known breakage rates curve drops off from a size of around 10 mm, reaching a minimum around 44 mm, then rising steeply to high breakage rates for the large rocks. Such a rise is against the understanding and measurement of breakage of large rocks in mills, which in fact have a low probability of breakage. The large rocks tend to 'wear out' through abrasion, which leads to the build-up of a critical size in the mill and motivates pebble porting to extract rocks for crushing. This apparent high breakage rate in the models is a result of back-fitting rates to satisfy a population balance model that is based on an assumption of equivalent residence time for all sizes of particles. However, the large rocks actually have a far longer residence time than fine particles, hence the back-fitted rates are exaggerated to compensate for this inadequacy of the modelling method. Incorporation of transport and differential residence time for particles by size will address such anomalies and provide improved predictive capability, especially for non-standard operations, ie outside of fitted databases.

In reality, the discharge from a grate-ended mill is only from the 'layer' exposed to the discharge grate. Only particles that are directly exposed to the slots of the discharge grate can flow out of the mill. Currently, a discharge function is used that is calculated based on the probability of the total mill contents leaving the mill. This simplification results in an artificial discharge function based on perfect mixing and incorporating a hidden differential of transport by size through the charge and along the mill. Referring back to the illustrations in Figures 3 to 5, it is clear that the calculated discharge must

be false due to the population at the end of the mill being quite different to the average contents. The discharge function will have to be artificially modified to fit identical mills with different degrees of rock segregation along the mill. This will lead to incorrect predictions of mill performance under changing conditions.

So-called mechanistic mill models, which rely on collision energy spectra from simulations of the charge using the discrete element method (DEM) (Weerasekara *et al,* 2013) and microscale descriptions of particle breakage using special population balance model descriptions, allow the prediction of preferential breakage of the more brittle particles and, therefore, survival of the tougher ones (Carvalho and Tavares, 2011). While this makes them amenable to, potentially, reproduce some of the practical observations observed in low diameter-length mills, these models require proper collision energy spectra along the mill and a realistic description of axial transport of coarse particles.

An example of the direct consequence of the lack of understanding and incorporation of transport in SAG mills is the poor utilisation and inconsistent loading of recycle crushers across the industry (Powell, Evertsson and Mainza, 2019). As blast fragmentation size, ore competence, variability in competence within the ore and the application of pre-crushing varies, the load on recycle crushers varies considerably, with idle or overloaded crushers a common issue. Extensive experimentation with pebble discharge ports is generally conducted over years to address this, but the chosen design can become inefficient with new feed characteristics. At the other extreme the common trend to pre-crushing can lead to unexpected loss of mill load and consequent negative impacts on mill and liner performance. The ability to more accurately and reliably predict the build-up and discharge potential of competent rock for the intrinsic competence distribution found in orebodies is expected to lead to more reliable and consistent circuit design. Site data collected by the authors shows loss of total circuit power utilisation in the range of 2 to 16 MW (Powell *et al,* 2021). Recapturing such large losses of available milling energy, should be highly motivating to the industry to improve this area of poor understanding and predictive modelling.

Example of applying diffusive transport terms

Diffusive transport terms have been incorporated in a dynamic mill model under development. The bulk flow is calculated as an advection term. A standard bulk diffusion term is applied and a diffusive term incorporated to capture the surface cascade mode described above. This was applied to a 2 m diameter mill being filled from empty at a fixed 1 t/h feedrate. Constant breakage and discharge functions were used for three sets of simulations with advection only, then bulk diffusion added, then cascade diffusion added. The transport of a set of tracer rocks is shown in Figure 12 as time to discharge from the mill (a) and the location within the mill after 2 minutes (b). The substantial difference in transport speed is clear with the addition of diffusion, providing considerably higher degree of mobility to the larger rocks (51–76 mm in this example).

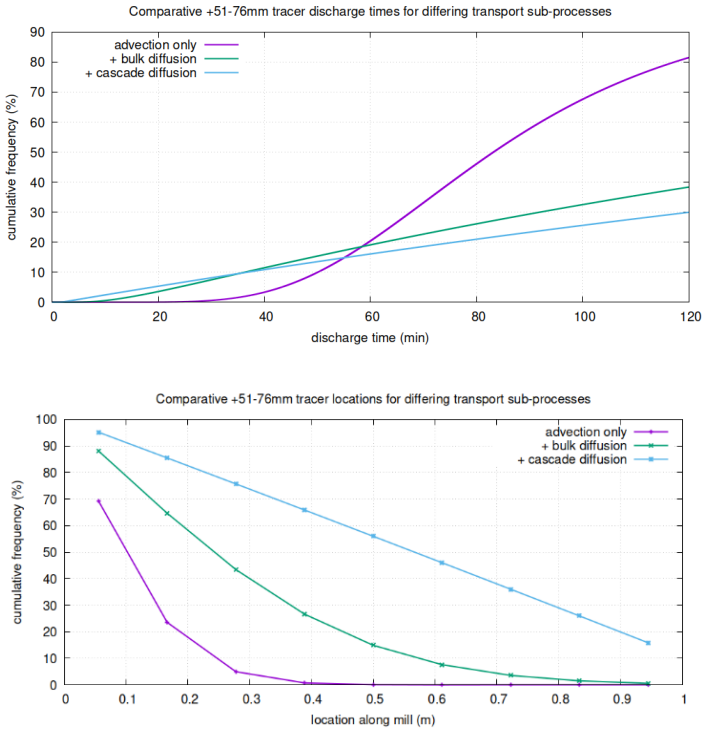

FIG 12 – Discharge time and distance travelled along the mill for tracer rocks.

The mass hold-up and resulting content size in the mill are shown in Figure 13. The case with no diffusion results in a considerably higher hold-up as the large rocks transport at the same rate as the bulk finer material. This also leads to a coarser mill content for the diffusion cases.

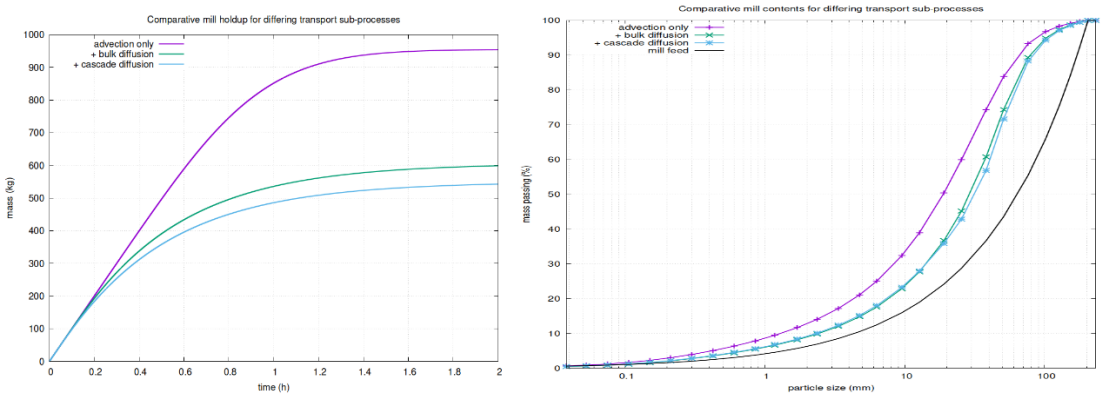

FIG 13 – Hold-up and content size distribution for different diffusive transport.

Although only a concept study, this example illustrates the substantial influence that differential transport by size through diffusive transport phenomena can have on the milling conditions. Currently this is hidden in bulk rates curves and discharge functions to compensate for this discrepancy, but these provide incorrect outcomes when feed or operating conditions change from the calibrated baseline.

Experimental tracer tests of a range of rock sizes conducted in a 1.7 m diameter by 1.4 m long pilot mill support these modelling outcomes (Powell *et al,* 2022).

CONCLUSIONS

The review presented here, and some initial simulation outcomes point to the value of making an effort to fully model the milling system with transport. The explicit prediction of pebble survival and discharge in AG mills needing pebble retention contrasting with the controlled discharge in SAG mills with a need for high pebble discharge, present a clear need for a transport function in mill modelling to capture these required outcomes. It is reasonable to state that the realistic modelling of the

mechanics within mills lags behind progress in understanding the micro-processes in breakage, thus diminishing the value for predictive mill modelling of such understanding.

Elements of a description of axial segregation in mills, based on granular flow dynamics with a meaningful definition of diffusion coefficient, demonstrates its great potential to describe size-dependent segregation to be integrated in more realistic mill models.

There is a clear influence on mill contents when incorporating transport and size-dependent diffusive terms in modelling outcomes. The dynamic structure of a model that includes transport allows future modelling of transients, such as pulses in feed, unstable feed rate, changes in feed type, mill speed, etc. This will be of considerable value in predicting the dynamics of the mill with variable feed and how the system responds to different control strategies, leading future incorporation of genuinely model based control.

These methods will be applied to recent tracer test work for subsequent presentation.

This widespread group of researchers within the global Comminution Collaborative (GCC), have for over 15 years been steadily building the tools and understanding to take this forward. Transport is one of the key elements to dynamic, mechanistic mill modelling. With the emphasis on improving the efficiency, especially in terms of energy use, while maximising use of the largest capital equipment on the mine site (where power utilisation has been measured to be up to 16 MW below available), the industry should be well-motivated to underwrite the final push to a fully-implemented dynamic model that can be used to explore future milling options. The improved modelling tools and outcomes are seen as a strong motivator to accelerate this work to the point of useful uptake.

ABSTRACT

Quantifying the performance of a comminution circuit relative to the potential that can be achieved is a standard requirement in justifying operating practice (the stick) and seeking operational upside (the carrot). Historic measures tend to focus on performance relative to laboratory design tests that provide a direct measure of specific grinding energy, such as the Bond Work index; or use drop-weight breakage tests calibrated to a substantial database of operating sites, such as the SMC methodology.

Although of value, such approaches are flawed in significant aspects. The assumption is that the laboratory prediction is correct and the single sample it is based on is representative. The database benchmarking methods are, by definition, locked into current average operating practice. These approaches do not illuminate upside; can 'punish' operations that are actually more efficient, such as grinding finer than standard operation; and reward poor operation that may comfortably produce a coarser grind than optimal for recovery or excess slimes that reduce recovery and increase water consumption and tailings volume.

The authors present a set of established and easily applied measures, that draw together daily operation, highlight areas of opportunity and inefficiency, use simple samples and data, and can be used to provide the 'size of the prize' in pursuing specific areas of process improvement. These tools include size specific energy (SSE), overall operating effectiveness (OEE) which includes product quality, theory of constraints, and links this to the end objective – maximising the efficient production of valuable metals. Feeds into objective function driven by economics – financial return, energy, environment.

INTRODUCTION

'It is necessary to measure performance in order to improve', is a well-known concept. However, application in practice is not straightforward. The types of measurements should be appropriate to the application, dictated by the objectives and drivers. The measures should also be reliable and provide direction as to how to improve the performance.

In mineral processing the emphasis tends to be on throughput and product size relative to targets. The efficiency of the process tends to be judged against standard measures, so as to provide a benchmark of performance and target for improvement. For example, what is the measured specific energy (SE), kWh/t of ore processed, versus the expected SE? Such measures allow the performance to be quantified, providing a quantifiable gap for improvement, such as the measured SE is 14.8 kWh/t against the expected SE based the ore characterisation and associated models of 13.2 kWh/t, therefore for a given available power, the throughput should be 12 per cent higher. The benchmark tends to be the stick to drive operations to higher production, with the predicted value being the carrot of operational upside.

Historic measures tend to focus on performance relative to laboratory design tests that provide a direct measure of specific grinding energy, such as the Bond Work index; a relative grinding energy such as the SPI or updated SAG grindability test (Starkey *et al* 2015); or use drop-weight breakage tests calibrated to a substantial database of operating sites, such as the SMC methodology (Morrell, 2009); or one or two of a number of other measures. The use of these measures are further

compounded by their inclusion in geometallurgical models that use statistical modelling to calibrate measured performance to the breakage properties mapped into the orebody. The processing plant can then be held to matching the throughput, grind, recovery predicted from the geomet model, and process efficiency measured against this.

Industrial process performance can be measured through a number of methods such as comprehensive survey(s), a quick check on product, operating data assessed via online measures along with automated or manual product shift samples. Although of value in highlighting potential upside in performance, such approaches are flawed in significant aspects. There are a number of assumptions that these comparisons are based on, and limitations that arise from these.

Laboratory test methods:

- The laboratory prediction is assumed to be correct. However, all are proxies for the real system and involve a model, scale-up factors, databases etc to predict the real circuit. They also do not include natural variability and the fact that the circuits are continuous not batch processes.
- The single sample, or few samples, the prediction is based on are assumed representative. This is of course unlikely, especially as the orebody is never equivalent throughout. The natural variability leads to fluctuating performance and thus not an ideal stable performance.
- Variable blending of different parts of an orebody or ore types in the deposit lead to non-linear responses that the ore tests do not predict. To overcome this limitation, the performance needs to be calibrated at the different blends.
- The mode of breakage captured in the laboratory test is assumed to represent the entire comminution circuit, yet some capture only the fine end, some only the coarse impact breakage, and others focus around abrasion milling.

Scale-up:

- Database benchmarking is assumed to represent the optimum performance. Whereas, using a database, by definition, locks into current average operating practice linked to data over the past 20 years or so.
- A laboratory energy value cannot capture the complexity of a circuit process, so the circuit performance has to be assumed to be fixed relative to a simple batch test.
- The scale-up calculations are calibrated to capture the difference in performance between the laboratory test and full-scale operations. Usually this is averaged over a number of calibrated data sets based on surveys of operating plants. These operating plants are by definition assumed to represent good operation, which is flawed in a few respects:
    - How is the absolute performance of the database calibrated?
    - What of the outliners? Where they good or poor or actually a measure of different performance not predicted by the laboratory test in question?
    - Is the distribution of the database reported and used in the ultimate comparison?

Plant performance measurement:

- Averaged daily operating data provides good power and throughput measures, which with the shift samples can be used to calculate SE and assess product against target size. In many ways this is the correct measure to use, for it is the ongoing production performance that matters to profitability. However, they can be misleading in terms of actual efficiency, such as:
    - Inclusion of inappropriate operating periods, such as when the feed is depleted due to delivery issues, fluctuations as ore type changes, variation in feed size with stockpile level and mine operation, and similar external influences.
    - Averaging performance with varying blends when throughput and grind are non-linear with blends by competence.
    - Single point of final production sample to assess overall circuit performance.

    - Lack of reliability and consistency of manual process samples and potential bias in both manual and automated samplers.
- Surveys are a good method to provide a more accurate snapshot of performance than the average daily operation and a basis of measuring operating efficiency under known conditions. However, their limitations are:
    - They do not highlight issues with the plants longer term operation.
    - They tend to be expensive and are thus seldom performed.
    - The final data and reporting is often long removed from the survey period.
    - They apply to the specific feed of the time.

Incorrect scaling with size distribution:

The calibration tests and scaling equations applied to compensate for changes in feed and product size are approximations of the response. As circuits produce a wide range of product sizes, the scaling equations are used in most assessments. The limitations in these include:

- The calculated measures can 'punish' operations that are actually more efficient, such as grinding finer than standard operation thereby moving up the Hukki curve (Hukki, 1962) but predicting a Bond style square root of P80 response.
- They can reward poor operation that may comfortably produce a coarser grind than optimal for recovery, delivering a low SE and low operating work index.
- The SMC method does have improved compensation for this size effect, although it is an average ore dependence whereas the gradient of the Hukki energy curve is ore-dependent.
- The operation may be meeting a simple P80 or SE objective but produce excess slimes that reduce recovery and increase water consumption and tailings volume.

Not quantifying upside:

- The generally applied measures of performance measurement do not illuminate potential upside when the 'expected' performance is met. Noting that this reflects average industry performance over a number of decades, continents, operators, ore types etc, the operations should be aiming to exceed the calibrated average performance of the past.
- The system measure hides where areas of low efficiency lie, such as in the SAG mill, crushers, ball mill, classification circuit, or control method.
- The single measures are not appropriate across the range of equipment, thus if they are applied through appropriate measure across-sections of a circuit, can incorrectly apportion poor performance, such as using Bond work index across the SAG mill (Ballantyne, Peukert and Powell, 2015; Powell *et al,* 2014).

An aspect that is actually central to measuring process efficiency is the appropriate product in terms of mineral liberation for recovery, the real objective function of mineral processing being to recover minerals not to grind rock. Although this aspect won't be addressed in the current paper, it is the basis for directing the operation of a comminution circuit. The improvement of recovery and reduction in water usage, tailing, pollutants should be passed up to the objective function of the comminution product.

The objective of the authors has been to overcome many of the listed limitations and bring quantifiable performance measures closer to operations in a manner that is both correct and meaningful.

THE BASIS OF OPERATING MEASURES

The calculation of efficiency requires input data, measures of operation, a calculation technique, and some comparative measure.

Data measures

Collecting data is fraught with error and uncertainty. A few standard sampling points with good automated or manual access can fulfil every criteria. For ongoing assessment of operating efficiency, the data should be standard measures, such as feed conveyor, equipment power, product sizes from automated samplers. To obtain greater value and discrimination from the measures, it is likely that additional sample access points will need to be engineered, such as crusher product (camera system), SAG product (bespoke sampling system), and even cyclone feed or ball mill product. These can be routine or accessed on a regular basis, such as a weekly check or during good or poor periods of operation.

Calculation of efficiency

The calculation methods should also meet the above criteria. A method that is dependent on complex models suffers from a number of drawbacks such as:

- The outcome is opaque to the site personnel, data into a black box with an output. This can lead to incorrect use and to dismissal of the outcomes.
- The value of the outcome is dependent on the quality and validity of the model. For example, the use of drop weight numbers relies on the use of a bespoke SAG mill model or crusher model.
- Calibrated models, such as the SMC indices, are locked into the database upon which they were developed, thus assuming average performance characteristics. They also tend to have hidden calibration parameters, such as the calculation of the internal indices.
- Geometallurgical models are far more fraught with uncertainty and bias, such as using SPI values to model the throughput and product size by using a multi-parameter empirical back-fit of SPI and assay data to correlated performance.
- The use of uncertainty and variability in the calculated outputs, even through simple standard deviation values, is often not available let alone used.

Comparative measure

The calculation of efficiency tends to be by comparison with the predictions of laboratory tests based on ore samples. These intrinsically suffer from the sampling issue:

- The samples are tiny compared to the production volumes.
- The samples are unlikely to be representative of the entire process stream under comparison.
- Measures are often inappropriately linearly averaged or Kriged between the spatial sample points to provide expected averages for the operating regime.
- Even production samples taken at the time of surveys tend by necessity to be only a single sample at the end of a trial, rather than representative over the trial period.

Additionally, the limitations outlined earlier apply.

Proposed methods

Some key points that are desired in assessing operating performance are that they should be:

- simple
- accurate
- relevant
- achievable
- reliable
- reproducible.

These objectives are interrelated, and consideration of the suite can provide some elegant solutions to assessment. ‘Simple’ refers to both the method of measure and the analysis thereof.

Based on decades of conducting rigorous sampling campaigns, the methods outlined above are not the favoured approach of the authors. In general, the effort and cost associated with the rigour were aimed at development of process models, rather than assessing processing efficiency. In this period of intensive site work, covering possibly 200 plant surveys across the authors, many lessons on technique and value have been learned. For example, based on the ‘blind’ nature of walking onto a plant and expecting to conduct a stable survey within a day or two, the value of first assessing the circuit response was highlighted, as described in the development of grinding curves by Powell and Mainza (2006), and later extended to the Grindcurves methodology (Powell, van der Westhuizen and Mainza, 2009).

In grappling with the issue of more appropriate measures to apply across circuits, Powell (2014) developed the concept of size specific energy (SSE). This method is based off the successful application of this measure at the fine end of product size that had been extensively used in the South African mining industry for over a hundred years (Davis, 1919) and applied to a laboratory testing technique by Levin (1992). Hilden and Suthers (2010) more recently demonstrated the linearity over a range of laboratory equipment, Musa and Morrison (2009) provided improved justification to the theory through analysis of the production of surface area at fine product sizes. The SSE was measured for the first time through single particle breakage testing down to final product sizes by Ballantyne, Peukert and Powell (2015). This has led to ongoing development of the laboratory measurement of SSE by Ballantyne *et al* (2015), Böttcher *et al* (2021) and Ali *et al* (2022). In parallel the use of SSE as a direct measure of energy efficiency on operating sites has evolved over sets of site survey work Powell *et al* (2018, 2021).

The inappropriate nature of standard measures when applied across different types of circuits grinding to a wide range of product size distributions has also been extensively studied, such as in the work of Powell *et al* (2014). The development of a method to more accurately gather measures of energy use in comminution process was developed by Ballantyne, Powell and Tiang (2012) and extended in the continuing study of Ballantyne and Powell (2014). This led to the evolution of measures of process efficiency, captured as ‘Efficiency curves’ by Ballantyne and Powell (2014) and Ballantyne, Mainza and Powell (2015) in order to benchmark relative performance of circuits processing a range of ores to required product sizes. One of the measures used in these curves is the SSE, based on its readily calculated value from production data (Ballantyne and Powell (2014), Ballantyne *et al* (2015), CEEC (2022).

An aspect that these energy measures lacked, was a measure of the effective use of equipment. Thus, a crusher could be run most efficiently in terms of energy use, but be only utilised for a small fraction of the time, thus rendering its overall effectiveness in production as low. The work of Evertsson had identified this need in assessing crushing plants in aggregate production, where utilisation is of primary importance on production of high volume products. To this end he adopted the Overall Equipment Effectiveness (OEE) measure developed in the car industry (Dal, Tugwell and Greatbanks, 2000).

Based on these range of readily utilised measures, the authors have been evolving a standard suite of measures to be of practical use in assessing comminution circuit efficiency. Their application and calculation are described.

SSE

Size specific energy (SSE) is a useful measure of ore competence for changing ores, or of circuit efficiency for a given ore. The concept is illustrated in Figure 1. As energy is cumulatively added to the circuit, the production of the fine final product, generally taken at 75 µm, is linear with the specific energy, in kWh/t. This is irrespective of the comminution equipment, as the efficiencies are similar. However, if one piece of equipment is operating at below the efficiency of the others in the circuit, it will fall below the line. Thus, a simple plot of % – 75 µm versus specific energy across the circuit, will highlight a poorly performing ball mill.

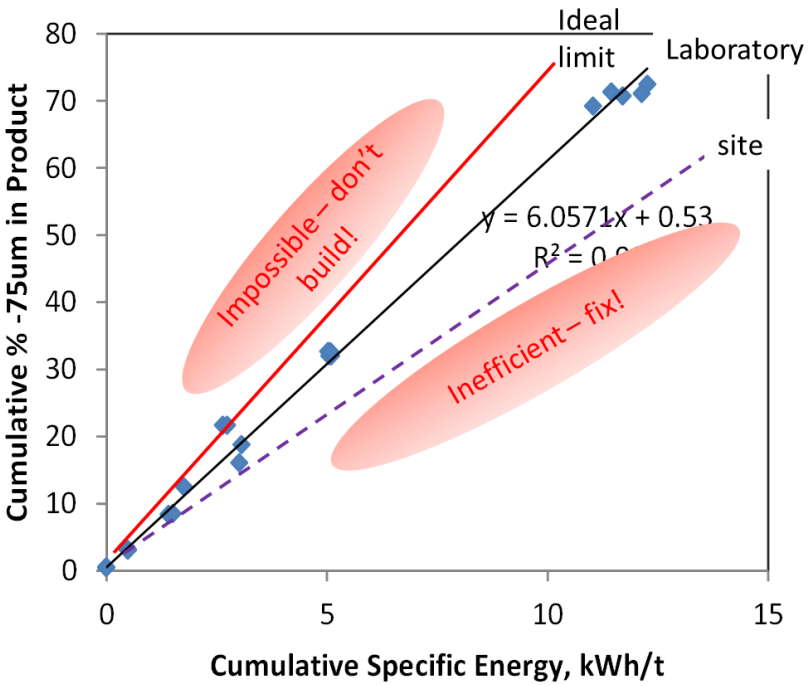

FIG 1 – Illustration of the SSE concept.

The methodology for calculating the SSE for individual comminution equipment within a circuit is described below to facilitate the use of this simple tool.

1. Segment circuit into individual components containing the minimum number of comminution devices either in parallel or series being careful to apply the system boundaries correctly to conserve mass.
2. Record comminution equipment power consumption and the mass flow rate through the subcircuit.
3. Calculate the flow rate of 75 µm (or alternative relevant marker size) material for the feed and product of each comminution device within the subcircuit.
4. Calculate specific energy (kWh/t) and the % new 75 µm generated within the subcircuit by dividing the production rate (t/h) of 75 µm by the total circuit throughput.
5. The size specific energy (SSE) is the specific energy divided by the new 75 µm expressed as a proportion.

Although not ideal and given there is no currently valid alternative, the Bond test results can provide an indication of ore competence in terms of SSE. This is simply done by obtaining the raw Bond test results and following the following process:

1. Use the calculated work index along with the test F80 and P80 to back calculate the assumed specific energy of the test using the Bond equation: $W = 10*Wi*(P80^{-0.5} - F80^{-0.5})$.
2. Calculate the % new 75 µm (or alternative relevant marker size) generated in the Bond test.
3. Calculate the equivalent SSE for the Bond test using the equation: SSE = W/% new 75 µm.

This value for the Bond SSE provides similar results as the Bond work index when the feed and product size distributions are parallel in log/log space. However, they can vary when the feed or product size distribution are relatively fines devoid or have excessive fines. The Bond SSE value can be used to provide a relative efficiency value for individual equipment, or to provide a relative efficiency at different points in time.

Overall equipment effectiveness (OEE)

OEE gives a single-figure measure of the utilised versus available production capability in equipment, based on the following relationship (Dal, Tugwell and Greatbanks, 2000):

OEE%= Availability × Performance × Quality × 100

Availability = actual operating time/planned operating time

Performance = actual rate of production/possible rate of production

Quality = fraction of acceptable product

For a crushing operation the standard manufacturing measures are not necessarily applicable, so equivalent available measures are used:

- Availability: time crusher switched on, ie drawing power/planned total availability (ie total hours – planned hours of maintenance). Thus planned maintenance is excluded, but should also be reviewed for potential production gains, as excessive planned maintenance give an optimistic OEE value.
- Performance: integral of the power draw over the operating time/peak practical capacity (the maximum continuous power that can be used, a reasonable value is 90 per cent of installed power).
- Product quality – percentage of product below desired top size is suitable.

An example of OEE method application taken from a ties operating data is shown in Figure 2. This example shows the OEE plot for a SAG mill circuit equipped with three pebble crushers. In this example, only power draw was analysed, as the product quality is not measured online. Often, online measurement of recycle crusher product is not available; however, it is preferable to include product quality as a parameter to be analysed.

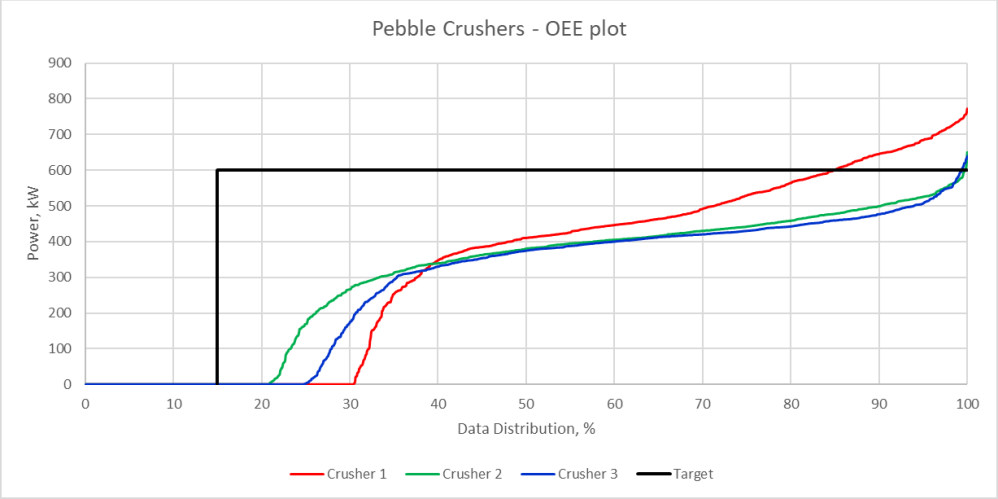

FIG 2 – OEE of a set of three recycle crushers.

The operating data is logged at reasonable resolution representative of the operation, at least five minute intervals, over a few months of operation. All non-numeric and out-of-range values need to be removed from the data. The data is sorted by power from lowest to highest value, then plotted as a cumulative distribution.

The planned availability is 85 per cent, and the power draw achieved is 600 kW for two of the three crushers, so this was set as the power target. The area under the black line gives the 100 per cent target, on which is based the OEE of each crusher. Figure 2 gives the OEE figures for the three crushers, clustered around 60 per cent. In addition to the OEE, the simple idle time can be used, which is given by the data from the OEE that falls below the idle power of the crushers, in this case 140 kW. Unusually, the idle time does not show up on the plots in Figure 2, a power plateau would be expected for a small percentage of operating time.

Unused available time is the difference between the budgeted downtime for mechanical maintenance and the actual idle time. By using the idle time average of 42 per cent and the sites budgeted 15 per cent maintenance time, it is shown that there is 27 per cent available operating time available that the crushers are idle. Another useful indicator is ramp-up time, the period the crusher

is receiving feed but not yet drawing operating power. For these crushers they are only operating in a semi-choke-fed condition from above 340 kW power draw. The difference in operating time between the minimum operating power and idle power gives the ramp-up time of the crusher over the monitored period.

PRACTICAL EXAMPLES

The authors have collected examples from dozens of operations when conducting research and when consulting for process improvement. A few are presented to illustrate the use of these simple measures. A key value of measuring energy efficiency is in how to improve it, so the measures should point to inefficiencies, the magnitude of potential improvement and where to address the issues.

Inefficient parts of a circuit

Total circuit assessment misses out on informing the operation of where a poor area of operation is, such as the SAG mill, ball mill, recycle crushers, unequal feed size distribution, or poor cyclone operation. The SSE method can be used to breakup the circuit into sections, provided good quality samples are taken between sections of the circuit. This can be notoriously difficult, such as SAG circuit product being quite inaccessible, but can usually be addressed with good engineering design and some investment of time and money.

Examples of how this data can be used are presented in Ballantyne, Mainza and Powell (2015), Ballantyne *et al* (2015), and Powell *et al* (2018). Figure 3 shows a circuit where the ball mills were at a lower efficiency than the SAG mill. If the operating issues of the ball mills are addressed, this offers a 10 per cent throughput gain or 5 per cent finer 75 µm product size for improved recovery.

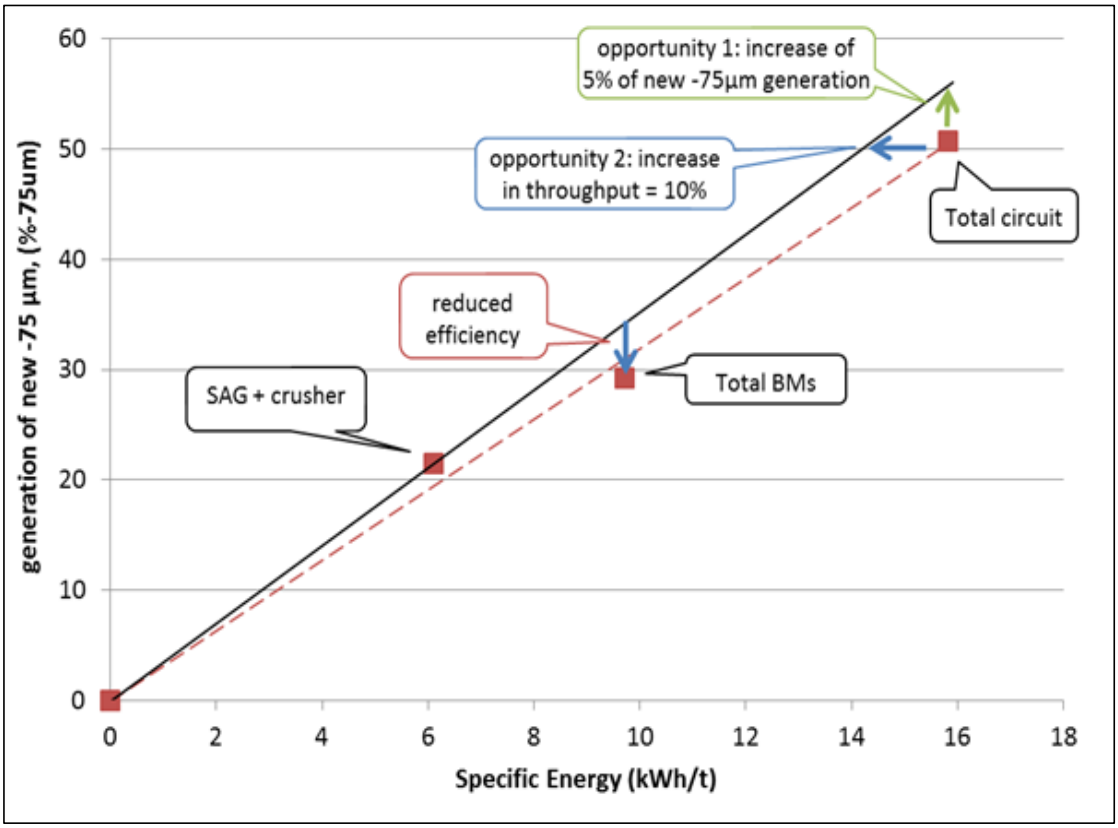

FIG 3 – Differential SSE across a circuit.

Figure 4 presents an example of an SABC circuit where ball mill 1 was markedly less efficient than the rest of the circuit, while ball mill 2 was by far the most efficient. This was tracked down to a biased split of the SAG mill sump product sending the coarser particles to ball mill 1 feed pump. Ball mill 1 was suffering from overload of oversize, while mill 2 was spared this. The impact on the ball mill performance is discussed in the work of Powell *et al* (2021).

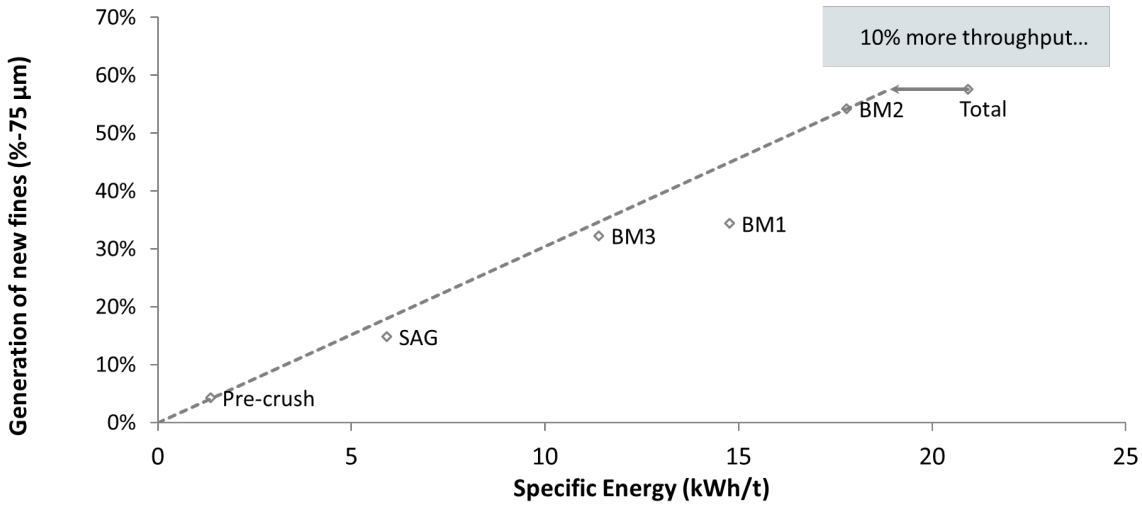

FIG 4 – SSE across a SABC circuit.

Large Cu-Porphyry operation

This comminution circuit has two SAG mills, three recycle crushers and two ball mills, with a total installed power of 80 MW. Table 1 summarises the performance over a year period. The presented OEE is actually optimistic, as this does not include product quality. This is tricky to apply when there is no measure of size between the SAG and ball mill circuits, but can be applied to overall circuit performance.

TABLE 1

Summary of energy efficiency indictors.

SAG Mill No		1	2	Average
OEE,%		85.3	87.7	86.5
Total% Idle		20.2	14.8	17.5
Unused Available%		15.2	9.8	12.5
Ball Mill No		1	2	Average
OEE,%		92	92	92
Total% Idle		9.4	9.0	9.2
Unused Available%		4	4	4
Crusher No	1	2	3	Average
OEE,%	51.7	49.2	42.5	47.8
Total% Idle	32.1	32.1	37.7	34.0
Unused Available%	22.1	22.1	27.7	24.0
Ramp-Up%	7.6	9.9	8.7	8.7

It can be seen from Table 1 and Figure 5 that SAG mill 2 consistently outperforms SAG mill 1, in terms of OEE, utilisation and feedrate, with distribution of feedrate showing a difference of about 10 per cent, despite a close match in mill load (total value of loadcell readings). This points to a need for the site to fucus on the differential, aiming to elevate SAG mill 1 to match the achieved performance of number 2 – clearly an achievable target. The wide range in power from 20 to 24 MW indicates that there is not a consistent target in power draw, which would show up as a plateau in the distribution of data. Upon further investigation it was found that, contrary to expectation of the site personnel, the less efficient SAG mill had a finer feed, lacking adequate rock grinding media in the mill. The control system was found to be dramatically over-responsive, cycling the mill load and

power with control responses at short intervals of 2 to 5 minutes, when the mill response lag is around 20 minutes. Switching off the control system on one mill and leaving on manual feedrate, the feed was steadily increased by 300 t/h with stable operation. The advice to site was that the control system should be replaced, which was actioned with considerable improvement in mill performance. It was also found that the control cap on power was below installed power, at 21 MW on these 24.5 MW motors. Some investigation pointed back to early limits applied by the motor supplier, so this limit was lifted over time to release the milling potential of the circuit.

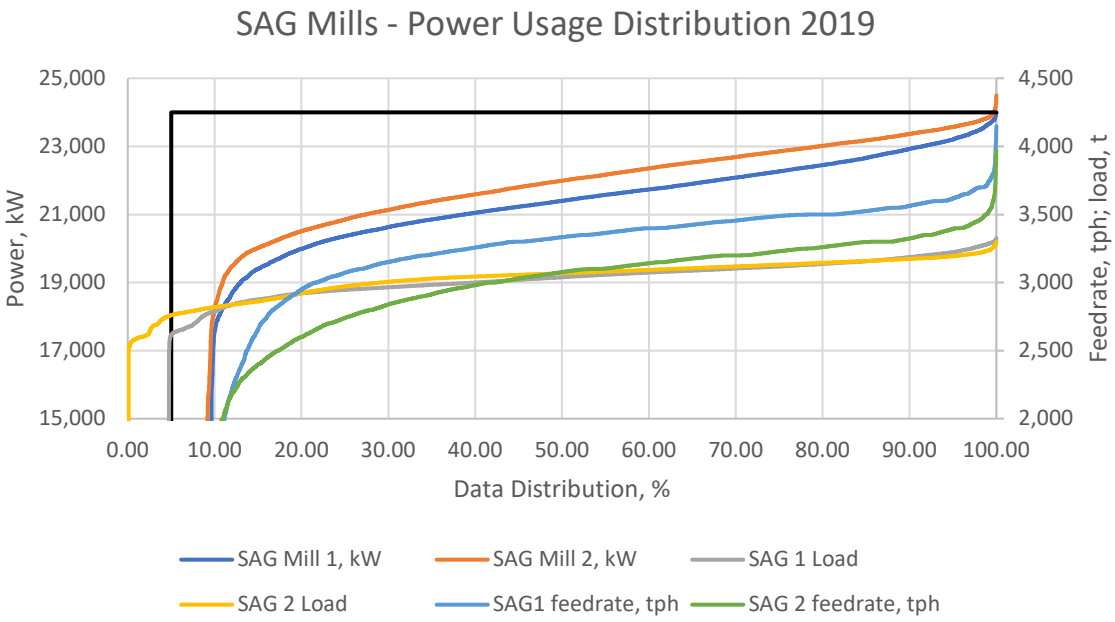

FIG 5 – Distribution of SAG mills performance.

The underutilisation of the balls mills was not as severe, at 8 per cent available capacity, but it is relatively simple, and desirable, to operate ball mills at maximum power. The distribution in load of 200 t, as shown in Figure 6, which was found to arise from the ball mills being overloaded and operating over the power peak, which leads to a drop in power. This had arisen from coarsening of the feed due to the SAG mill screen being opened up, as described in the work of Powell *et al* (2021).

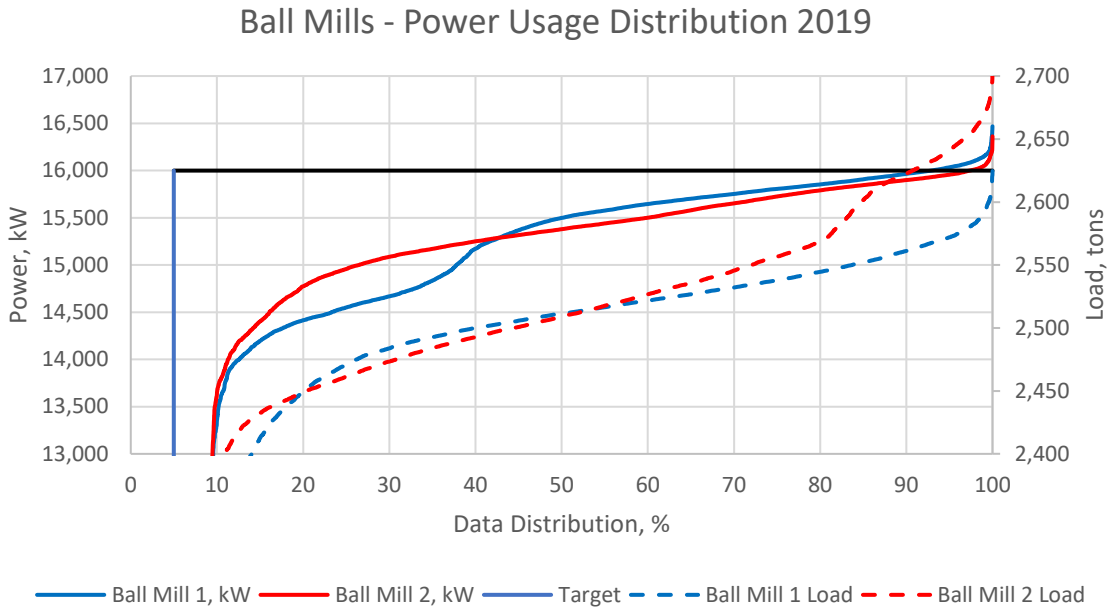

FIG 6 – Distribution of ball mill performance.

The pebble mills suffer from dramatic underutilisation, with an OEE under 50 per cent, with the distribution of utilisation plotted in Figure 7. The crushers have both a low utilisation, at below 70 per cent, and low power draw, ranging from 300–600 kW of the installed 750 kW. The low power draw was linked to excessive time between gap resetting, incorrect chamber design and biased feed distribution. This results in poor use of the available power and a coarse crusher product. This simple illustration also helped avert the commitment to a quite unnecessary fourth crusher that an engineering company was recommending. More information on this common underutilisation of recycle crushers is presented in the work of Powell, Evertsson and Mainza (2019).

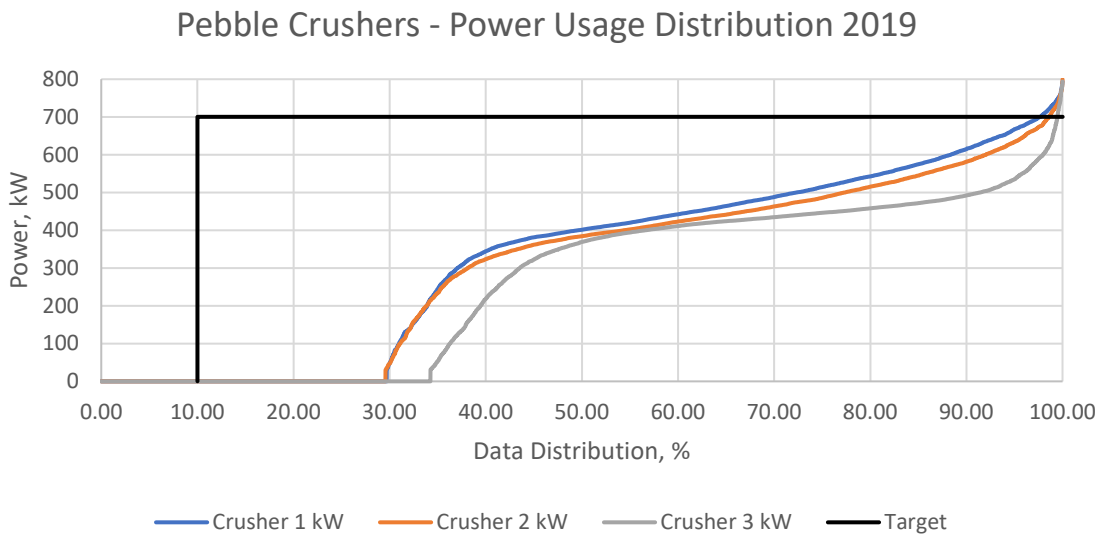

FIG 7 – Distribution of recycle crusher performance.

The SSE based on 230 µm produced was used to analyse the circuit, as this is the standard marker size recorded by the online sampler. The power is the total circuit utilisation (SAG, ball and crusher) averaged over an hour for each separate circuit. The data is filtered for extremes and bad readings. Figure 8 shows the overall trend of the two circuits.

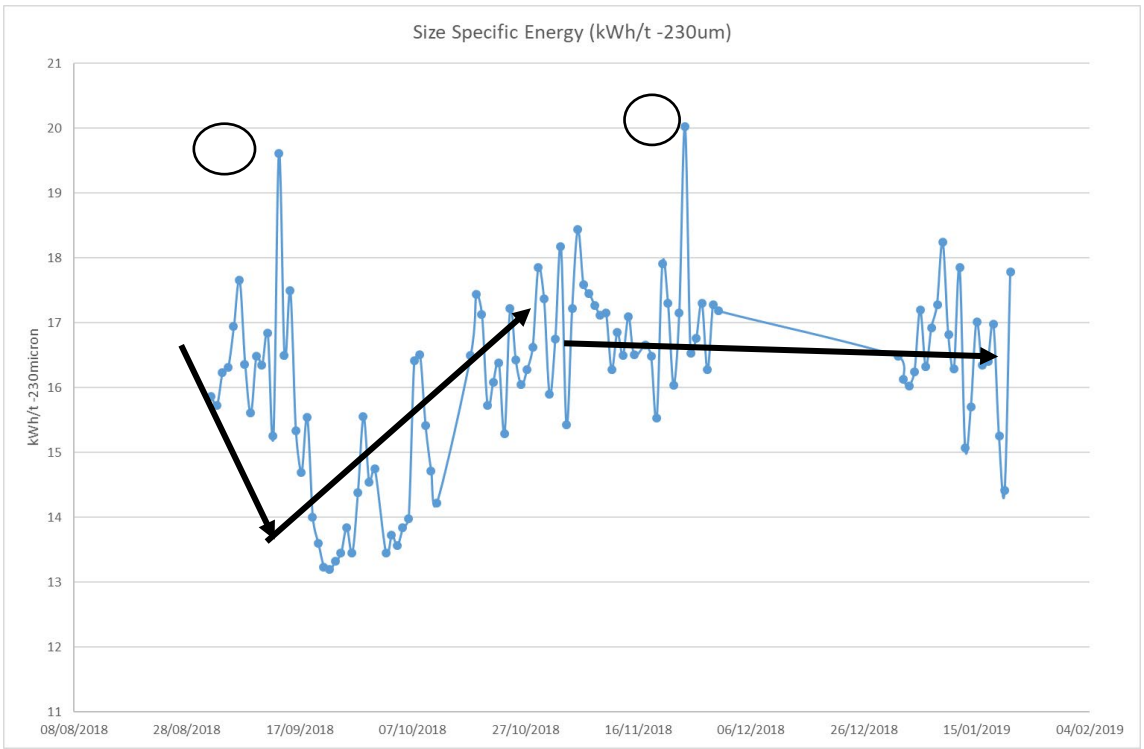

FIG 8 – Size specific energy for the entire comminution circuit over 6 months.

The steadily decreasing trend in SSE through August to September results in a substantial decrease from 16.5 to 14 kWh/t - 230 µm. This rises backup to 17 by November. Such a gross change reflects a markedly softer ore being processed. The extreme outliers arise from periods of low throughput, which drives up the SSE as the ball mills continue to draw full power without the equivalent benefit in reduced grind size, showing up the wasted energy (and ball consumption) in these periods. Superimposed on this are consistent fluctuations of ±1 kWh/t - 230 µm on a daily basis. As it is unexpected that such consistent strong changes in ore competence would be experienced, the cause of such fluctuations should be tracked down. This could point to the need for more consistent blending or control issues that result in fluctuating efficiency of the milling plant.

The SSE distributions in Figure 9, support the conclusion that circuit 2 has a lower efficiency or has more competent feed. Circuit 1 has about 20 per cent of periods with a decidedly softer ore, likely the periods of high fines feed, shown by the excessively low SSE values below 15 kWh/t - 230 µm. The extended shoulders of the distributions, above the indicator lines, also highlight the periods of excessively high energy use for about 10 per cent of operational time. Analysing the operational conditions during these periods should highlight some of the causes of the low efficiency.

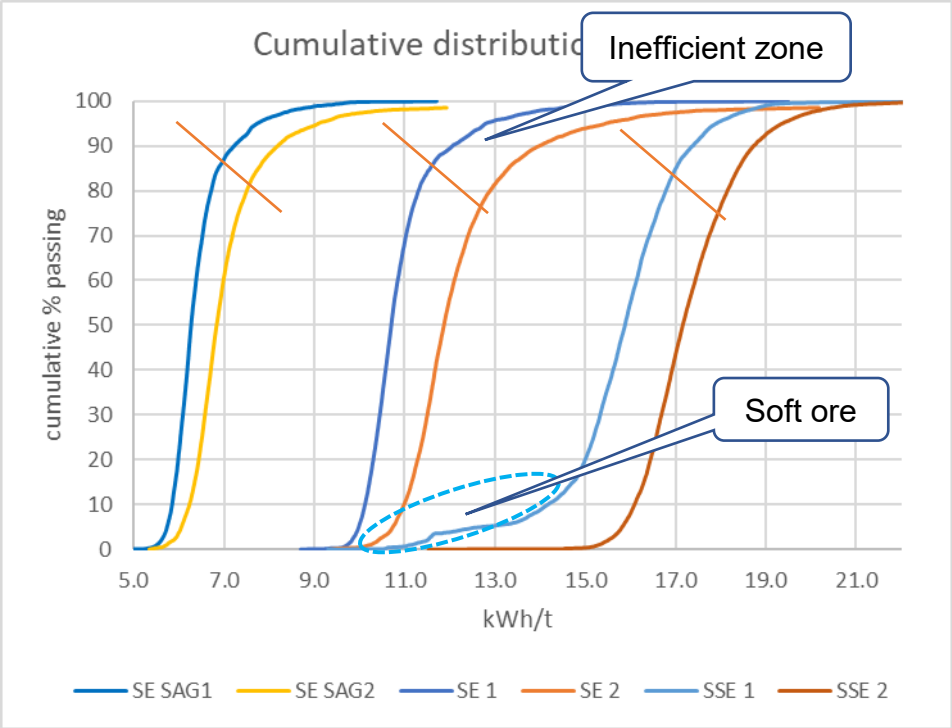

FIG 9 – Cumulative distribution of SE and SSE Dec–Jan 2019.

Small gold operation

For a smaller operation reviewed, the OEE of the SAG mill was exceedingly low at 72 per cent, as shown in Figure 10. This reflects periods of non-use arising from circuit reliability issues and poor liner life. Additionally, the wide variation in power draw shown in Figure 11, point to why the power use is so low.

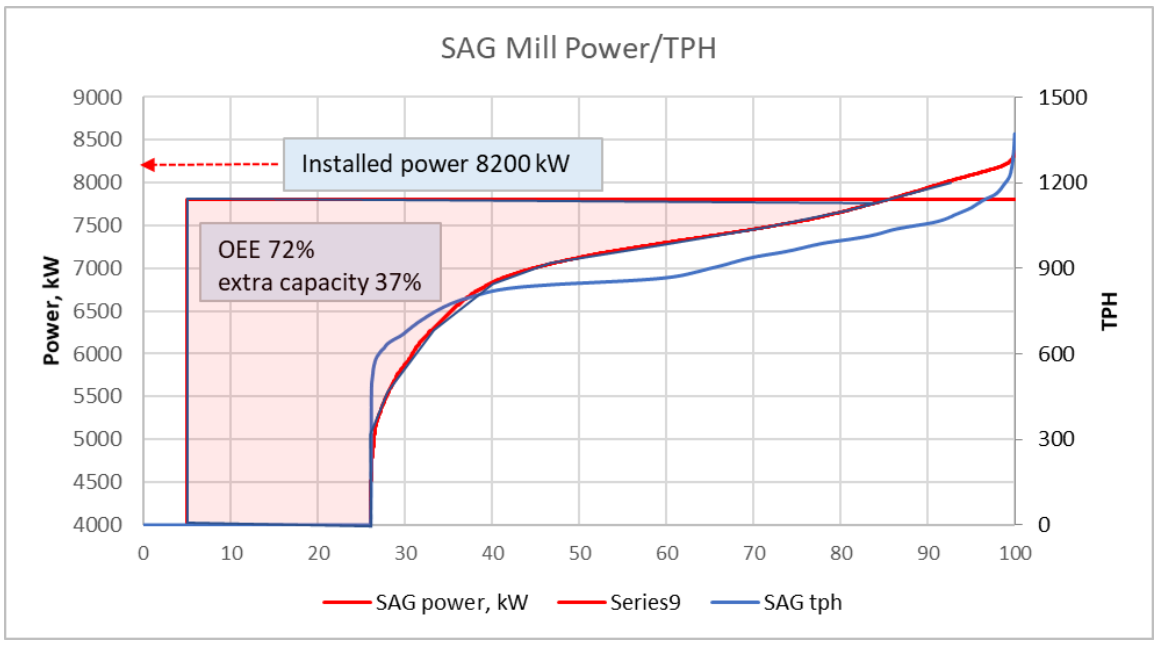

FIG 10 – OEE of a small SAG mill.

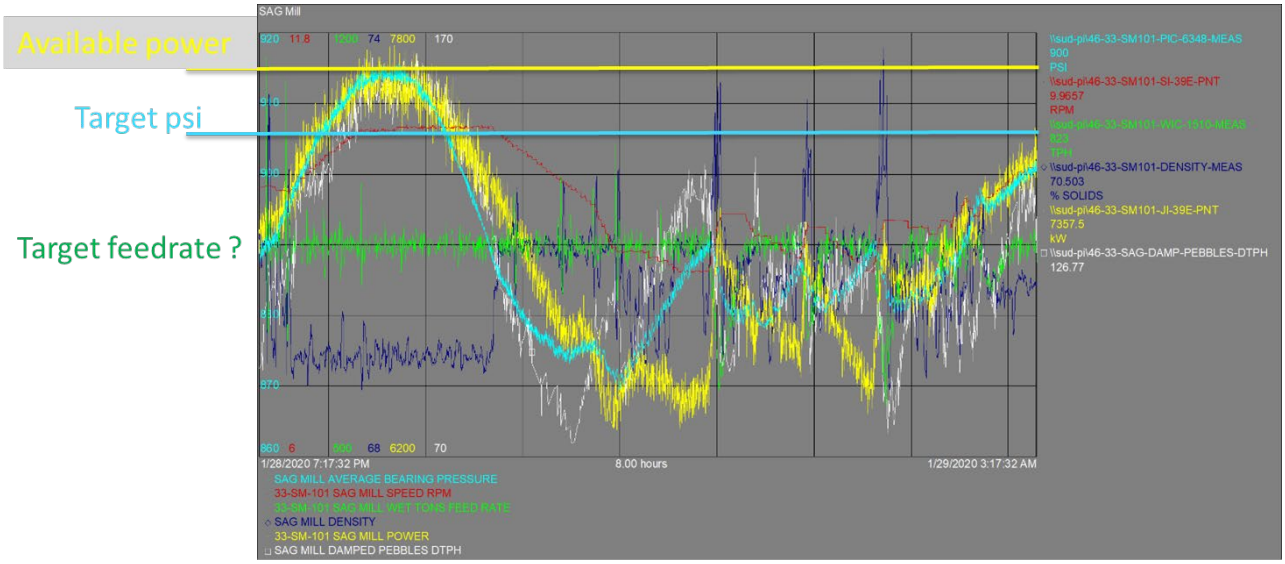

FIG 11 – Process trends for the SAG mill over 8 hours.

As shown in Figure 11, for a random 8 hour period during the site visit, the power varied by 1.3 MW (yellow trend), the load indicator of bearing pressure (blue line) by 45 psi (target window 905 ± 5 psi), while mill speed and water addition were used to try and hold the target feedrate of 850 t/h. The pebble discharge rate varies from 80 to 160 t/h and the product size will be highly variable with the change in power, speed and water addition.

This wide variation in performance was tracked back to lack of control or tracking of the ore dumping and storage in the feed bin, that receives ore from multiple sources. The fluctuation in feed was amplified by an over-responsive control system. The combination of the OEE curves and demonstrated variability in short-term performance provide the basis a business case to address the option of ore tracking and blending.

Iron ore operation

With the increased need to process Magnetite and fine-grained iron ores, the energy-efficient grinding of these relatively soft ores has an increasing importance. A critical aspect of grinding is to minimise the production of slimes that are lost to slimes washing prior to concentration. For this operation there are seven parallel milling streams with a tripper distributing feed between the process

lines. The minus 100 µm fines are washed to slimes on fine screens, representing direct loss of recovery. The distribution of the desired product range being fed to each recovery plant is plotted in Figure 12. Line 7 has a decided lower fraction at 10 per cent lower than lines 2 and 3.

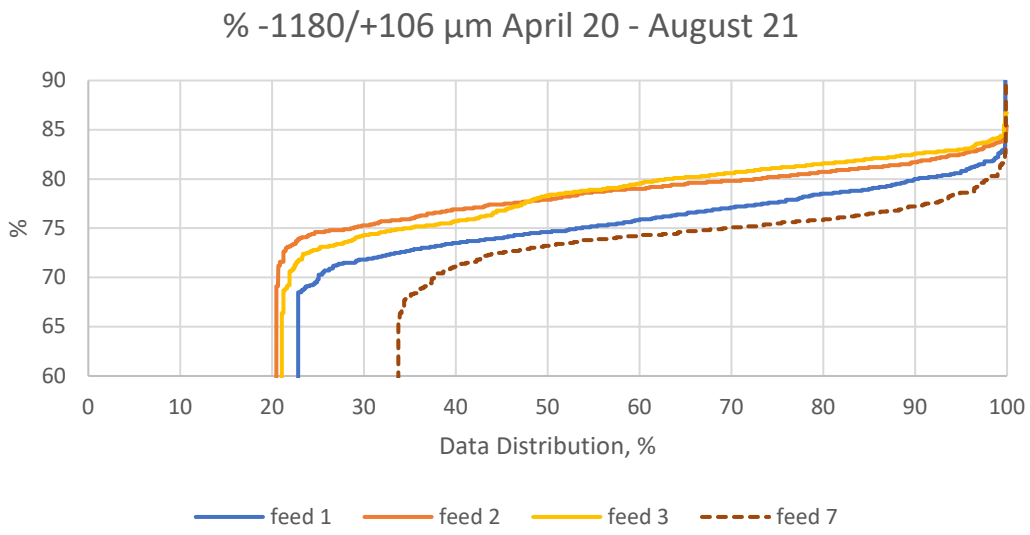

FIG 12 – Distribution of the % of desired product size.

The distributions of SSE are about 4 kWh/t 106 µm higher for lines 7 and 3 compared to the more efficient lines, as shown in Figure 13. This is a difference of around 20 per cent, which bears investigation. The site were encouraged to conduct a detailed comparison of operating conditions between lines 1, 2 and 7 to identify the causes of poor efficiency, with the performance of line 2 as the achievable target.

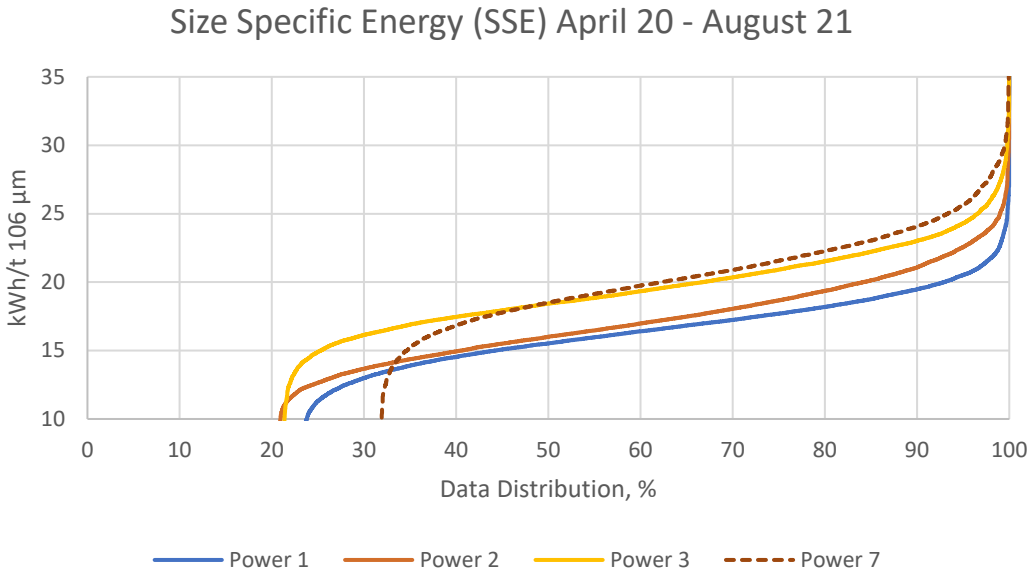

FIG 13 – Distribution of SSE for four milling lines.

CONCLUSIONS

Some alternative options for simple assessments of process efficiency are presented. These are relatively simple to apply with logged process data and supplemented by some more careful sampling. A key aspect that is often overlooked, and tends to only be captured in long and expensive surveys, is the transfer size distribution across-sections of a circuit, such as separate feed size to grinding lines, product size from the SAG mill circuit and recycle crushers. These separate measures are required to identify good and poor performing parts of a circuit.

The authors encourage measures that are easily accessed by site, identify where inefficiencies lie and point to realistically achievable goals – such as the best performing part of a circuit. Caution should be applied in benchmarking against inadequate, often single, feed samples tested at laboratory scale. Additionally, the value of laboratory tests is dependent upon the energy scaling relationships associated with them. It is also noted that all the data benchmarking methods are aspiring to the average performance over the past 20 years, not to future targets the industry should be striving to achieve.

The few measures presented here are only part of the techniques that should be regularly applied in ongoing process improvement and addressing the pressure to focus on efficient energy utilisation. This is an ongoing process where a toolbox of a limited set of valid and achievable measures can be utilised.

Effort is being applied to developing more precise and generally applicable tests that provide a more accurate and reliable measure of performance against what is achievable with current equipment. A target within this is to be able to test a statistically significant number of feed samples against which to compare plant performance. A laboratory test method under development is presented in the work of Ali *et al* (2022). The Geopyörä test presented by Bueno *et al* (2021) and Chavez Matus *et al* (2021) has also been recently developed to better fill this gap. Importantly, such measures are aimed at setting the realistic goals for the energy efficiencies of future circuits.

ABSTRACT

The depletion of the richest ore deposits and the increase in number of mining projects involving deposits with complex mineralogy, higher competence and lower grade has led to an eminent need for improving understanding on multicomponent behaviour in mineral processing. One particularly relevant case is the ball milling of itabirite iron ores fed to the processing plant of Minas-Rio operation in Brazil. Dealing with the two main mineralogical components of the ore, namely hematite and quartz, the operation faces some challenges to improve understanding on how the two components behave in the process. Mathematical models have showed potential to give support in this task, but its applications to describe this type of industrial-scale grinding is still missing. The present work demonstrates the application of a multi-component ball mill model to simulate a closed ball mill circuit with hydrocyclones using the commercial software Integrated Extraction Simulator (IES). Model was calibrated on the basis of bench-scale tests and industrial surveys. Multi-component simulation results are then compared to those considering a single component in the feed, demonstrating the value and great insights that can be achieved by using the former in optimising plant operation.

INTRODUCTION

The complex and heterogenous composition of orebodies is a well-known challenge in comminution operations. Yet, it is common to assume that the orebody responds as a single component to the various comminution and size separation operations. However, it is worth mentioning that, when the ore is ground in large tonnages, a proper understanding on how the different components behave individually and interact with each other is key to improve operations from the point of view of size reduction and liberation (Venkataraman and Fuerstenau, 1984).

Indeed, the current increase in metal demand coupled with significant depletion of the richest ore deposits are placing mineral processing plants in a delicate position to provide a rapid solution when dealing with the so-called multicomponent environment. Direct consequences of these are the growing of ore competence and hardness in the run-of-mine (ROM), the reduction of wear lifetime of parts and machines and the lower ore grade.

With the aim of overcoming the challenges presented above, several studies have been proposed to investigate in-depth the multicomponent behaviour in size reduction. For instance, some authors have performed experimental works to assess performance of AG and SAG milling (Mainza *et al*, 2011; Bueno *et al*, 2011), multicomponent ball milling (Dündar and Benzer, 2015) and component interaction inside hydrocyclone classifiers (Padhi *et al*, 2021). Aligned to the experimental works, advances in the mathematical modelling for multicomponent environments have proven to be a potential solution for process optimisation. Fuerstenau and co-workers (Venkataraman and Fuerstenau, 1984; Fuerstenau and Kapur, 1995) were the pioneers to propose ball mill models relying on multi-component feeds using the population balance model. They partially validated the modelling approach with laboratory experiments but did not report application at industrial-scale.

Additionally, the poor description of ore breakage behaviour and the narrow range of application of these models have limited its appropriate use as a predictive tool.

One type of ore that is facing the challenges of increasing competence and reduced grades is iron ore, which stands out also for the large throughputs processed around the world. One particular and relevant example is the itabirite iron ore in the Minas-Rio operation, from Anglo American (Brazil). In short, the wet part of the circuit consists of primary ball milling in close circuit with hydrocyclones, which processes the ore which may be represented as a binary mixture of Iron Minerals (mostly hematite, with minor amounts of goethite and magnetite) and Gangue (mostly quartz). A recent work reported several challenges to map the presence of different mineralogical components in an iron ore, besides a detailed investigation of its liberation, but also the feasibility of describing it as a binary system in the realm of ball milling (França *et al*, 2020).

The present work proposes a modelling approach describing the industrial-scale closed ball milling circuit processing an itabirite iron ore as a multicomponent mixture. The circuit is simulated in processing a binary mixture of Iron Minerals and Gangue. The multicomponent ball mill model is calibrated on the basis of batch grinding tests and results are validated with industrial survey data. Multicomponent simulations are then compared to those considering a single component in the feed, demonstrating the value and great insights that can be gained when using the multicomponent approach.

MODELLING BACKGROUND

To describe size reduction and classification in an integrated circuit when dealing with a multicomponent approach, the following sections present a multicomponent ball mill model and a multicomponent classification model.

Multicomponent ball mill model

The multicomponent ball mill model is based on the Herbst and Fuerstenau ball mill model (Herbst and Fuerstenau, 1980) with modifications to account for the different breakage responses of different components in the feed.

The model developed by Herbst and Fuerstenau (1980) is based on the population balance model that considers a mass balance for the material in the size class i according to the specific energy (E) applied. Description of size reduction relying on a multicomponent environment follows a similar approach depicted elsewhere (Venkataraman and Fuerstenau, 1984) and is given by:

$$\frac{d[w_i(E_k)]}{d\overline{E}} = -\kappa_{i,k} s^E_{i,k} w_{i,k}(E_k) + \sum_{j=1}^{i-1} b_{ij,k} \kappa_{j,k} s^E_{j,k} w_{j,k}(E_k) \quad (1)$$

where $s^E_{i,k}$ is the specific breakage rate in size class i for component k (t/kWh), $w_{i,k}$ is the mass fraction in size class i for component k, $b_{ij,k}$ is the breakage function in density form for each component k and $\kappa_{i,k}$ is the energy split factor for each component k and size class i that allows to divert breakage for a component when ground in a mixture (Kapur and Fuerstenau, 1988). The specific energy input to the mill for each component k (E_k) is obtained from the ratio between the mill power and the solids feed rate (t/h), being the mill power for each component determined according to its average volumetric fraction in the feed. Volumetric component distribution is simply obtained from the weight component distribution and the measured specific gravities for each component. A key simplifying assumption of the model at this point is the assumption that both components follow the same residence time distribution within the mill. As such, from a feed size distribution given by w_0, an analytical solution for Equation 1 can be stated as follows:

$$w_{f,k} = \left(T_k J_k {T_k}^{-1}\right) w_0 \chi_k \quad (2)$$

where $w_{f,k}$ is the mass fraction in each size class in the product of each component k, w_0 is the mass fraction in each size class in the feed and χ_k is the weight distribution for each component k. The matrixes *T* and *J* may be found elsewhere (Herbst and Fuerstenau, 1980).

The energy split factor ($\kappa_{i,k}$), which allows preferable breakage for one component over the other (Kapur and Fuerstenau, 1988) in a mixture, is calculated as:

$$\kappa_{i,k} = \kappa_{0,k}\hat{x}_i^{\sigma_k} \tag{3}$$

where $\kappa_{0,k}$ and σ_k are fitting parameters for each component κ and $\hat{x}_i$ is the geometric mean size given by $\hat{x}_i = \sqrt{x_i x_{i-1}}$.

In order to solve the model in a continuum operation, the residence time distribution is calculated on the basis of *N* perfect mixers in series model, in which the number of perfect mixers may be estimated by (Austin and Concha, 1994):

$$N = \frac{0.26R_e^{\frac{L_m}{D_m}}}{\sqrt{U_{cs}}} + 1.3 \tag{4}$$

where L_m is the mill length (m), D_m is the mill diameter (m), U_{cs} is the fraction of the critical mill speed and R_e is the Reynolds number.

In order to solve the system of differential equations, the model relies on the non-normalisable breakage function (King, 2001) and the specific selection function (Herbst and Fuerstenau, 1980). The cumulative breakage function is calculated as:

$$B_{ij,k} = \phi_k\left(\frac{x_i}{x_j}\right)^{\gamma_k} + \left(1-\phi_k\right)\left(\frac{x_i}{x_j}\right)^{\beta_k} \text{ for } x_i \geq \omega_k$$

$$B_{ij,k} = \phi_k\left(\frac{x_i}{\omega_k}\right)^{\eta_k}\left(\frac{x_i}{x_j}\right)^{\gamma_k} + \left(1-\phi_k\right)\left(\frac{x_i}{x_j}\right)^{\beta_k} \text{ for } x_i < \omega_k \tag{5}$$

where x_i is the particle size and ϕ_k, γ_k, β_k, ω_k and η_k are fitting parameters for each component k and $b_{ij,k} = B_{i-1,j,k} - B_{i,j,k}$.

On the other hand, the specific selection function is calculated as:

$$\ln\left(s_{i,k}^E/s_{1,k}^E\right) = \xi_{1,k}\ln(\hat{x}_i/\hat{x}_1) + \xi_{2,k}[\ln(\hat{x}_i/\hat{x}_1)]^2 \tag{6}$$

where $\xi_{1,k}$, $\xi_{2,k}$ and $s_{1,k}^E$ are selection function parameters for each component k. The current model takes into account that the $\hat{x}_1$ (reference size) in Equation 6 is equal to 1 mm. Finally, the breakage rates can be described as:

$$S_{i,k} = \frac{P_{Mill,k}}{H_k}s_{i,k}^E \tag{7}$$

where $S_{i,k}$ is the breakage rate for each size class and component k, H_k is the holdup for each component (t) and $P_{Mill,k}$ is the power for each component calculated based on the average volumetric composition of each component (kW).

Aiming to simulate the mill in processing the feed as a single component, the same model is suitable, by considering k = 1.

Multi-component classification model

To describe the classification in the multi-component environment, the proportion of material reported to the oversize (c_{dp}) is then defined for each component as:

$$c_{dp} = 1 - C_{ov}\frac{exp(\alpha_k)-1}{exp\left(\alpha\frac{\hat{x}}{d_{50_k}}\right)+exp(\alpha_k)-2} \tag{8}$$

where d_{50_k} is the size where the probability of going to the oversize is equal to 50 per cent for each component k in the corrected curve, C_{ov} is the water split to the overflow and α_k is a fitting parameter for each component k. Model assumes C_{ov} constant and equal for both components.

METHODOLOGY

The following sections present the experimental work conducted and the modelling and simulation approach. After defining the flow sheet to be studied, industrial surveys were carried out to characterise the plant performance from collecting samples and operational information from the circuit. Samples were characterised through bench-scale tests, through which data was used to

calibrate the mathematical models. Details about model implementation and simulation are also presented.

Since operations of interest consist of ball milling and classification in hydrocyclones, the components defined are Iron Minerals (mostly hematite) and Gangue (mostly quartz). The description used here considers a simplified assumption that both components are fully liberated in the mixture, even though Iron Mineral particles with sizes above about 200 μm may be regarded as locked, with around 80 per cent of hematite and 20 per cent quartz.

Experimental

Industrial survey

A survey was carried out in the Minas-Rio circuit from Anglo American (Brazil). The survey was carried out in the ball milling and classification circuit. Information about operating conditions was recorded from the supervisory system, whereas samples were collected in the fresh feed, ball mill product and both hydrocyclone products. Remaining streams were obtained by mass balance reconciliation. The ball mill investigated has 7.92 m in diameter and 12.8 m in length, whereas the hydrocyclone cluster is composed by eight cyclones with 33 inches of diameter. Ball milling was operating under 27 per cent of mill filling, 76 per cent of critical speed and 70 mm of make-up ball size.

In the lab, samples were subjected to dry sieving in Rotap® sieve shaker until the 75 μm sieve, with the material passing being subjected to wet sieving until the 20 μm sieve. Samples of individual fractions were then ground below 75 μm and analysed in an energy dispersive X-ray fluorescence spectrometer Simutix 14 (Rigaku) for chemical composition, besides analyses of loss on ignition. The fresh feed solids rate was 2856 t/h, whereas the average component composition was 53 per cent Iron Minerals and 47 per cent Gangue in weight, corresponding to 37 per cent Fe. Specific gravity of each component was measured using Helium pycnometry.

Batch grinding tests

Batch grinding tests were carried out with individual components in the narrow size ranges 1.18–0.60 mm and 2.36–1.18 mm. Each component was prepared by dry high-intensity magnetic separation carried out in multiple stages in the device presented elsewhere (André *et al*, 2019) with fresh mill feed samples collected in the industrial survey. Two products generated in magnetic separations were used for each test, namely the Iron Minerals, containing about 85 per cent of hematite and goethite, and the Gangue, with more than 95 per cent of quartz. Batch grinding tests were performed in a ball mill with 30 cm in diameter and 30 cm in length, equipped with six shell lifters. A torque sensor allowed to accurately estimate the mill power consumption. Grinding times of 2, 4 and 10 minutes were used. Tests considered a solids concentration in the slurry by volume equal to 57 per cent. A summary of the conditions used in the grinding experiments is presented in Table 1.

Additional tests with the original samples collected in the fresh feed of the ball milling circuit were also performed. The test relied on a feed size distribution with a top particle size of 19 mm. These tests were carried out with in a bench-scale ball mill with a diameter of 58 cm and a length of 24 cm. The mill was equipped with eight shell lifters and a torque sensor able to record the torque during grinding. Solids concentration by volume was also maintained at 57 per cent, corresponding to a solids concentration by weight of 83 per cent, whereas top size ball diameter was equal to 63 mm. Five grinding times were used (1, 2, 4, 8 and 16 minutes) in order to cover specific energies below and above the one usually observed in the industrial-scale grinding operation, equal to 1.7 kWh/t. A summary of the main grinding conditions, which were selected to mimic the industrial-scale grinding operation, are presented in Table 1.

All feed and product size distributions from each test were analysed using the same approach used to deal with the samples from the industrial survey.

TABLE 1

Summary of the conditions used in the batch grinding tests.

	Single component (composite ore)	Multicomponent (Iron minerals, gangue and mixture)
Mill diameter (cm)	58.0	30.5
Mill length (cm)	24.0	30.5
Mill filling (%)	27.0	24.0
Top ball size (mm)	63.0	36.5
% Critical speed	76.0	76.0
Mill speed (rev/min)	44.2	61.4
Interstitial filling (%)*	100	100

*Estimated from industrial surveys.

Model implementation and parameter fitting

Fitting of parameters in the breakage and selection functions (Equations 5 and 6) from the multi-component ball mill model (section 'Modelling background') was performed using a nonlinear constrained optimisation method able to find the minimum of a multivariable scalar function using the Nelder-Mead method from an initial estimation. Initially this parameter fitting was conducted with batch grinding tests at different grinding times and the objective function was defined from the differences between the experimental and calculated cumulative product size distribution using the least-square method. Breakage parameters for a single-component approach were calibrated with batch grinding data carried out with the complete feed size distribution in the 58 cm diameter batch ball mill (section 'Batch grinding tests'). On the other hand, for a multicomponent approach, parameters from Iron Minerals and Gangue were calibrated from batch grinding tests with material in the narrow size ranges 1.18–0.60 mm and 2.36–1.18 mm.

Integrated simulations

The ball mill model presented in the 'Modelling background' section was implemented in the Integrated Extraction Simulator (IES) as part of the present work to simulate the operation in integrated circuits. Open-circuit and closed-circuit ball mill simulations were carried out following the operating conditions listed in 'Industrial surveys' section. The flow sheet of this ball milling and classification circuit implemented in IES is presented in Figure 1.

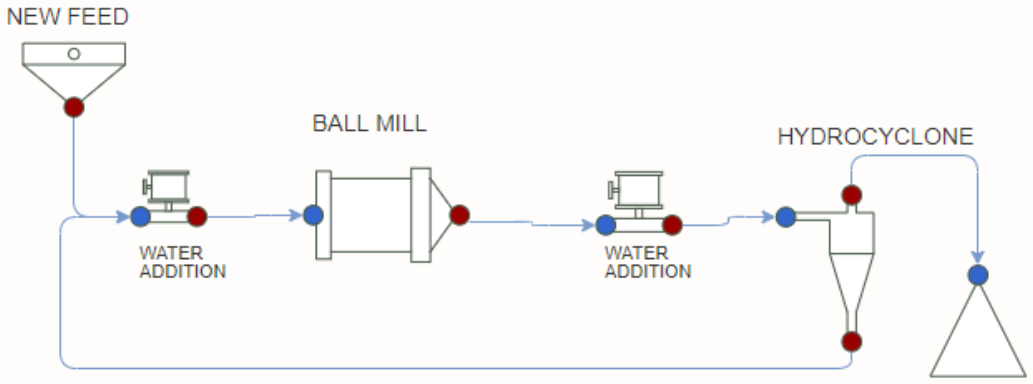

FIG 1 – Flow sheet of the ball milling and classification circuit implemented in IES for simulation.

RESULTS AND DISCUSSION

Experimental results

Evidence of the multicomponent behaviour of the itabirite iron ore processed in the grinding circuit was observed with a careful analysis of size distribution and chemical composition of samples collected in the industrial survey. Figure 2a presents the component distribution by weight in each size class for the underflow of the hydrocyclone cluster, which demonstrates the high iron content throughout the size classes. Results from Figure 2a may be explained by the high specific gravity of the Iron Minerals (4.75 t/m³), which are responsible for their higher tendency to concentrate in the circulating load to the mill. On the other hand, when analysing the component distribution in the hydrocyclone overflow (Figure 2b), the limited proportion of Iron Minerals in the coarser size ranges that report to the desliming stages. These results demonstrate the importance of describing separately the different components in the ore in the hydraulic classification stage.

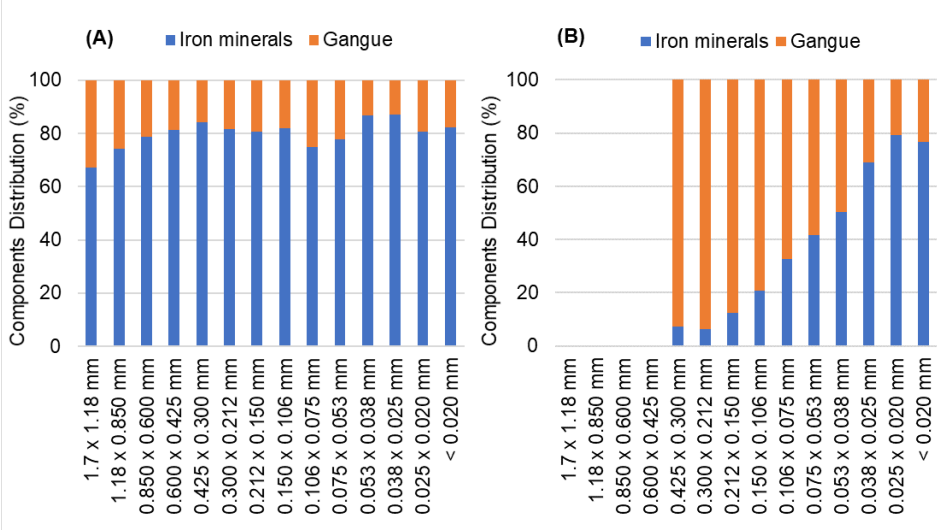

FIG 2 – Component distribution by weight obtained by X-ray fluorescence analysis for the hydrocyclones: (a) underflow; and (b) overflow.

Model calibration

The optimisation of parameters from breakage and selection functions on the basis of batch grinding data when considering the fresh feed as a single component is presented in Figure 3, where very good agreement between fitted and experimental values is evident. These results indicated a small proportion of material remaining in the coarser size classes after 2 min of grinding time (approximately 1 kWh/t), whereas a small but progressive shift was observed in the fine part of the size distribution as grinding progresses. Fitted breakage and selection functions are presented in Figure 4.

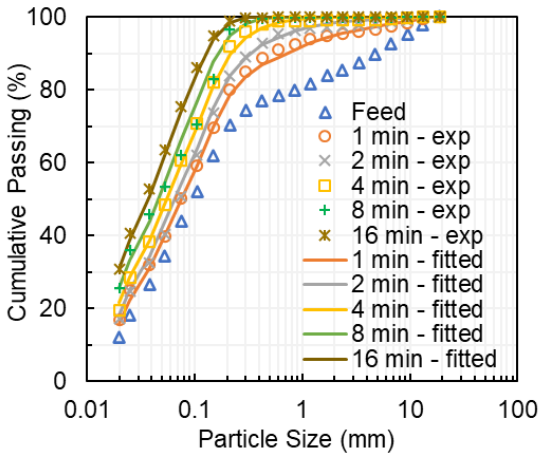

FIG 3 – Comparison between fitted and experimental values for the batch grinding tests carried out with the fresh feed in five different grinding times.

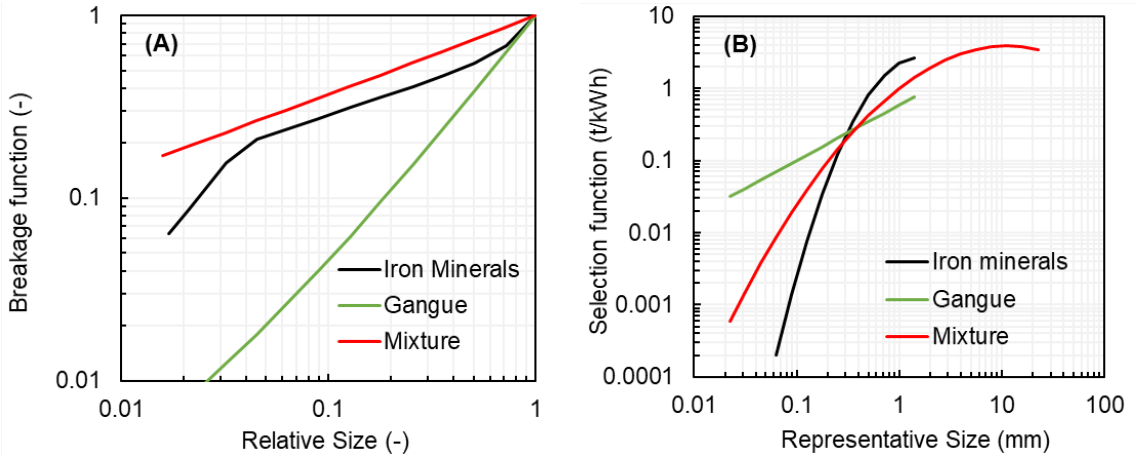

FIG 4 – Comparison of breakage functions (A) and specific selection functions (B) fitted from the batch grinding tests when considering both single and multicomponent approaches.

Parameter optimisation was also carried out for the multicomponent approach when dealing with each component separately in the narrow size ranges of 1.18–0.60 mm and 2.36–1.18 mm, with results presented in Figure 5. Results in Figure 5a demonstrate the well-known behaviour of Brazilian iron ores with a non-normalisable progeny size distribution in respect to the parent particle size for the Iron Minerals component. Beyond the good agreement in Figure 5a, it is also worth mentioning the inflexion point in the size distribution around 53 µm, which is in line with other observation by the authors (Faria *et al*, 2019; Campos *et al*, 2019). On the other hand, progeny size distribution for the Gangue component presented a linear trend in log axes with very good agreement between fitted and experimental values. Additional analyses of results in Figure 5 allows to demonstrate the greater amenability of the Iron Minerals to breakage, being the percent passing the 75 µm sieve equal to 54.4 per cent for Iron Minerals and 20.6 per cent for Gangue after 10 min of grinding. Comparison between fitted and experimental values for the narrow size range of 2.36–1.18 mm was omitted for brevity.

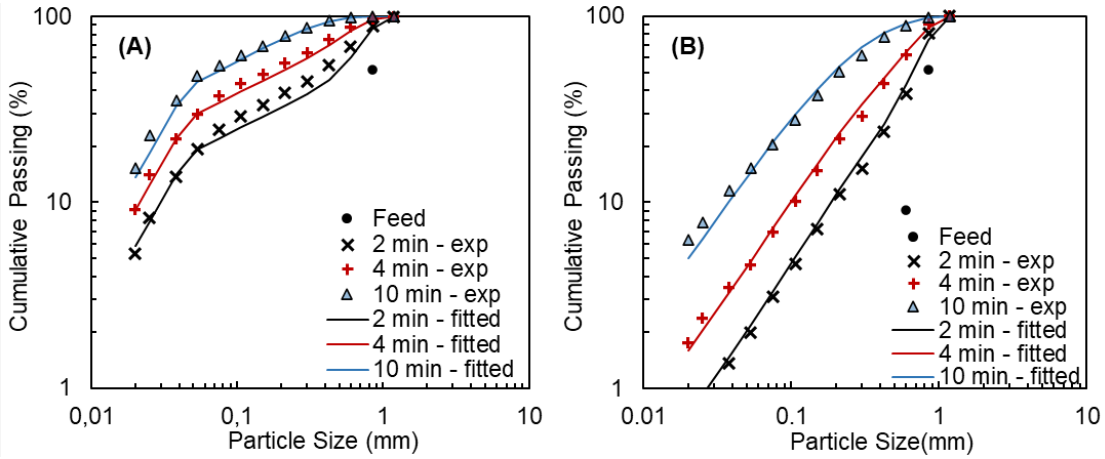

FIG 5 – Comparison between fitted and experimental size distributions from the batch grinding tests carried separately with the: (a) Iron Minerals component; and (b) the Gangue component in the narrow size range of 1.18–0.60 mm.

Breakage and selection functions for each component fitted in Figure 5 are presented in Figure 4 with a comparison between them and the ones fitted in Figure 3 for the fresh feed sample as a single component. Results shown a finer breakage function when considering the ore as a single component (Figure 3), whereas the breakage rate for the ore assumed intermediate values between the Iron Minerals and the Gangue components. Breakage function for the single component approach did not require a non-normalisable breakage behaviour to describe the progeny size distribution. This may be, at least in part, explained by the very large proportion of fines shown in Figure 3, thus dampening the particle segregation effect in these selected size classes.

Beyond the ball mill model calibration, results from the mass balance reconciliation of the survey data showed good results and relative deviations from measurements up to 1 per cent for the mass flow rates and solids concentration. These results were also used to calibrate the classification model (Equation 8). Mass balanced results from each stream were then used to calculate partition data and a comparison between fitted and experimental size distributions is presented in Figure 6 for the single component model (a), as well as when considering the multicomponent model with Iron Minerals (b) and Gangue (c).

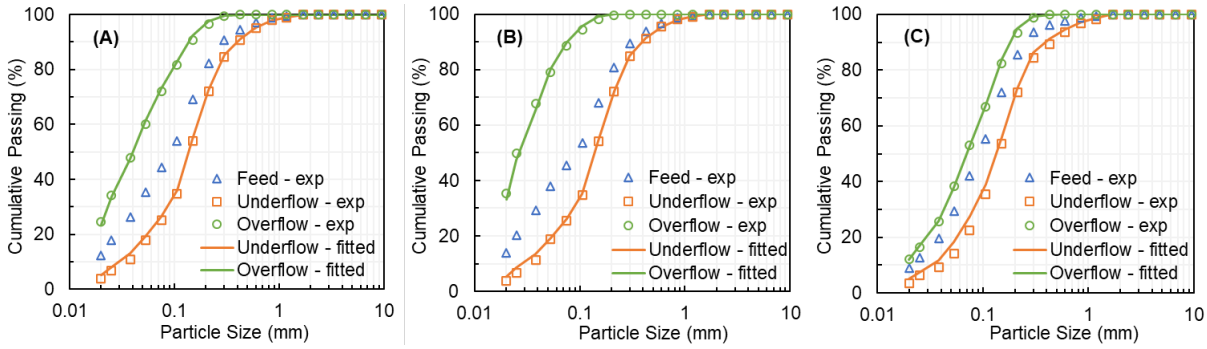

FIG 6 – Measured size distributions from streams around the hydrocyclone cluster and fitted results using a partition curve model considering a single component approach (a), and for both Iron Minerals (b) and Gangue (c) in a multicomponent approach.

For optimisation, the d_{50c} and water split to undersize (C_{ov}) were gathered from experimental analyses, while the remaining parameter (α) was fitted in the IES platform. As shown in Figure 6, very good agreement was reached for the three curves. In addition to Figure 6, results showing the proportion of solids reported to the oversize are then presented in Figure 7. These results indicated a high proportion of Iron Minerals reporting to the hydrocyclone underflow with a d50c of 64 μm and α of 2.1, while the Gangue component presenting a d50c of 214 μm and α of 1.9. The water split to the undersize was constant for both components and equal to 0.77. Fitted results for the mixture in the average between each component demonstrated the good agreement between data used.

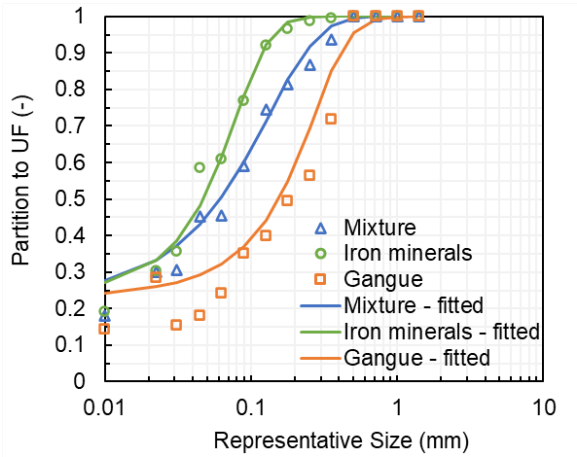

FIG 7 – Partition curve to the underflow (oversize) of the Iron Minerals, the Gangue, and the mixture.

Model validation

Validation of the models was carried out by performing simulations of the industrial grinding circuit operation. Figure 8 shows a comparison between experiments and model predictions when dealing with the ball mill as an open circuit unit, where Figure 8a describes the model prediction when dealing with a single component model and Figure 8b shows the multicomponent one. Very good agreement was reached between experiments and predictions made through both modelling approaches. Parameters fitted for each component separately, even though using narrow size ranges, demonstrated the feasibility to describe the particle breakage behaviour of the ore. An additional point should be raised regarding the single component model: it required a minor adjustment of the s_1^E parameter (Equation 6) fitted from the batch-grinding test in order to describe the industrial-scale results. This adjustment may be explained, at least in part, by conditions in the batch grinding tests (Table 1) that differed from the industrial-scale.

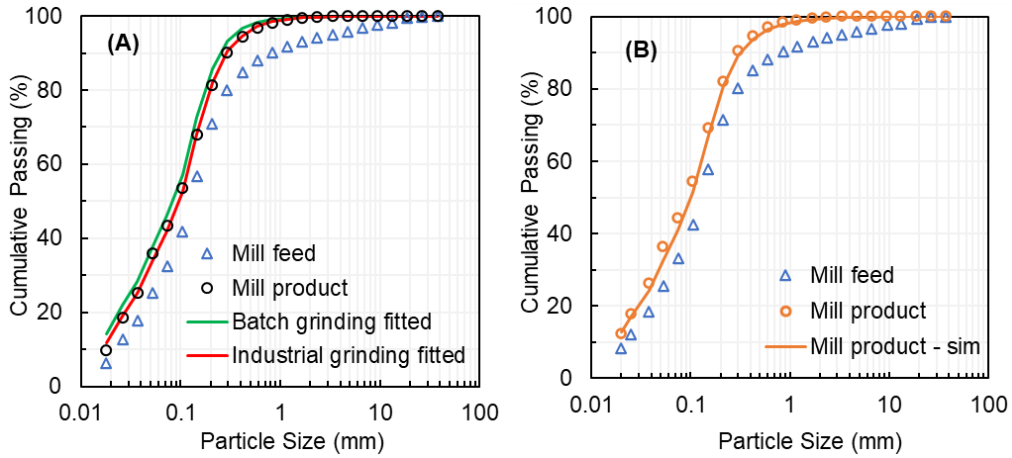

FIG 8 – Comparison between model predictions and experiments for the industrial-scale ball mill analysed in open circuit using the single component model (a) and the multicomponent model (b).

Figure 9 shows the comparison between experimental and predicted product size distributions for each component for the case of the ball mill operating in open circuit. Very good agreement was reached for Iron minerals component, whereas the Gangue product presented good agreement in the fine part of the size distribution and an underestimation in the coarser size classes. This may be explained by the assumption that Gangue is fully liberated in the coarser size classes (section 'Component definition'), which is not entirely valid. Indeed, experimental evidence up to this point indicates that quartz composing the locked particles (coarser size classes) presented higher amenability to breakage in comparison to its behaviour when ground fully liberated. Unfortunately, no mathematical description of this different behaviour has been used in the present work.

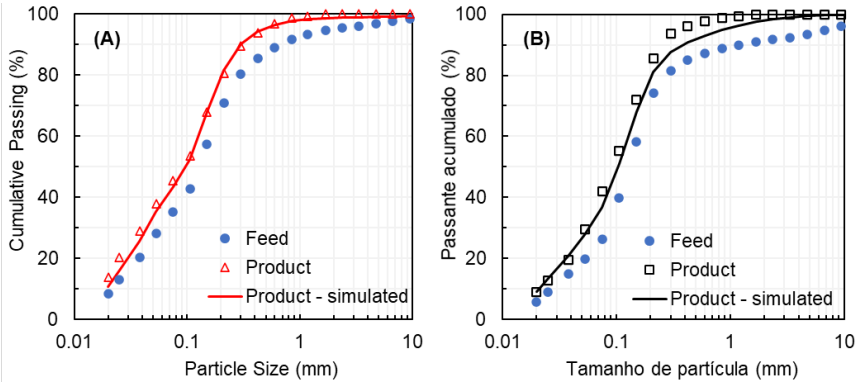

FIG 9 – Experimental and simulated particle size distributions of Iron Minerals (a) and Ganga (b) in the mill product.

Integrated simulations

The multicomponent model was applied to describe the closed ball mill circuit. A comparison is shown in Figure 10 between model and experiments on the ball mill discharge (Figure 10a) and the hydrocyclone products (Figure 10b). Relatively good agreement was achieved is some streams when using the multicomponent model to describe the size reduction, but significant underestimations also became evident. Poor agreement in the coarser size classes for the Gangue component (Figure 9b) was responsible for limiting these predictions. Description of the closed-circuit ball mill performed considering a single component model was very good and is shown in Figure 10c and 10d. Nevertheless, it is worth mentioning that the multicomponent modelling approach justifies its used by the strong capability of mapping the proportion valuable and deleterious components in the mixture, thus allowing to propose changes in the operational strategy or circuit configuration to overcome, for instance, overgrinding of liberated Iron Minerals.

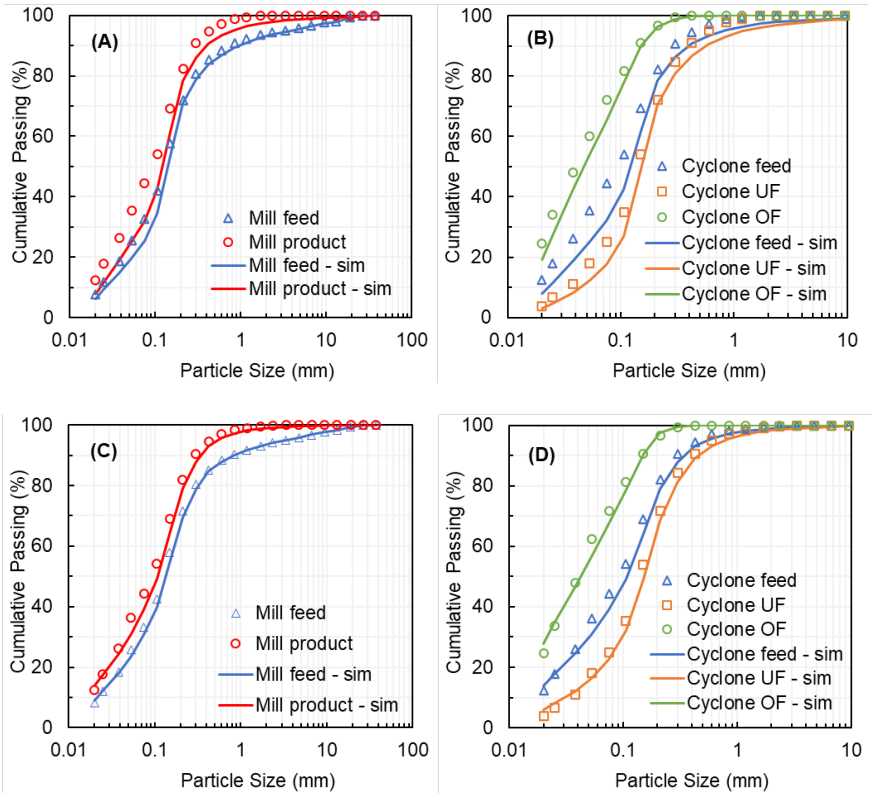

FIG 10 – Comparison between model and experiments for the mill product (a) and the hydrocyclone products (b) using a multicomponent modelling approach (top), whereas comparison between model and experiments for the mill discharge (c) and the hydrocyclone products (d) using a single component modelling approach (bottom).

Table 2 presents a comparison between some performance variables obtained through the multicomponent simulation and during the industrial survey. Results showed some important deviations in the circulating load and in solids feed rate to the mill feed, even though model being able to accurately predict the component content in each stream evaluated, clearly demonstrating the enrichment of Iron Minerals in the hydrocyclone underflow.

TABLE 2

Comparison between the main performance variables obtained during the industrial survey and from the multicomponent simulation.

Performance parameter		Iron minerals		Gangue	
		Experimental	**Simulated**	**Experimental**	**Simulated**
Ball mill	Composite feed rate (t/h)	4760	6421	2096	2856
	Composite feed component content (%)	69.4	69.2	30.6	30.8
	Composite feed F_{80} (μm)	297	265	281	579
	Composite P_{80} (μm)	208	204	186	355
Cyclones	Product passing 75 μm sieve (%)	35.4	27.3	26.3	21.3
	Circulation load ratio (%)	217	328	58	115
	Underflow content (%)	81.0	76.3	19.0	23.7
	Overflow content (%)	53.0	53.0	47.0	47.0

CONCLUSIONS

The present work investigated an industrial-scale ball milling and classification circuit from standpoint of multicomponent response. Definition of components resulted in characterising the iron ore as a binary mixture composed by Iron Minerals and Gangue.

Hydrocyclone classification survey results were used to describe the behaviour of each component, where substantial enrichment of the Iron Minerals component was observed in the hydrocyclone underflow.

A multicomponent modelling approach was used to simulate the industrial-scale ball mill circuit. Calibration of the model on the basis of batch grinding tests showed feasibility to describe the component breakage behaviour, with results being partially validated in industrial-scale. Limitation when describing the Gangue component was reported and associated to the simplified assumption that particles are fully liberated in the entire size classes. The underestimation of size reduction of the Gangue component had direct effects on the prediction of the mixture when the model was not able to properly predict the closed ball mill circuit.

A comparison between single and multicomponent approaches to describe the same industrial-scale circuit showed similar results between them, with single-component approach presenting closer predictions to measure results when applied to simulate stream size distributions in the closed circuit. Nevertheless, the ability of the multicomponent model to map the component within the circuit was demonstrated and provided insights, which suggests that it can serve as the basis for investigating different operation strategies so as to, for instance, prevent regrinding or fully liberated hematite.

ACKNOWLEDGEMENTS

We thank you Anglo American S.A for the financial and technical support and the Brazilian agencies CAPES and CNPq for the additional financial support.

ABSTRACT

Inertia cone crushers have found applications mostly in steel slag crushing operations in China. Compared with conventional eccentric cone crushers, the crusher has an obvious advantage in reducing product size. In addition, they are mostly used in two-stage open circuit crushing flow sheet, which simplifies the crushing process. However, inertia cone crushers are not widely used in the mineral processing industry due to their low crushing capacity. In this paper, the throughput performance of the inertia cone crusher was investigated in a laboratory-scale inertia cone crusher and relationships between operational parameters were identified. Iron ore was crushed using orthogonal experimental method under different machine parameters and operational conditions. The crusher throughput and product size distributions were determined. The effects of parameters such as eccentric speed, discharge gap, eccentric mass and eccentric distance on product mass flow and product size were investigated. The results of this study can help reduce the feed size of the mill in order to reduce total energy consumption of comminution.

INTRODUCTION

Inertia cone crusher (Vaisberg, Zarogatsky and Turkin, 2004) was designed by the former Soviet Union based on the vibration theory. The biggest difference between inertia cone crusher and eccentric cone crusher is that the motion of the moving cone is excited by a vibrator (unbalanced rotor) rather than the eccentric sleeve. The vibrator is fixed on the sliding bearing around the shaft of the moving cone. The moving cone swings around the centre of the spherical support under the inertial centrifugal force generated by the vibrator. The main body is located on the rubber shock absorber. The structure diagram of the inertia cone crusher is shown in Figure 1.

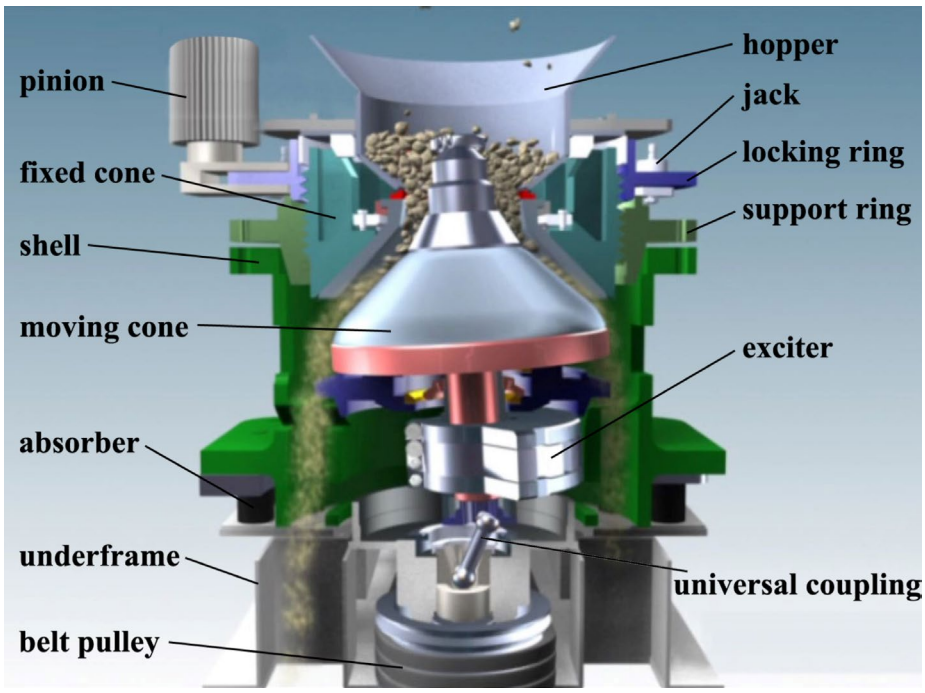

FIG 1 – Structure diagram of inertia cone crusher.

In conventional cone crushers, the motion of the moving cone is independent of the loading of the crusher. The eccentricity and the stroke amplitude are constant (Evertsson, 2000). In order to achieve interparticle breakage, choke fed conditions are recommended. In inertia cone crushers, the stroke amplitude of the moving cone is unconstrained (Blekhman, 2000). The crushing force of the inertia cone crusher is influenced by the eccentric speed, eccentric mass, eccentric distance, the chamber geometry and the material property. The concept of the discharge gap which is called 2S is different from the closed side setting (CSS) in eccentric cone crushers. Particles are more likely to be compressed into a compact state, leading to interparticle breakage (Vaisberg and Zarogatskii, 2003). Due to this characteristic, choke fed conditions are required at all times (Xia *et al,* 2009). Starved feeding conditions will cause severe damage to the crusher.

The power input of the inertia cone crusher is successively transmitted to the crushing mechanism through the universal transmission device and the sliding bearing. The centrifugal rotational motion of the vibrator is not limited by the spatial position of the moving cone. Since there is no rigid connection, when the oscillating motion of the moving cone is stopped by an uncrushable body in the chamber, the mechanical transmission keeps running around the sliding bearing. Due to this feature, the inertia cone crusher is suitable for tramp iron conditions. In addition, the particles undergo more crushing times under the high-frequency vibration crushing process, and the final products have fine particle size. Compared with conventional eccentric cone crushers, the crusher has an obvious advantage in reducing product size. Based on the above two advantages, inertia cone crushers have found applications mostly in steel slag crushing operations in China (Xia and Luo, 2015). It can be well applied to iron-containing materials, better realise the dissociation of slag and iron, recover metal and produce steel slag micropowder at the same time. In addition, due to the high proportion of fines in the product, closed circuit crushing and sieving flow sheet are usually not required. They are mostly used in two-stage open circuit crushing flow sheet, which simplifies the crushing process. However, inertia cone crushers are not widely used in the mineral processing industry due to the low crushing capacity. Due to the low-grade of the ore, more ores need to be processed in order to obtain sufficient metal. The production scale of the mineral processing industry is usually large, which leads to higher requirements for the processing capacity of the crushing equipment. It is necessary to increase the processing capacity of the inertia cone crusher while maintaining the product size to meet the crushing demand of the mineral processing industry. Because the grinding operation consumes more energy than the crushing operation, inertia cone crushers will help reduce the feed size of the mill and reduce the total energy consumption of comminution.

EXPERIMENTAL

Laboratory-scale GYP100 inertia cone crusher

The equipment used in the experiment is a laboratory-scale GYP100 inertia cone crusher. The bottom diameter of the moving cone is 100 mm. It can be used to crush brittle materials such as ores, refractories, abrasives, ceramics and so on. The structure diagram of the GYP100 inertia cone crusher is shown in Figure 2.

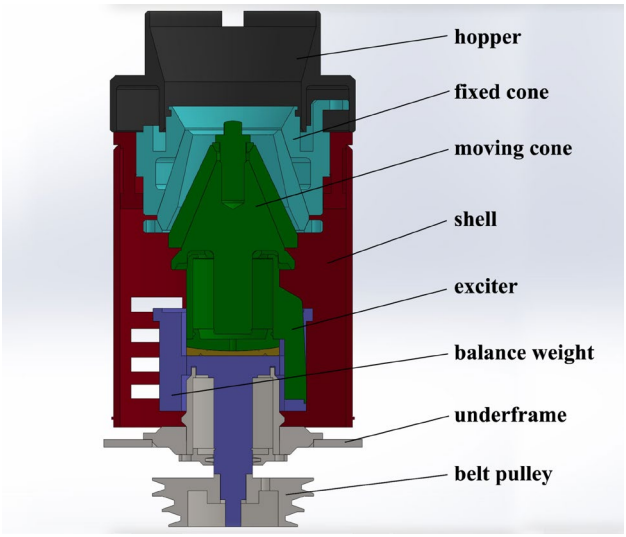

FIG 2 – Laboratory-scale GYP100 inertia cone crusher.

Experimental conditions and procedures

Crusher throughput, product size distribution and working current were investigated under different equipment parameters and operating conditions. Unlike previous experiments, this experiment introduces how the centripetal force component (m*r) works. Eccentric mass (m) is composed of an eccentric body and several counterweights installed on different locations. It is changed by adjusting the number of counterweights. Eccentricity (r) is influenced both by the number of counterweights and their installation location on the eccentric body. Their values are automatically calculated by 3D drawing software. The vibrator diagram with eccentric body and all nine counterweights is shown in Figure 3, which is displayed in bottom orientation.

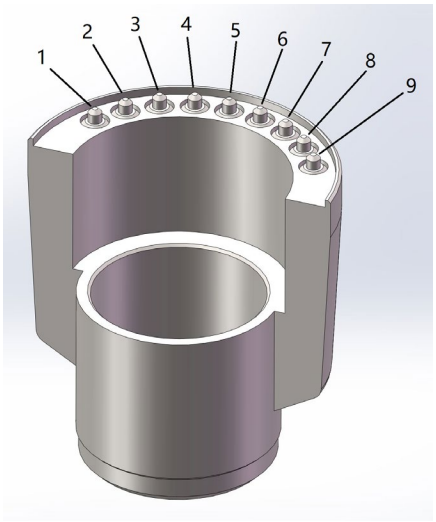

FIG 3 – Vibrator diagram with an eccentric body and 9 counterweights.

The experimental conditions include eccentric speed (ω), discharge gap (2S) and centripetal force component. Each condition has three values according to the structural parameters, operating

instructions and limitations. Different eccentric speeds are obtained based on the belt pulley design of the crusher. The crusher gives three standard eccentric speeds by changing the belt transmission ratio. The discharge gap of the equipment called 2S should not exceed 6 mm.

The materials used in the experiment are iron ore with a magnetic iron content of around 3.5 per cent. Ore minerals are mainly magnetite and pyrite, with a small amount of hematite and limonite. Gangue minerals include quartz, plagioclase, potassium feldspar and biotite. The feed size of the GYP100 inertia cone crusher should not exceed 12 mm. The minerals used in the experiment were mainly in the size range of 2–8 mm.

In order to reduce the number of tests and to cover all parameter combinations to the greatest extent, the orthogonal test method was used. Orthogonal experimental design is a method of scientific analysis by rationally arranging multi-factor experiments using orthogonal tables. According to the number of factors and levels, the orthogonal table was selected. The header design of the orthogonal table with three factors and three levels was completed. Nine experimental combinations (No. 1–9) were obtained. The above experiments include the effect of the centripetal force component under different conditions. However, counterweight and eccentricity affect the crushing force ($m*r*\omega^2$) in different ways. In order to study the effect of counterweight and eccentricity, six groups of supplementary experiments (No. 10–15) were carried out. The experimental conditions and results are shown in Table 1. Installation location corresponds to the circular holes arranged in order in Figure 3.

In each experiment, the weight of the crushed material was about 1 kg and the crushing time varied between 3 and 5 minutes. The current was measured throughout the crushing process. Products were gathered when the equipment was working steadily. After the crushing test, the materials were sieved with a vibrating screen and weighed separately. All of these tests were performed under choke fed conditions. The crushing process and product characteristics were measured under different equipment parameters and operating conditions. The experimental process is shown in Figure 4.

FIG 4 – The experimental process.

Through the record of the crushing time and weight of the product, the crusher throughput and current of 15 groups of parameters combination were obtained.

RESULTS AND DISCUSSION

Crusher throughput

First, the crusher throughput of the first nine groups of orthogonal experiments was analysed. In order to study the effect of each factor on the experimental results, an intuitive analysis is carried out, which is also called range analysis. The larger the range, the more important the corresponding factor. The purpose of the range analysis is to determine the order of primary and secondary factors in order to select a better parameter. In order to visualise the range analysis results, a trend graph (effect curve graph) was drawn as shown in Figure 5. These data were calculated from the first nine groups of orthogonal test results (No. 1 to No. 9) by using range analysis calculation method.

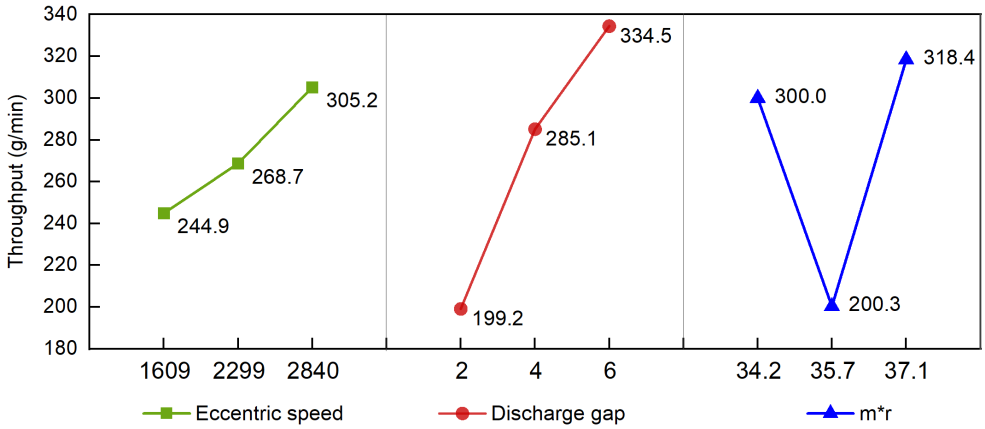

FIG 5 – Effect plot for range analysis of test No. 1 to No. 9.

The range analysis results show that the discharge gap has the greatest impact on crusher throughput, followed by the centripetal force component and finally the eccentric speed. The largest and smallest values differ by a factor of 1.68, and the change is faster and the curve is steeper. From the overall trend of curves, except for the centripetal force component, the crusher throughput is proportional to eccentric speed and discharge gap. It is large at both ends and small in the middle of the centripetal force component. A larger discharge gap provides a larger swing range of the moving cone. More crushing force is generated by a larger vibrator rotation radius. The space between the mantle and concave increases at the same time. These cause more

crushing to occur and rapid vertical flow-through the crushing chamber, resulting in higher throughput. In terms of eccentric speed, there is a contradiction with the results of previous papers (Wang *et al,* 2021). The difference is that all nine counterweights were installed in the previous experiment. In this experiment, most of the counterweights were removed. Three installation methods were used in the orthogonal test with only 2–4 counterweights. Less counterweights reduce the centripetal force component and affect the inertial force. For some of the tests there wasn't enough crushing force to break the feed, so the results are in two bands – before there wasn't enough force, and after there was enough force. The previous work always applied enough force to be in the 'ideal crushing phase', which means the feed is always broken with enough crushing force during the steadystate downward movement.

The current value fluctuates within a certain range when the crusher is working. The current value and amplitude range can be used as a reference for power consumption. The relationship between current and throughput under different centripetal force components is shown in Figure 6.

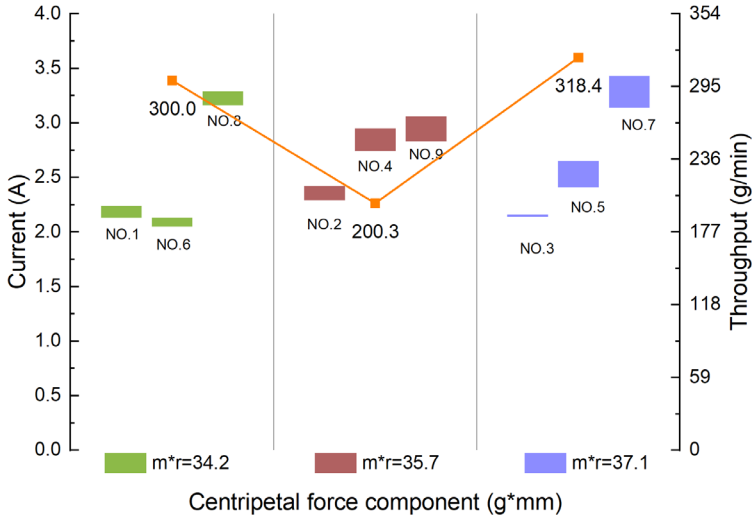

FIG 6 – Relationship between current and throughput under different centripetal force component.

When the centripetal force component increases, both the current value and the amplitude range increase. The greater centripetal force component requires more power to drive. In the case of less counterweights, the eccentric excitation force is not enough to meet the force threshold required for material crushing. The crusher throughput is limited by the crushing force. When the inertial force exceeds the force threshold required for material crushing, the crusher throughput is limited by the volume space of the crushing chamber. From this moment on, the crusher throughput decreases with the increase of the eccentric speed. Therefore, in addition to the traditional method of adjusting the discharge gap, selecting the appropriate eccentric speed and vibrator installation method is an important way to adjust crusher throughput. Above all, the first step is to find the 'ideal crushing phase' when facing materials with different mechanical properties and to make sure the crusher operates in that phase.

Second, the influence of different installation methods under the same centripetal force component is analysed. Two groups of experiments were selected for analysis, and the results are shown in Figure 7.

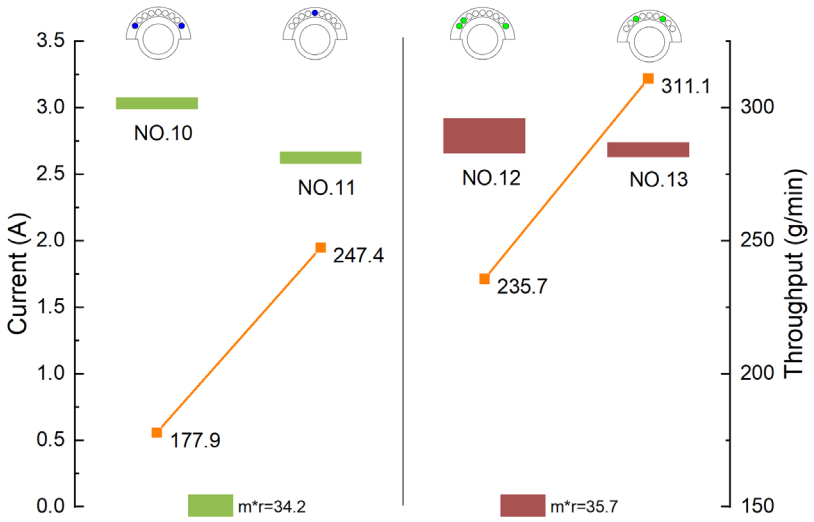

FIG 7 – Results showing the effect of changing counterweight installation location under the same centripetal force component with 34.2 and 35.7 respectively.

By comparing the two groups of experiments, it can be seen that the crusher throughput is larger when less counterweights are concentrated in the middle than that when more counterweights are evenly distributed on both sides.

Finally, the variation of eccentricity is analysed under the same counterweight condition. The results of four test data are shown in Figure 8.

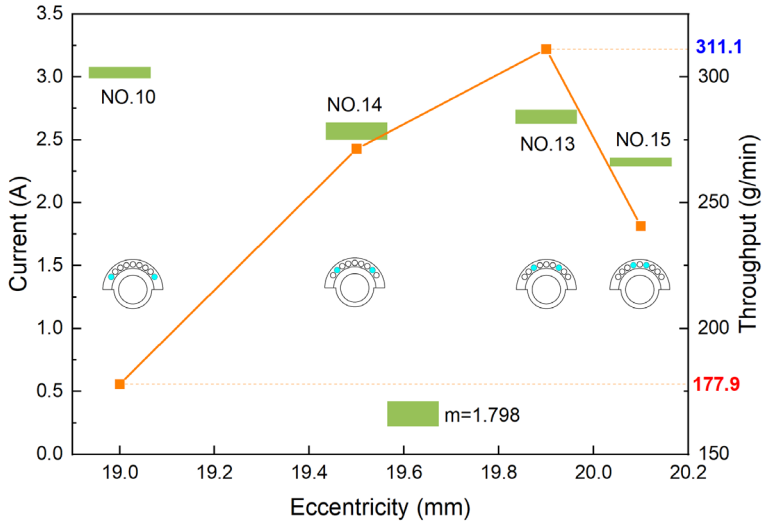

FIG 8 – Results showing the effect of different eccentricity under the same eccentric mass of 1.798.

Maximum throughput occurred at test No. 13 with 311.1 g/min and minimum throughput occurred at test No. 10 with 177.9 g/min. When the current fluctuation is not much different (in the range of 2.63–3.08 A), the crusher throughput is nearly 1.75 times different. The data in Figure 7 and Figure 8 are from the last six groups (No. 10 to No. 15) of experiments, which belong to single factor and multi-level experiments. There are some contradictions with the previous orthogonal test results of three factors and three levels in terms of crusher throughput. The difference is that the crusher throughput varies at both ends with the change of the centripetal force component. This may be because the single factor experiment results are insufficient. Under multi-factor and multi-level conditions, they cannot fully cover all the data. This phenomenon will be further tested at other levels by single factor experiments.

Product size distributions

There are 15 groups of tests, all of which use the same material as the feed. To represent the feed size, three samples were randomly selected from the raw materials. The sieving results of the feed materials are represented in Figure 9 by the dashed lines. The product size distributions of nine groups of products in the orthogonal tests were first analysed, as shown in Figure 9.

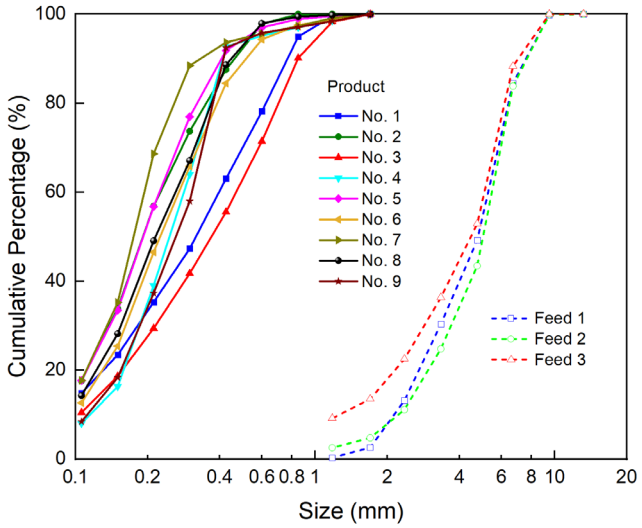

FIG 9 – Feed and product particle size distribution in orthogonal test.

The P_{80} product size in all nine groups of experiments is below 0.8 mm. The coarse and fine ends of the curves correspond to test No. 3 and No. 7. Test No. 3 uses the minimum eccentric speed, the maximum discharge gap and the maximum centripetal force component. Test No. 7 uses the maximum eccentric speed, the minimum discharge gap and the maximum centripetal force component. The eccentric speed controls the period of the precession of the compression zone around the concave circumference of the crusher. This in turn determines the duration of the compression of the particles when the bed is in the compression phase and the time available for particles to move lower during the expansion phase of the crusher cycle. High eccentric speed shortens the expansion phase of the crusher motion, which leads to a reduced vertical downward displacement per rotation cycle. More crushing frequency increases the chance of particles being broken, which leads to an increase in breakage, resulting in a finer product. The increase in the discharge gap creates more space for particles to flow-through the crusher chamber per unit time, and bigger particles are more likely to be discharged. As a result, the product size becomes coarser.

The two coarser products of test No. 1 and No. 3 in the curves use the minimum eccentric speed. In test No. 1, the inertial force is insufficient because the centripetal force component is small and the discharge gap is small, resulting in a low degree of breakage. In test No. 3, although the crushing force is increased, the degree of breakage will still decrease due to the increase in the discharge gap. In terms of influence on product size, the eccentric speed is the highest, the discharge gap is the second, and the centripetal force component is the lowest.

Figure 10 shows the product size distribution of the last six groups of tests, which are single factor and multi-level experiments. The effect of the centripetal force component on product size is studied. From the density of the curve distribution, the particle sizes of the last six groups of products are relatively closer to the results in the orthogonal tests. The best product comes from test No. 15, which uses the maximum centripetal force component. This result is consistent with the orthogonal test result. Under the four test conditions shown in Figure 7, with the same centripetal force component and relatively the same current, the crusher throughput varies greatly, but from Figure 10, the product size does not change significantly. The results show that reasonable parameter matching can effectively increase crusher throughput while keeping product size stable without increasing power consumption. It also shows that when the parameter settings are unreasonable, less energy is used for crushing operations and more energy is used for internal mechanical transmission, vibration and friction loss. A typical example in industrial applications is

the direct impact and wear between two liners. This conclusion can also be proved from the product size distribution of test No. 10 and No. 13 in Figure 8. The particle size is relatively close, but the crusher throughput differs by a factor of nearly 1.75. In addition, the power consumption is higher in the case of low crusher throughput. The kinetic motion of the equipment consumes more energy than the crushing operation. Inertia cone crushers are generally heavier than eccentric cone crushers under the same diameter of the moving cone and consume more energy in terms of equipment dynamics. Future work includes optimising the parameters of rigid body and bulk material coupling vibrating crushing system to achieve a reasonable distribution of crushing energy. Two-way coupled simulation using discrete element method and multi-body dynamics is an effective way to achieve this goal.

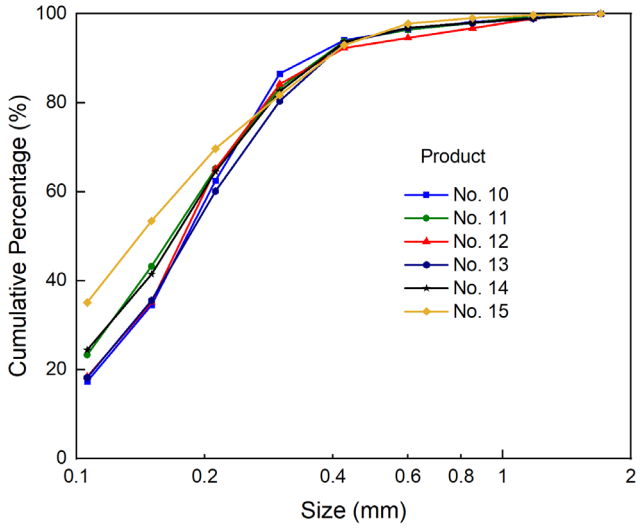

FIG 10 – Feed and product size distribution in the last six groups of tests.

CONCLUSIONS

A laboratory-scale GYP100 inertia cone crusher was investigated by orthogonal test method. The effects of changes in mechanical parameters and operating conditions on product characteristics were investigated. The main conclusions can be summarised as follows:

- The discharge gap has the greatest impact on crusher throughput, followed by the centripetal force component, and finally the rotational speed.
- The eccentric speed has the greatest impact on product size, followed by the discharge gap, and finally the centripetal force component.
- Whether the crusher throughput is limited by the power or the volume of the crushing chamber depends on whether the eccentric excitation system can provide enough crushing force required for material crushing.
- Reasonable parameters matching can effectively increase the crusher throughput while keeping the product size stable without increasing the power consumption. Parameter design directly affects whether energy consumption is used for crushing or mechanical transmission loss to a large extent.

ABSTRACT

High-Pressure Grinding Roll (HPGR) is one of the efficient methods for increasing the specific surface area (SSA) of iron ore concentrate for pellet feed production. HPGR grinding mechanism implies that material should compressed between the two rolls, therefore layer of material must be able to resist required pressure for achieving suitable grinding conditions. In this study, by doing SSA increasing tests with pilot HPGR, the effects of silica reduction on SSA increasing results were investigated. For this purpose, HPGR tests were performed on an Iranian magnetite concentrate before and after reverse flotation silica reduction tests. Based on the laboratory test results, silicates have been concentrated in two fraction sizes of the sample comprises coarser than 150 microns in form of quartz and finer than 7 microns in form of iron silicates. These silicates have been effected on reduction of concentrate bed pressure resistance by creating a pasty and sticky mud. In this condition, HPGR cannot work properly and operation results are not acceptable. According to flotation silica reduction tests, with 90 per cent weight recovery, concentrate Fe grade is increased from 67.8 per cent to 69.5 per cent and SiO_2 content is reduced from 1.98 per cent to 0.9 per cent and especially for lower than 7 microns fraction size, as a critical fraction, SiO_2 content decreased from 4.45 per cent to 2.35 per cent. HPGR tests were performed on 8 per cent moisture in 4 N/mm^2 specific force and according to the results after silica reduction HPGR operation conditions are optimised. Results showed that the working gap increased from 7 to 10.5 mm and specific throughput of material raised from 180 ts/hm^3 to 250 ts/hm^3, and SSA increased by 300 cm^2/gr in a single pass.

INTRODUCTION

The formation of high-quality pellets depends on the preparation of fines defined by both size distribution and specific surface area (SSA) (Van Der Meer, 2015) therefore, mostly iron ore concentrate SSA increased in a grinding circuit for produce pellet feed.

Before feeding to pelletising plants, iron ore concentrate, is generally grinding by two methods of High pressure grinding roll (HPGR) or dry grinding circuit by ball mill. These methods' results are different, and the shape of particles from HPGR would be more angular as compared to ball mill products (Bleifuss, 1997). These features together with a high proportion of fines would allow an HPGR product to be suitable for pelletising at a lower Blaine value from a presumed better packing and density in generated pellets (Van Der Meer, 2015). Additionally, stronger pellets were produced from the HPGR products, with a lower binder requirement (Ehrentraut and Ramachandra Rao, 2001). Using HPGR pre-treatment on magnetite concentrate, it was found better quality pellets would be produced at lower bentonite consumption rates (Zhu *et al*, 2004).

HPGR increases the specific surface area (eg Blaine cm^2/g) as a result of compression grinding and attrition or abrasion of the particle surfaces. The size reduction and associated increment in the specific surface area depend on the size distribution and specific surface area of the HPGR feed (Van Der Meer, 2015). Based on HPGR grinding mechanism, the materials layer between the rolls should be able to resist the required pressure for optimal grinding. Main parameter for optimal performance and material compressing in HPGR is resistance required pressure with the optimal working gap, effect of working gap on HPGR specific throughput and capacity are shown in following

Equations 1 and 2. Specific throughput is a parameter frequently used for sizing HPGR capacity (Van Der Meer and Gruendken, 2010).

$$m° \ (ts/hm^3) = Q / (D \times L \times v) \quad (1)$$

$$Q \ (t/h) = s \times L \times v \times \rho \times 3.6/1000 \quad (2)$$

- m° specific throughput
- Q HPGR capacity
- D roll diameter
- L roll length
- v roll speed
- s working gap
- ρ material density between the gap

If material pressure resistance was low, material does not able to tolerate the required pressure for suitable grinding and product Blaine value will be decreased. Moreover, HPGR working gap will be low and based on the formula, HPGR capacity will be decreased.

Pressure resistance depends on condition and material specifications such as particle size distribution, moisture, particle shape, surface texture and fines and clay content, therefore by reducing impurities, material pressure resistance and HPGR operating results were (are) improved.

Chemical/traditional flotation is one of the most effective methods for separating valuable particles from waste minerals, which is used in most mineral processing industries. In the iron ore processing industry, the major impurities present in iron ore concentrate include sulfur, silica and phosphorus (Xiong *et al*, 2015), which are often carried out by reverse flotation methods for the removal of sulfide and oxide impurities (Araujo *et al*, 2005; Ma, 2012; Frommer, 1967).

Generally, silica impurities of iron concentrates are of two types: quartz-containing minerals and silicate minerals such as pyroxene, clinopyroxene, amphibole and the like. Often, when quartz is the main mineral that forms silica of the sample, the silica flotation process is easily carried out by amine collectors. But, when the iron silicates are typical of the siliceous main minerals, the process of flotation is often complicated and the efficiency of the method is also relatively low (Frommer, 1967; Filippov *et al*, 2010; Houot, 1983).

This study was performed on an industrial case, that's final concentrate (filter cake) specific surface area increased by HPGR. Operation results showed that HPGR working gap was the same as zero gap and HPGR capacity was very low. Material was very pasty and sticky and could not go between the rollers gap. HPGR capacity was reduced by half compared to the design, without a very noticeable change in feeding moisture. Material analysis showed that due to the increasing clay minerals (SiO_2, Al_2O_3) content in plant feed (crushed ore), produced concentrate SiO_2 content increased more than 380 per cent compared to the design value (Table 1). Thus, silica reduction as an optimisation plan was investigated.

TABLE 1

Feed and concentrate specification compared to design value.

Sample name	Specification	Design	Actual	Difference
Feed (crushed ore)	Fe (%)	54.8	53.02	-3%
	FeO (%)	22.51	20.44	-9%
	SiO_2 (%)	6.47	8.50	**+31%**
	Al_2O_3 (%)	1.37	1.91	**+39%**
	CaO (%)	2.6	2.99	**+15%**
Concentrate (studied sample)	Fe (%)	70.5	68.06	-3%
	FeO (%)	26	27.54	+6%
	SiO_2 (%)	0.41	1.98	**+383%**

The purpose of this study was to investigate the silica reduction effect on HPGR operation conditions and improved SSA increasing results. For this purpose HPGR regrinding tests were performed on industrial concentrate sample, before and after reverse silica reduction flotation test and HPGR main effective parameters such as specific throughput (m dot), working gap and amount of SSA increasing was compared.

MATERIALS AND METHODS

In this study, flotation and regrinding tests with HPGR were performed on the prepared samples in FSTCO Mineral Processing and Metallurgy Research Centre (FSTRC).

Sample characteristic

The sample used in the experiments included magnetite concentrate which was prepared from one of the iron beneficiation plants in Iran. Screen analysis showed that in the studied samples, D99 and D80 were around 500 and 110 microns, respectively. Also sample Fe grade was 68.06 per cent and SiO_2 content was 1.98 per cent.

Flotation tests

Flotation test was performed with the silica reduction purpose. In order to perform reverse flotation tests, the chemical modifiers were used including sodium carbonate as a dispersion of impurities containing silica and starch with the aim of depressing iron minerals. Meanwhile, the Flotigam EDA was used as a collector. Flotation tests were carried out at pH values of 8.5 to 9.5. The device used for traditional flotation experiments included the DENVER Pilot Mechanical Flotation Machine with six cells and each cell volume was 25 L.

HPGR regrinding tests

HPGR regrinding tests were performed by pilot HPGR, with the aim of increasing concentrate specific surface area in the FSTCO Mineral Processing and Metallurgy Research Centre (FSTRC). The device was manufactured by Koppern consist of a roll diameter of 1030 mm and 250 mm widths, motors with power of 2 × 132 kW and adjustable roll speed of 6.2 to 31 rev/min. Tests were performed in four moisture levels from 6–9 per cent, with 4 kN/m^2 pressing force in an open circuit. To investigate the silica reduction effect, HPGR regrinding tests were performed on concentrate before and after of flotation tests.

RESULTS AND DISCUTION

Sample metal screen analysis – before flotation

The variation in the weight percentage of particles at different fractions in addition to iron and silica content of each fraction was measured individually and shown in Table 2.

TABLE 2

Screen metal analysis of concentrate sample – before flotation.

Size (micron)	Weight (%)	Fe (%)	SiO_2 (%)
> 150	8.4	62.50	6.02
106–150	14.08	67.25	2.61
75–106	13.80	68.35	1.75
53–75	14.76	69.10	1.10
38–53	12.01	69.69	0.90
25–38	6.24	69.68	0.83
19–25	9.08	70.12	0.36
13–19	5.45	69.96	0.58
9–13	4.24	69.34	1.27
7–9	3.39	69.22	1.33
< 7	8.54	64.34	4.45
Total		68.06	1.98

Distribution evaluation of iron and silicate minerals at different fractions showed that in coarse (>150 micron) and fine (<7 micron) fractions, Fe content was low and silica content was high. In fact, silica impurities were concentrated in both coarse and fine fractions. Silica impurities in the coarse fraction were in form of quartz but in the fine fraction is silicate minerals such as pyroxene, clinopyroxene and amphibole.

Silica reduction tests by flotation

In order to silica reduction, reverse flotation tests performed on concentrate. Tests results showed that, with 90.72 per cent weight recovery, SiO_2 content reduced from 1.98 per cent to 0.9 per cent and Fe content of the product increased from 68.06 to 69.16 per cent.

Sample metal screen analysis – after flotation

After flotation tests, screen and chemical analysis were performed on the concentrate to compare silica contents and to investigate the flotation effect on silica reduction. The variation in the weight percentage of particles at different fractions In addition of iron and silica content of each fraction was measured individually and shown in Table 3.

Results showed that Fe grade in the concentrate was increased from 68.06 per cent to 69.5 per cent and SiO_2 content was reduced from 1.98 per cent to 0.9 per cent. Especially for lower than 7 microns fraction size, as a critical fraction, SiO_2 content decreased from 4.45 per cent to 2.35 per cent.

TABLE 3

Screen metal analysis – flotation product.

Size (micron)	Weight (%)	Fe (%)	SiO_2 (%)
> 150	14.04	65.25	2.55

< 7	5.12	65.81	2.35
Total		69.16	0.90

HPGR regrinding tests result

HPGR regrinding test was performed on studied sample, before and after flotation tests, regrinding tests condition and the results are presented in Table 4.

TABLE 4

HPGR regrinding test.

		Before Silica Reduction				After Silica Reduction			
Test No.	**Unit**	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**
Static gap	mm	5				5			
Spec. press force	kN/m^2	4				4			
Feed SSA (Blaine method)	(cm^2/g)	1050				980			
Feed Moisture	%	6	7.0	8.0	9.0	6	7.0	8.0	9.0
Working gap	Mm	10.3	7.2	6.9	5.1	14.7	11.7	10.5	6.5
$W_{spec.}$	kWh/t	1.1	1.1	1.5	0.9	0.9	1.0	1.3	1.45
m-dot	ts/hm^3	265	220	180	60	310	280	250	165
Product SSA (Blaine method)	(cm^2/g)	1450	1380	1350	1320	1459	1410	1398	1330
SSA Increasing (Blaine method)		400	330	300	270	478	429	417	349

According to regrinding test results, before silica reduction, only at 6 per cent moisture, HPGR specific throughput was more than 250 ts/hm^3 and the working gap was obvious. In 7 per cent working gap was very low and this situation was not suitable for perfect operation. In 8 per cent and 9 per cent moisture, the material was completely sticky and the working gap was the same as zero gap. Therefore specific throughput was very low and HPGR did not work properly. After flotation tests, specific throughput in each moisture increased. Results showed that better working condition can be obtained by HPGR. Additionally, results revealed that in 8 per cent moisture after flotation tests and reduced SiO_2 content, HPGR working gap increased up to 10.5 mm and specific throughput increased from 180 ts/hm^3 to 250 ts/hm^3.

Comparison tests result

HPGR regrinding test result on concentrate samples showed that at moisture content between 7 to 9 per cent, HPGR have not significant working gap and specific throughput was very low. Moreover, chemical analysis of HPGR feed sample showed SiO_2 content of studied sample increased more than 380 per cent compared to the design value. SiO_2 content was concentrated on two fraction size, coarser than 150 microns metre and finer than 7 microns. Generally, silica impurities of iron concentrates are of two types: quartz-containing minerals in coarse fraction and silicate minerals such as pyroxene, clinopyroxene, amphibole and the like, in the fine fraction. Basically, fine silicate minerals have a higher water absorption capability. By increasing silicate minerals in the fine fraction, the layers of material could not be able to resist the required pressure for achieving suitable grinding conditions and the material was sticky and unsuitable for HPGR feeding.

Therefore silica reduction as an optimisation plan was performed on the studied sample, compared results are shown in Figure 1. As it can be seen, flotation tests have a suitable effect on silica reduction, Based on the results, in the coarse fraction SiO_2 content decreased from 6.02 to 2.55 per cent. In the fine fraction, especially for lower than 7 microns fraction size, as a critical fraction, SiO_2 content decreased from 4.45 per cent to 2.35 per cent.

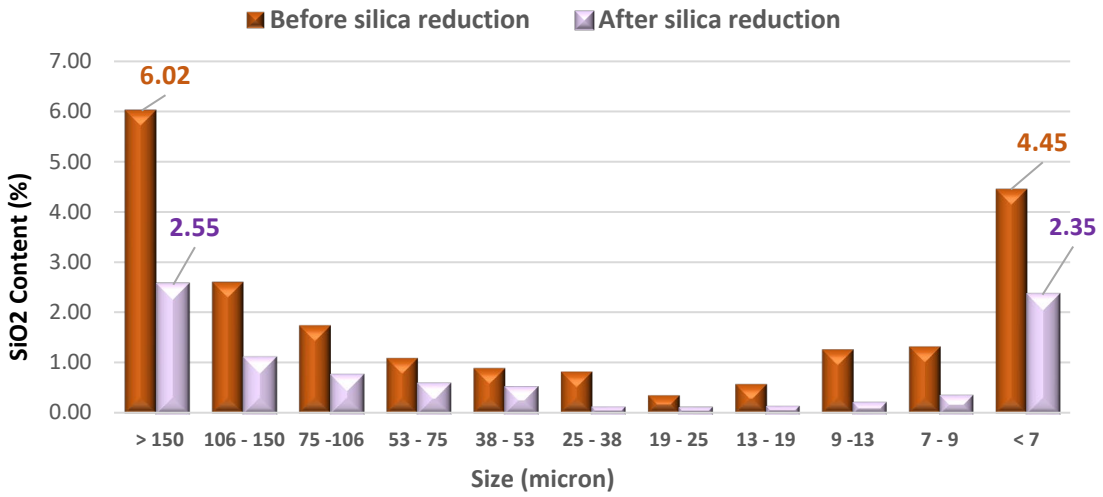

FIG 1 – SiO_2 content before and after flotation test.

Finally, after flotation tests, SiO_2 content of the studied sample reduced from 1.98 to 0.9 per cent and especially in the fine fraction dropped significantly from 4.45 per cent to 2.35 per cent. HPGR tests were performed on the studied samples before and after of flotation test, compared results show in Figure 2. According to results, after flotation test and reduction in SiO_2 content, HPGR working gap and specific throughput increased, as a results in same condition material bed ability to pressure resistance were increased. Results showed that before silica reduction, in 8 per cent moisture as a design value, HPGR working gap was very low and material could not go through the roller gap, therefore specific throughput was lower than 200 ts/hm^3. However, after silica reduction, HPGR working gap had significant changes and increased from around 7 mm to 10.5 mm. According to this changes after silica content reduction, specific throughput increased from 180 ts/hm^3 to 250 ts/hm^3, HPGR can be worked with this material and operating condition optimised.

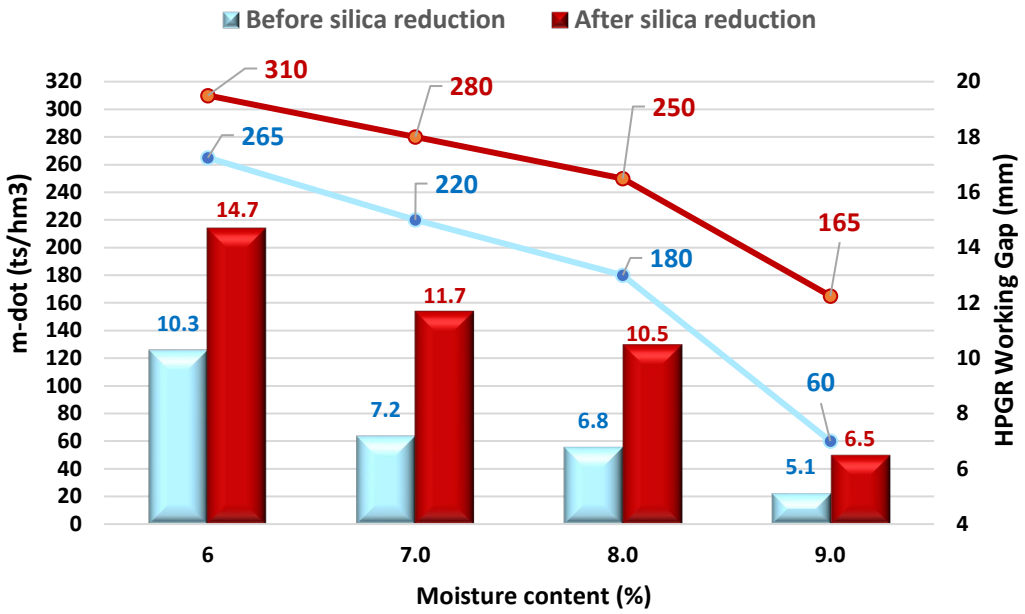

FIG 2 – Comparative results of HPGR tests.

CONCLUSIONS

HPGR grinding mechanism implied that, in the aim of suitable grinding conditions, the material should be able to resist required pressure to compress between two rolls. Also clay minerals content such as silicate minerals especially in the fine fraction, reduced material bed pressure resistance.

In this study, silica reduction effect on HPGR working conditions was investigated. Result showed that flotation tests had a suitable effect on silica reduction and with 90 per cent weight recovery, Fe grade in the concentrate increased from 67.8 per cent to 69.5 per cent and SiO_2 content reduced from 1.98 per cent to 0.9 per cent. Especially for lower than 7 microns fraction size, as a critical fraction, SiO_2 content decreased from 4.45 per cent to 2.35 per cent.

Compared results of HPGR test showed that due to silica reduction, material bed ability to resist the required pressure was increased and HPGR operation condition was optimised. As a result, in 8 per cent moisture the working gap increased from 7 to 10.5 mm and specific throughput of material raised from 180 ts/hm^3 to 250 ts/hm^3, and SSA increased 300 cm^2/gr in a single pass.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the financial and technical support of Fakoor Sanat Tehran Company (FSTCO), as well as the research and development department and Mineral Processing and Metallurgy Research Center (FSTRC) for the technical and operational assistances.

ABSTRACT

Copper porphyries represent complex alteration zones, hosting variable grades of Cu- (Au-Mo), but also Pb, Zn, Te, Bi and Ag. Moreover, environmental harmful elements, such as As or Cd are present. It is therefore crucial that mining companies get reliable chemical and mineralogical drill core data from the earliest exploration state on to avoid project failure and to obtain three-dimensional models for mine and processing planning. Systematic sensor-based drill core logging and material sorting coupled with smart data evaluation is the ideal solution for accurate in-field and in-plant real time decision-making to reduce waste and anticipate dysfunction during metal production. Risks and operational costs can be reduced while increasing resource efficiency.

In this paper, as an example, specific alteration zones of the Niaz porphyry copper (Mo)-deposit in north-western Iran were investigated by laser-induced breakdown spectroscopy (LIBS), X-ray Fluorescence (XRF), time-gated Raman spectroscopy, dual energy X-ray transmission (DE-XRT), multi energy X-ray transmission (ME-XRT) and X-ray computed tomography (CT). Most of these instruments were combined in the European Institute of Innovation and Technology (EIT) RawMaterials project ANCORELOG. The sensor results were compared and evaluated against laboratory results obtained by scanning electron microscopy (SEM) coupled with energy dispersive spectroscopy (EDS), and optical microscopy for calibration.

Fast LIBS, Raman and XRF core-scanner instruments clearly allow to distinguish the alteration zones: The potassic-phyllic alteration zone is characterised by two differently mineralised rock types: (i) the Cu-mineralised quartz diorite where the key minerals are chlorite and barite, quartz, albite/oligoclase, muscovite and the major ore mineral is chalcopyrite; (ii) the Cu-Mo-mineralised monzonite, where carbonates, orthoclase and albite/oligoclase are the key minerals. Ore minerals are molybdenite and chalcopyrite. The propylitic alteration zone is characterised by a coarse-grained diorite. Key minerals are orthoclase, epidote, sphene and apatite. Molybdenite is the major ore mineral. The phyllic-argillic mineralised zone is represented by a microgranular quartz-diorite. Key minerals are kaolinite-dickite, quartz, albite, muscovite-sericite and apatite. The major ore mineral is chalcopyrite. The peripheral part of the porphyry is a coarse-grained skarn with andradite, calcite, tremolite and epidote as key minerals. The major ore mineral is chalcopyrite. LIBS elemental mapping clearly reflects the ore mineralogy and texture. Analysis of reconstructed three-dimensional CT volume data revealed structural information as well as two to three different groups of grey values. After calibration, eg by SEM or LIBS, mine-geologists can assign these grey values to minerals or elements with low (eg Al, Si), medium (eg Fe, Cu), and high (eg Mo) effective atomic numbers. Our study shows that sensor-based characterisation of successive alteration zones and Cu-Mo mineralised zones is possible for unknown samples. XRF, Raman spectroscopy, LIBS and XRT can be used and adapted in-field on mine and exploration sites as well as in plants. Selected samples of drill cores can then be sent for CT analysis and detailed LIBS imaging.

INTRODUCTION

Porphyry systems (Cu, Mo, Au) are intensively drilled to be efficiently explored, modelled, and mined. Orebody modelling, exploration and mine planning must rely on a solid and reliable data basis, which can be achieved by systematic chemical and/or mineralogical logging using analytical sensors. These data can then feed three-dimensional (3D) geological modelling and/or design appropriate beneficiation. The EIT RawMaterials projects ANCORELOG and T-REX (EIT RawMaterials, 2022a, 2022b, both until 2021) provide the basis to bring a modular drill core scanner to the market. X-ray fluorescence (XRF), Raman spectroscopy and laser-induced breakdown spectroscopy (LIBS) were upscaled and adapted for use in exploration and mining. These methods were combined with dual energy (DE) and multi energy (ME) X-ray transmission (XRT) as well as X-ray computed tomography (CT). However, the optimal use of these instruments requires the definition of smart mineralogical and chemical parameters to reach real time accurate decision-making for optimal exploration campaigns, mine planning and processing methodology.

Porphyry deposits together with iron-oxide-copper-gold (IOCG) deposits account for more than 60 per cent of the global primary copper production. Moreover, globally, 100 per cent of the molybdenum production, 10 per cent to 15 per cent of uranium, and an important part of gold production are provided by these ore deposit types. Giant porphyry systems are Grasberg (Indonesia), La Escondida (Chile), Rio Blanco (Peru), Continental (Arizona, USA), Butte (Montana, USA), El Teniente (Chile) ending up with the supergiant Chuquicamata (Chile) deposit. Copper grades range from 0.3 per cent to about 2 per cent. These grades are low to moderate; therefore, the size makes it profitable (Ayuso *et al*, 2010 and references therein). All these deposits are drilled at several ten thousand of drill core metres per annum. They are mainly manually logged and stored.

The definition of mineralogical and chemical logging parameters considers major and minor ore minerals, typical associated silicates and metals, environmental harmful metals to avoid soil, atmosphere, and hydrosphere contamination, but also contaminating metals for the commercial products (eg Cd, Pb, As, Hg, U and Th; Tabelin *et al*, 2021). The main characteristics of Cu porphyry deposits are disseminated Cu bearing minerals in the rocks, Cu minerals in veins and fractured rocks distributed in large rock volumes. They form high tonnage (>100 Mt) of low to moderate grade ores. The host rocks are composed of granitoids, and adjacent rocks are altered at various degrees (Ayuso *et al*, 2010; Chang *et al*, 2011; Seedorff *et al*, 2005).

Cu porphyry systems can be closely related to skarns (Ayuso *et al,* 2010; Taghipour *et al,* 2013 and references therein). A famous example is the Grasberg deposit in Indonesia (Sillitoe, 2010 and references therein). These types of deposits are usually high-grade, but relatively small and patchy. They can contain red garnets, green pyroxenes, and amphiboles. Cu (and Mo) grades can be locally

very high and heterogeneously distributed. This heterogeneous ore-distribution makes skarn-related Cu porphyries challenging for mining and processing.

For processing, these rocks are very hard and thus have high milling costs (Michaud, 2014). Efficient and early separation of barren from economic valuable materials needs planning and testing at the exploration stage to ensure a constant Cu production over time while reducing waste production at each stage of processing. Leaving the barren material in the ground will also reduce hazardous waste, as Cu-Mo-Au ores may host harmful metals (Pb, Hg, As and U; Tabelin *et al,* 2021, and references therein). High density drilling combined with systematic data acquisition as well as material sorting in valuables, hazardous and non-hazardous barren fractions from the exploration stage on will reduce processing costs mainly driven by energy and water consumption.

The samples studied here belong to the skarn type porphyry deposits, coming from the Niaz porphyry in north-west Iran (Hassanpour *et al*, 2015; Omrani *et al*, 2008). This deposit is a Cu and Mo porphyry. The samples cover the major alteration zones (potassic-phyllic, propylitic, phyllic-argillic and the peripheral skarn, Figure 1). These alteration zones, corresponding to spatial and temporal hydrothermal and supergene events, are used to vector the Cu-Mo mineralisation during exploration drilling.

FIG 1 – Cu-Mo porphyry deposits scheme. Left: The sample locations on the alteration zones and the major vectoring minerals; Right: Alteration zones showing the major mineralisations from high-grade Cu and Mo to low-grade Pb, Zn, Au and Ag ores (modified from Lowell and Guilbert, 1970).

The five samples, which are characteristic for porphyry alteration zones, have previously been examined with scanning electron microscopy (SEM, at ISTeP, Sorbonne Université, Paris, France), DE-XRT, ME-XRT and CT (at Fraunhofer IIS, Fürth, Germany) to quantify the fractions of elements with low and high atomic numbers, which are correlated roughly to waste and valuables (Bauer *et al*, 2021b). This work's objective is to demonstrate the potential of these methods in combination with XRF and Raman spectroscopy of the ANCORELOG core scanner (DMT, Essen, Germany) and LIBS (BGR, Hannover, Germany). The combination allows to correlate regions of low and high atomic number elements to minerals. A calibration of XRT data with the other methods enables the in-field definition of alteration zones as well as Cu-Mo-Zn-Pb mineralisations and strengthens the data set from other sensors, so that real time sorting of waste from ore can be achieved.

ANALYTICAL METHODS

ANCORELOG – Raman spectroscopy and X-ray fluorescence

ANCORELOG (Analytical Core Logger) is a multi-sensor scanner which can be applied to drill cores and/or loose materials (crushed, milled etc). It can be modularly equipped with several analytical sensors. It allows data acquisition through spatial sensor co-registration. All data from the different

sensors are combined into a dedicated database. Machine learning algorithms applied on the multi-sensor data enable a classification of rock-types and/or material into site-specific geological domains, waste, and valuable material.

The ANCORELOG's semi-automated scan process is presently designed to scan drill core samples with a high scan rate of up to 14 mm/s depending on the chosen sensor combination and the required accuracy and resolution. The sensor combination of ANCORELOG used in this study consists of an XRF and a Raman sensor.

XRF spectroscopy is a non-destructive analytical method that measures characteristic X-ray emission spectra from a sample while being excited by a primary X-ray source. The emitted spectra are composed of intensity peaks in certain energy lines that are characteristic for the elemental composition of the measured sample. Handheld XRF devices are widely used in the exploration and mining industry for predicting the elemental composition of rock samples. ANCORELOG's XRF sensor is a special adaptation of J&C Bachmann's TEXAS device designed for both, single point measurements and continuous profile measurements along a defined scan path. The XRF measurements were performed in the profile scan mode, moving the sensor over the sample surface at a speed of 1 mm/s. This results in a continuous measurement profile of 5 mm width over the complete sample length as indicated by the red frame in Figure 2. The emission signal was integrated over the complete profile to a single measurement for each sample. The results are obtained as counts normalised to 120 s integration time for each element peak area after background signal subtraction and thus indicating a qualitative estimation of elemental concentrations. A conversion into quantitative elemental concentrations would require a site-specific sensor calibration against representative samples.

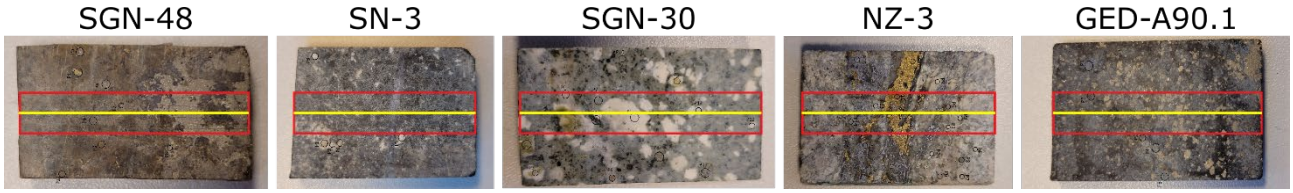

FIG 2 – Block samples analysed in this study. From left to right: SGN 48 (peripheral skarn); SN 3 (phyllic-argillic alteration zone); SGN 30 (propylitic alteration zone), NZ 3 and GED-A90.1 (potassic-phyllic alteration zone). Red frames indicate the measurement area of the XRF sensor. Yellow lines indicate the measurement profile of the time-gated Raman sensor. Sample height is approximately 2.5 cm.

Raman spectroscopy is a spectroscopic analytical method that detects energy shifts of photons emitted from a monochromatic excitation source, in this case a 532 nm pulsed picosecond range laser, caused by an interaction with primarily molecular vibrations in the measured sample. By detecting the characteristic energy shifts of molecules, typical Raman shift fingerprints allow the determination of the mineralogical sample composition.

The Raman technology used in ANCORELOG is a time-gated Raman sensor (T-REX, Timegated Raman for Exploration, special adaptation of Timegate Instruments' PicoRaman device). The time-gated Raman measurements were conducted in a combination of profile and single point scan mode. In the continuous profile scan mode, the Raman sensor moved over the sample at a speed of 5 mm/s resulting in a 160 µm wide profile line at the centre of each sample as indicated by the yellow line in Figure 2. The measurement has been integrated over the complete profile length resulting in one mixed Raman spectrum per sample profile. Additionally, several randomly selected single points have been measured on each sample. Characteristic peaks in the measured spectra have been automatically compared to reference spectra of given target minerals from the RRUFF™ database (Lafuente *et al*, 2015). Due to the different Raman signal intensities the detectability of target minerals with low signal intensities such as pyrite or chalcopyrite by the time-gated Raman sensor is limited when analysing a mixed spectrum. The technical specifications of both sensors are summarised in Table 1.

TABLE 1

Technical specifications of the XRF and time-gated Raman sensors used in this study.

XRF sensor specification		Timegated Raman sensor specifications	
X-ray source	RTW MCB 65C-0,2 Mo, run at 30kV and 300 µA	Laser Excitation Wavelength	532 nm
		Laser Repetition Rate	250 kHz
X-ray detector	Amptek DP5-X 25 mm^2 SDD, 8192 energy channels	Laser Power	230 mW max.
		Gating Adjustment Resolution	10 ps

Laser induced breakdown spectroscopy

LIBS is a multi-elemental technology for application in core scanner and industrial instrumentation to investigate compositional variations in rocks and sediments (eg Kuhn *et al*, 2016; Rifai *et al*, 2020). The technology is based on atomic emission spectroscopy, in which the excitation of the atomic species occurs *in situ* on the sample surface using a highly energetic pulsed laser. Excellent reviews are presented by eg Hahn and Omenetto (2012) and Harmon and Senesi (2021). In this study, imaging LIBS was applied, which yields detailed information on the spatial distribution of the different target elements on the sample surface, reflecting spatial variation in mineral chemistry.

The GeoLIBScanner (LTB, 2021) was used in this study, which is a device for fast, high resolution (both spectral and spatial) LIBS-scanning of drill cores in one or two dimensions (1D or 2D). It has the capability to be loaded with core boxes, without the need to manipulate the actual drill cores within. Prior to the actual LIBS scanning, an overview image is taken, and a morphological scan of the sample's topography is performed. This allows for the precise on-the-fly focal adjustment during the LIBS-scan. Both hyperspectral LIBS images and fast depth profile scans with configurable numbers of repetitions are the scope of the instrument. The system is equipped with a Nd:YAG laser at 1064 nm, emitting 25 mJ at 100 Hz (M NANO, Montfort Laser GmbH, Austria) and a high-resolution echelle spectrometer with a spectral range of 200 nm to 1000 nm and a resolving power above 4000 (Aryelle-150, LTB Lasertechnik Berlin GmbH, Germany) especially chosen for general purpose scanning of unknown geological material. The detector is an Evolve 512 Delta EMCCD camera (Photometrics, USA) capable of taking up to 67 full frames per second. Spectra can be either stored to disc or analysed on the fly. The results are then visualised and mapped on top of the photographic image of the core box.

Imaging LIBS measurements on the complete sample surfaces were performed using single-pulse measurements, a laser spot size of about 50 µm, a step size of 50 µm, and air suction to keep dust particles away from the spot area. The intensity of several characteristic emission lines for rock-forming elements as well as for sulfide-forming elements was calculated using an integration window of 0.1 nm (ultraviolet-visible region) or 0.2 nm (infrared region). The software ENVI version 5.3 (by Exelis Inc) was applied for visualisation of intensity distribution images. Normalisation with respect to the total intensity was applied for the emission lines of Si to highlight quartz minerals which generally have very weak emission properties. The results presented here are qualitative. A conversion into elemental concentrations would require a site-specific sensor calibration against representative samples.

X-ray transmission

While XRF detects fluorescence from elements close to the sample surface, XRT measures the intensity of X-rays transmitted through a sample. The detected signal is determined by the X-ray attenuation that the radiation experienced along the beam path. The resulting radiograph is therefore a projection of the X-ray attenuation of the sample into 2D space.

One drawback of XRT is that a high *Z* material with low density can lead to the same grey value in an X-ray projection as a low *Z* material with high density, ie no material information is gained by XRT. This disadvantage can be eliminated by making use of the energy dependence of the X-ray attenuation. By combining radiographs recorded with different X-ray spectra, information on the

chemical sample composition can be obtained. Both DE-XRT and ME-XRT were applied in this study as described below.

Dual energy X-ray transmission

The DE-XRT set-up consists of an X-ray source (Comet MXR-225HP/11) and a line detector with 0.8 mm pixel pitch (DT X-Scan 0.8iL-410 DE-USB-C2). This detector is a sandwich detector made of two layers. The first layer records mainly the low energy (LE) photons transmitted through the sample. Thereby it acts as a prefilter for the second detector layer that mainly records the high energy (HE) photons. The difference between both layers is enhanced by an additional filter of 0.6 mm Cu between both layers. An X-ray tube voltage and current of 220 kV and 2.2 mA and a 0.5 mm Cu prefilter were used for the measurements. A linear manipulation system moved the samples between source and detector at 340 mm/s while X-ray projections were recorded with 2.67 ms per line.

The two spectrally different projections were analysed by basis material decomposition (BMD) (Firsching *et al*, 2011). When applied to two known pure materials, this method reveals their respective areal densities (mass per area). For complex materials it yields the areal densities of two groups of elements with (effective) atomic number close to the chosen basis materials (here: Cu with $Z = 29$ und quartz glass with $Z_{eff} = 11.65$, Wagner *et al*, 2022; Bauer *et al*, 2021a, 2021b). In combination with methods like XRF or LIBS, these groups can be correlated with chemical elements or minerals.

Multi energy X-ray transmission

The ME-XRT set-up uses the same source as the facility for DE-XRT. The main difference between both machines is the line detector. The MultiX ME100 multi energy detector with 0.8 mm pixel pitch collects X-ray photons between 20 keV and 160 keV in 128 energy channels. The measurements were performed with 160 kV tube voltage, 0.5 mA tube current and 1 mm Ti as prefilter. Samples were moved between source and detector with 40 mm/s and the exposure time was 20 ms per line.

The data were analysed with a method published in (Alvarez, 2011, 2016). It requires calibration measurements with the materials of interest in different thicknesses. Here, quartz glass, Cu and W were used for calibration. Like DE-XRT analysis, the result gives the areal density of groups of elements with similar effective atomic number. Here, these are low-Z ($Z \approx 12$), medium-Z ($Z \approx 29$) and high-Z elements ($Z \approx 74$), which can be further assigned to single elements or minerals in combination with other methods. The analysis requires combining the 128 energy channels into three energy bins. These three bins were chosen to contain channels 1 to 44, 45 to 80 and 81 to 128, respectively. The first bin boundary corresponds approximately to the K-absorption edge of W. Along the direction of sample movement a 3 × 1 median filter was applied to the detected X-ray attenuation in all energy bins.

The flexibility of the energy binning, which can be adapted to the application, and the possibility to distinguish more than two materials if an absorption edge is present in the detected energy range are the advantages of ME X-ray detectors, which are currently not as well established as DE detectors.

Computed tomography

While XRT scans result in one projection of the sample's X-ray attenuation into 2D space, CT requires several projections from different directions. These radiographs can be reconstructed into a 3D volume data set. This volume can be sliced virtually into arbitrary directions to gain insight into the internal sample structure. The grey value in the volume is correlated with the X-ray attenuation, leading to a brighter colour of areas that consist of high-Z materials and/or have high density.

The CT set-up is equipped with an Yxlon FXE-225.99(48) microfocus X-ray source. A PerkinElmer XRD 1621 flat panel detector with CsI scintillator and 200 µm effective pixel pitch was used. Measurements were performed with 220 kV tube voltage and a current of 140 µA. A helical scanning trajectory was chosen (Kalender *et al*, 1990), where the sample rotated between source and detector and at the same time moved parallel to its rotational axis. The prefilter, exposure time and number of projections were adapted to the sample attenuation: 2.5 mm Cu, 1000 ms and 1600 projections

per 360° rotation were used for NZ-3, 1 mm Cu, 555 ms and 1200 projections per 360° rotation were applied for the other four samples. The voxels of the reconstructed volume have an edge length of 36 µm. To obtain the fraction of materials with similar grey values, which correspond to materials with similar Z_{eff} and attenuation, blob analysis was used. For details of this method, see Bauer *et al* (2021a, 2021b).

SAMPLE DESCRIPTION

The Niaz porphyry Cu-Mo deposit is located in the Arasbaran metallogenic belt of north-western Iran. It presents the northern part of the 2000 km north-west–south-east trending Cu-porphyry belt system which is about 50 km wide (Omrani *et al*, 2008, and references therein). It is low-grade Cu-Mo-porphyry with grades varying from 0.1 wt. per cent to 0.4 wt. per cent of Cu, and 50 ppm to 200 ppm of Mo (Hassanpour *et al*, 2015). More details about the samples are described in Bauer *et al* (2021b).

The major Niaz porphyry rock types are microdiorite, monzonite and granodiorite. They show porphyritic to microcrystalline porphyry textures. The rocks are cut by several generations of quartz-sulfide, quartz-oxide, and sulfide veinlets of different sizes. It represents a typical stockwork texture.

Five samples representative of four temporally and spatially distinguishable alteration zones were studied (Figure 2): (1) peripheral skarn (SGN-48), (2) phyllic-argillic (SN-3), (3) propylitic alteration (SGN-30) and (4) potassic-phyllic (NZ-3, GED-A90.1).

RESULTS

Mineralogy

Optical microscopy and scanning electron microscopy

All samples were studied by transmitted and reflected light microscopy, and SEM (ZEISS Supra 55 VP in Backscattered Electron (BSE) mode coupled to Energy Dispersive Spectroscopy (EDS)) at ISTeP (Sorbonne Université, Paris, France). The methodology and results were described in Bauer *et al* (2021b). These results are the base for reliable interpretation of the subsequent results from Raman spectroscopy, XRF (core scanner), LIBS, ME-XRT, DE-XRT, and CT measurements. The mineralogy of each sample is reported in Table 2 in comparison to the mineralogy found by the time-gated Raman spectrometer.

The petrology and detailed mineralogy of the studied samples was already presented in Bauer *et al*, 2021b. Here, relevant data which are necessary for sensor calibration and mineralogical interpretation are presented.

The peripheral part of the porphyry is represented by sample SGN-48. The sample is greenish and coarse-grained, cross-cut by a centimetre-thick white vein. It is a skarn composed of garnet (andradite) and tremolite, actinolite, chlorite, epidote, calcite, phosphates, and ilmenite. Ore minerals are pyrite, chalcopyrite, magnetite, sphalerite (ZnS) and galena (PbS), as inclusions in pyrite and chalcopyrite, and Ag-sulfides and TeBi, forming clusters. Scheelite ($CaWO_4$) is also observed.

The phyllic-argillic mineralised zone in quartz diorite is represented by sample SN-3. It is light grey, fine-grained, and cross-cut by a white vein. This sample is composed of 35 per cent albite, 30 per cent orthoclase, 15 per cent biotite and hornblende, sericite, clay minerals, and minor apatite, magnetite, and rutile. The ore minerals Cu-sulfides, barite, monazite (rare earth elements phosphate), thorite $(Th,U)SiO_4$ and galena (PbS) occur in the rock matrix. The vein hosts quartz and carbonate $(Ca,Fe,Mg)CO_3$.

The propylitic alteration zone in diorite is represented by sample SGN-30. It is light-grey, whitish coarse-grained rock. The mineralogy is orthoclase, amphiboles and epidote, minor calcite, apatite (Ca-phosphate), zircon ($ZrSiO_4$), sphene ($CaTiSiO_5$), and ilmenite ($FeTiO_3$). The mineralisation comprises disseminated pyrite with molybdenite MoS_2, PbS and TeBi inclusions. Rare sphalerite (ZnS) is observed.

TABLE 2

Mineralogy of the studied samples using optical microscopy (M), SEM combined with EDS (S) (data from Bauer *et al*, 2021b), and time-gated Raman spectroscopy (R). Target minerals which can be assessed by time-gated Raman are marked in grey.

Two samples represent the potassic-phyllic alteration zone in the inner part of the porphyry system: (i) the Cu-Mo-mineralised in monzonite is represented by sample NZ-3. The sample is light grey to green. It hosts albite, orthoclase, muscovite, sericite, quartz, chlorite, biotite and hornblende. Carbonates (calcite ($CaCO_3$) and ankerite (Ca, Mg, Fe)CO_3) and barite ($BaSO_4$) also occur. The ore minerals occur in veinlets. They are Cu-sulfides (major $CuFeS_2$), pyrite (FeS_2), molybdenite (MoS_2) (millimetric size). Molybdenite is cross-cut by micrometric veins, which are filled with galena (PbS), Cu-Bi and Cu-sulfides hosting Cd, Sb and As.

(ii) the Cu-mineralised quartz diorite, represented by sample GED-A90.1. This sample is dark grey, finer grained than sample NZ-3 with large white minerals. It is composed of about 40 per cent plagioclase (albite), 25 per cent biotite, minor muscovite and 25 per cent quartz as veinlets. Ore minerals comprise 10 per cent of pyrite, Cu-sulfides, and magnetite. Chalcopyrite is also associated with barite ($BaSO_4$). Pyrite hosts chalcopyrite, pyrrhotite (FeS) and galena (PbS). Furthermore, ilmenite (Fe,Mn)TiO_3 is present.

Figure 3 represents SEM-BSE mosaic images of the whole sample surface showing the repartition of the ore and matrix minerals in SGN-30 and SGN-48. Figure 4 shows SEM-BSE pictures of matrix and ore mineral associations at higher resolution (A: NZ-3, B: GED-A90.1).

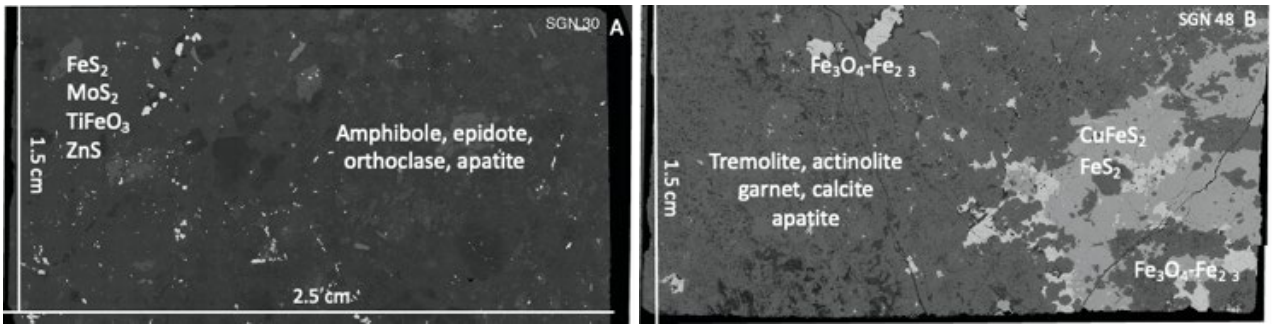

FIG 3 – SEM-Mosaic images showing the ore mineral and silicate-carbonate distribution at the entire sample surface scale (A: SGN-30; B: SGN-48).

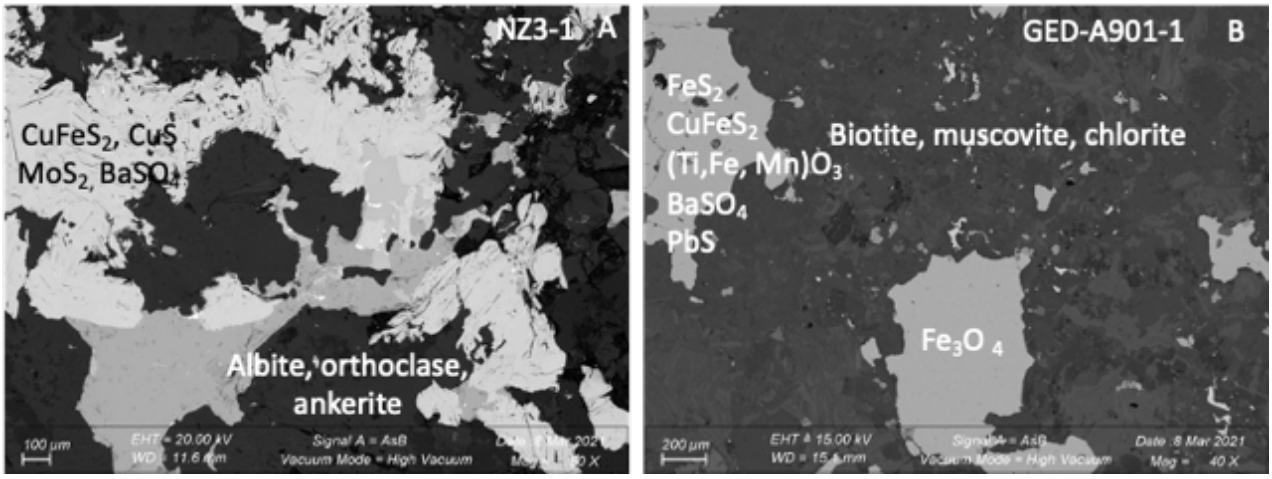

FIG 4 – SEM micrographs. A: NZ-3, Matrix silicates and carbonates and ore minerals (chalcopyrite, CuS and molybdenite), B: GED-A90.1, Matrix silicates and ore mineral association (modified from Bauer *et al*, 2021b).

Table 2 shows (i) the minerals which can be used as exploration tools, such as orthoclase, amphiboles, micas, clay-minerals, carbonates, sulfates, garnets, epidote and sphene, and (ii) the ore minerals, in this case Cu-sulfides and molybdenite.

Time-gated Raman

The spectra obtained from profile and single point time-gated Raman measurements were analysed with the aim of extracting characteristic intensity peaks of the minerals identified by means of optical

microscopy and SEM combined with EDS. The mixed spectra from the profile measurements contain the signature of several minerals as exemplarily shown in Figure 5.

FIG 5 – Feature extraction from mixed Raman spectra: The blue line shows the mixed spectrum from a profile measurement. The green line shows a reference spectrum of a mineral found in the mixed spectrum. The red line shows a reference spectrum of a mineral that is not identifiable in the mixed spectrum.

The occurrence of minerals with high Raman signal intensities may obstruct the signatures of minerals with lower Raman intensities and therefore a software tool dedicated to extract mineralogical signatures from mixed Raman spectra by comparison with mineralogical reference spectra was used in this study. The software was developed within the ANCORELOG project. Spectra from the RRUFF™ database (Lafuente *et al*, 2015) were used as a reference. Single point measurements can also lead to mixed spectra depending on grain sizes of the samples taking into consideration a measurement spot size of 160 µm.

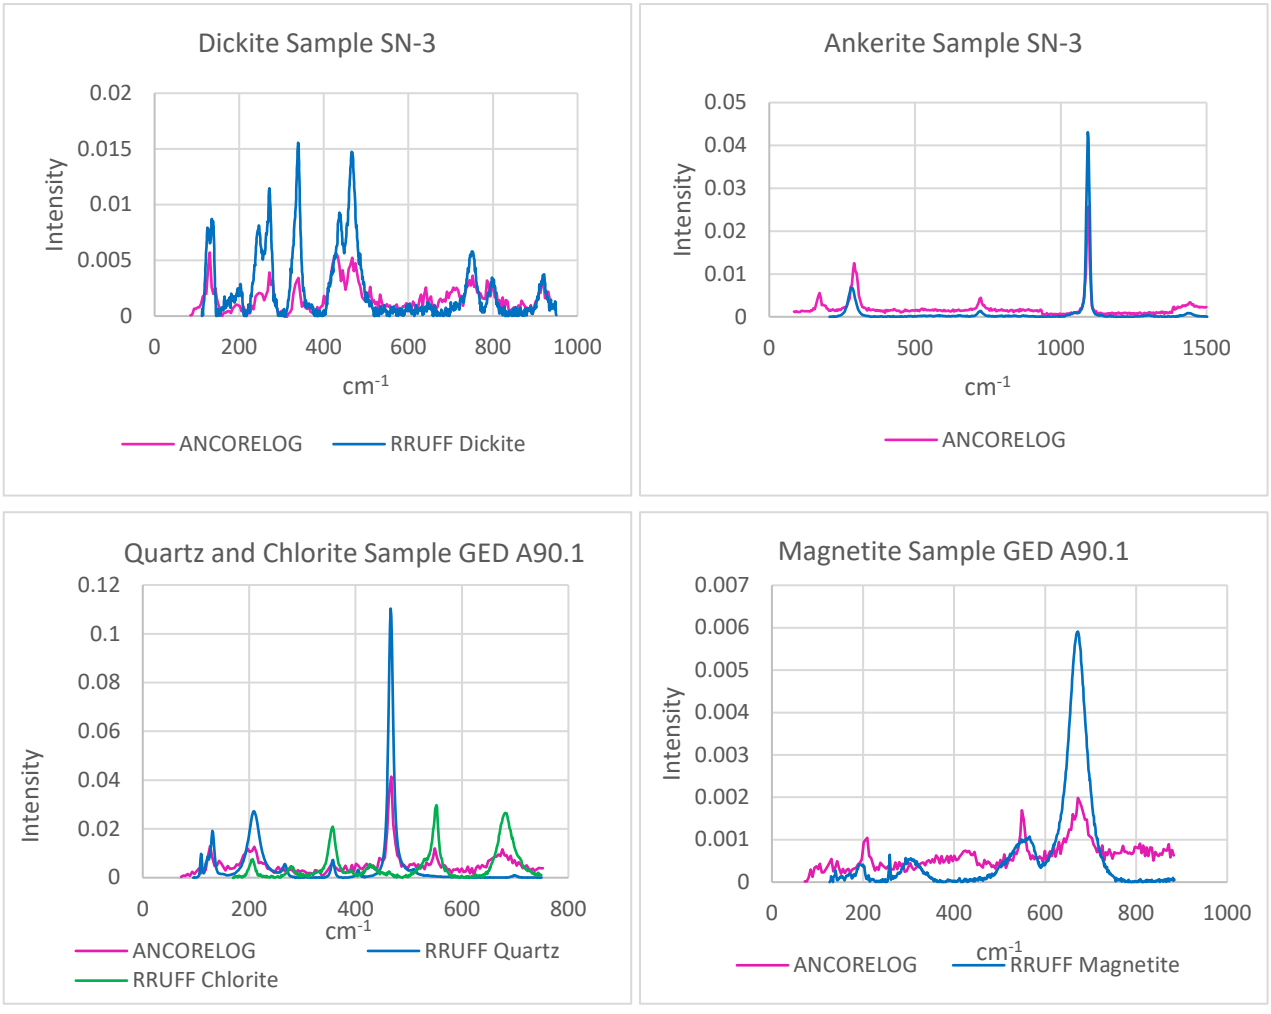
The minerals identified by the time-gated Raman sensor are listed in Tables 2 and 3.

TABLE 3

Minerals and their characteristic Raman peaks observed in the measurement spectra.

Mineral	Raman Peaks [cm^{-1}]	Sample
Quartz	~466, ~355, ~207, ~128	SN-3, NZ-3, GED-A90.1
Orthoclase	~512, ~285, ~157	SN-3, SGN-30, NZ-3
Albite	~508, ~479, ~291	SN-3, NZ-3 and GED-A90.1
Chlorite	~683, ~552, ~357	SGN-48, NZ-3, GED-A90.1
Andradite	~874, ~843, ~816, ~516, ~493, ~371, ~352, ~174	SGN-48
Sphene	~910, ~857, ~615, ~545, ~468	SGN-30
Epidote	~1087, ~983, ~917, ~604, ~572, ~514, ~455, ~350	SGN-48, SGN-30
Dickite	~915, ~749, ~460, ~434, ~336, ~270, ~247, ~131	SN-3
Calcite	~1085	SGN-48, NZ-3
Ankerite	~1092	SN-3
Molybdenite	~408, ~382	NZ-3
Magnetite	~670, ~560	GED-A90.1

Figure 6 shows an extract of detected mineral signatures with their respective reference spectra from the RRUFF™ database.



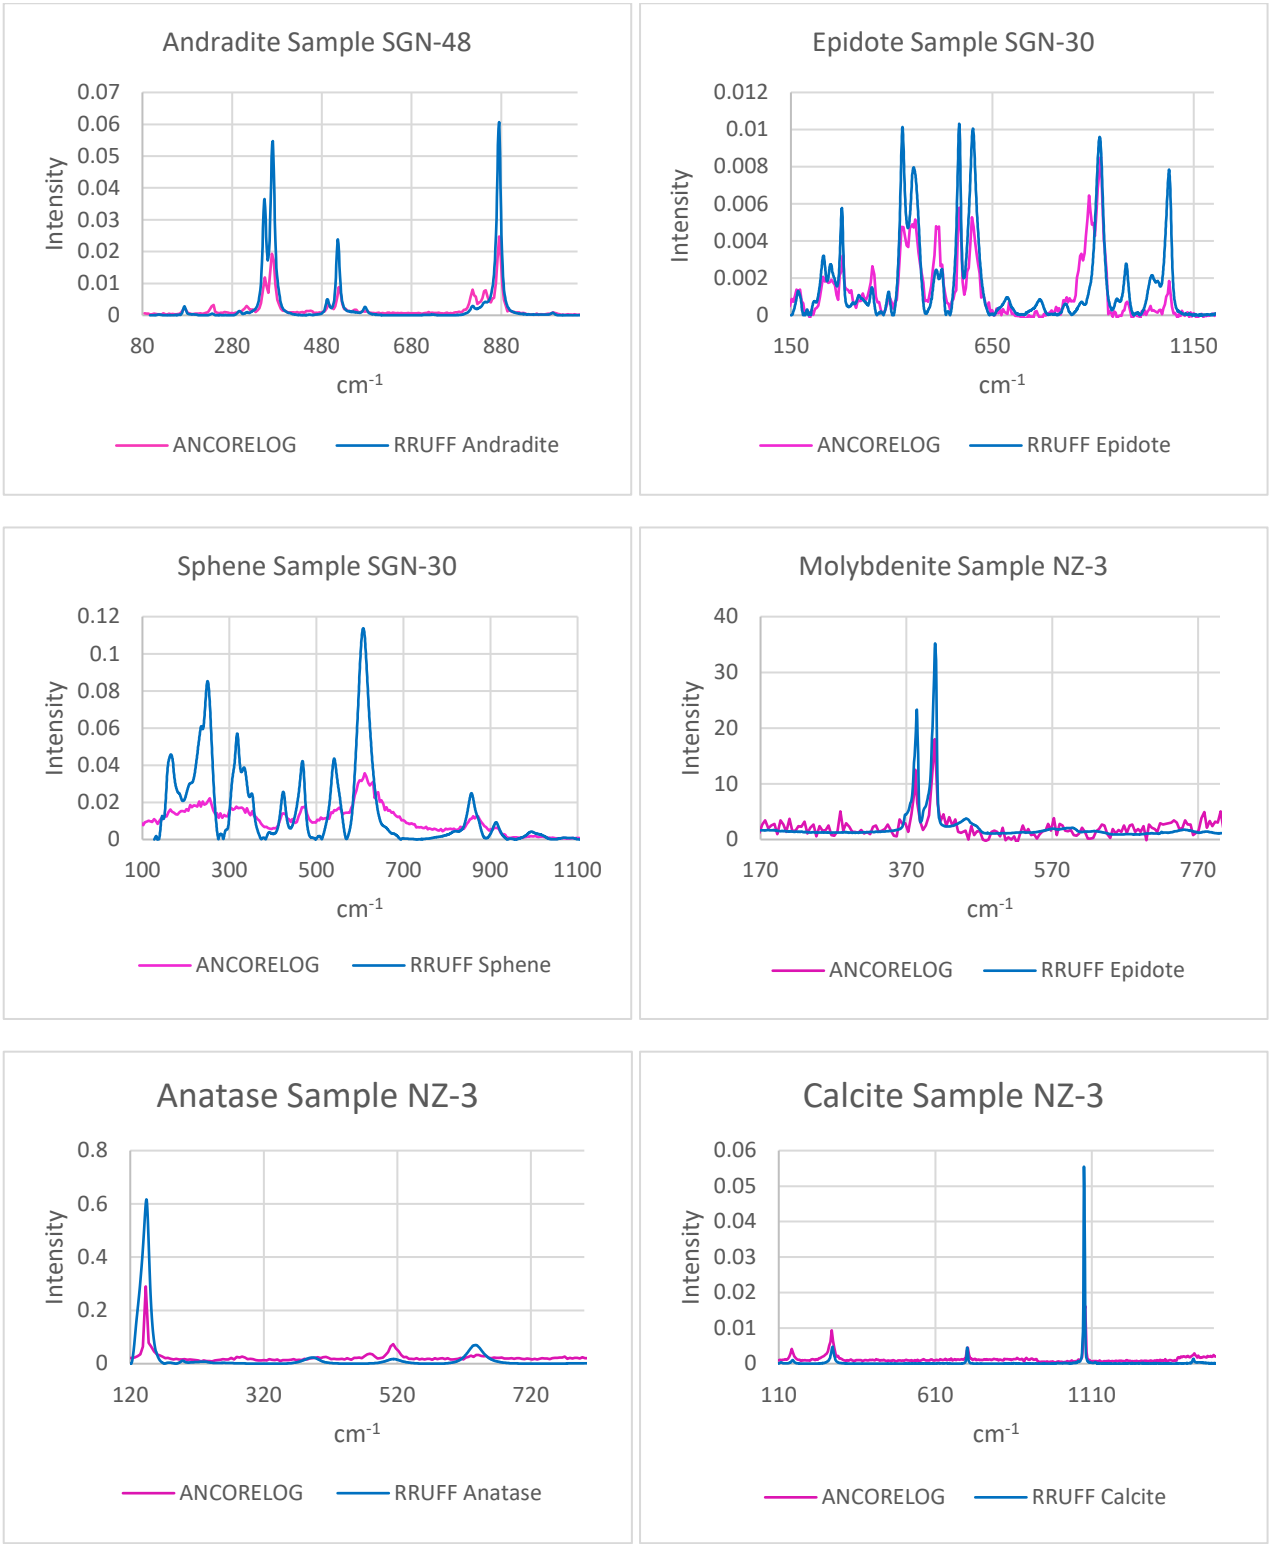


FIG 6 – Extracted mineral signatures from ANCORELOG's time-gated Raman measurements matched with reference spectra from the RRUFF database.

Geochemistry

Laser induced breakdown spectroscopy

Figure 7 shows LIBS-based intensity distribution images (heat maps) of characteristic emission lines for major rock-forming and sulfide-forming elements. The upper graphs represent the distribution of the major rock-forming elements Si, Al, Na, K, Ca, and Mg. The bottom graphs represent the distribution of the sulfide-forming elements Fe, S, Cu, Mo, and Zn. The data reflect the extreme heterogeneity of the sample sections. Please note that the relationship between LIBS intensity and

element concentration is often not linear because of matrix effects (eg Hahn and Omenetto, 2012). An advantage of LIBS compared to XRF is that light elements (Na, Mg, Al: Figure 7) can be measured as well. Furthermore, following appropriate calibration routines, LIBS can also be used for quantitative analysis (eg Kuhn *et al*, 2016; Rifai *et al*, 2020; Harmon and Senesi, 2021).

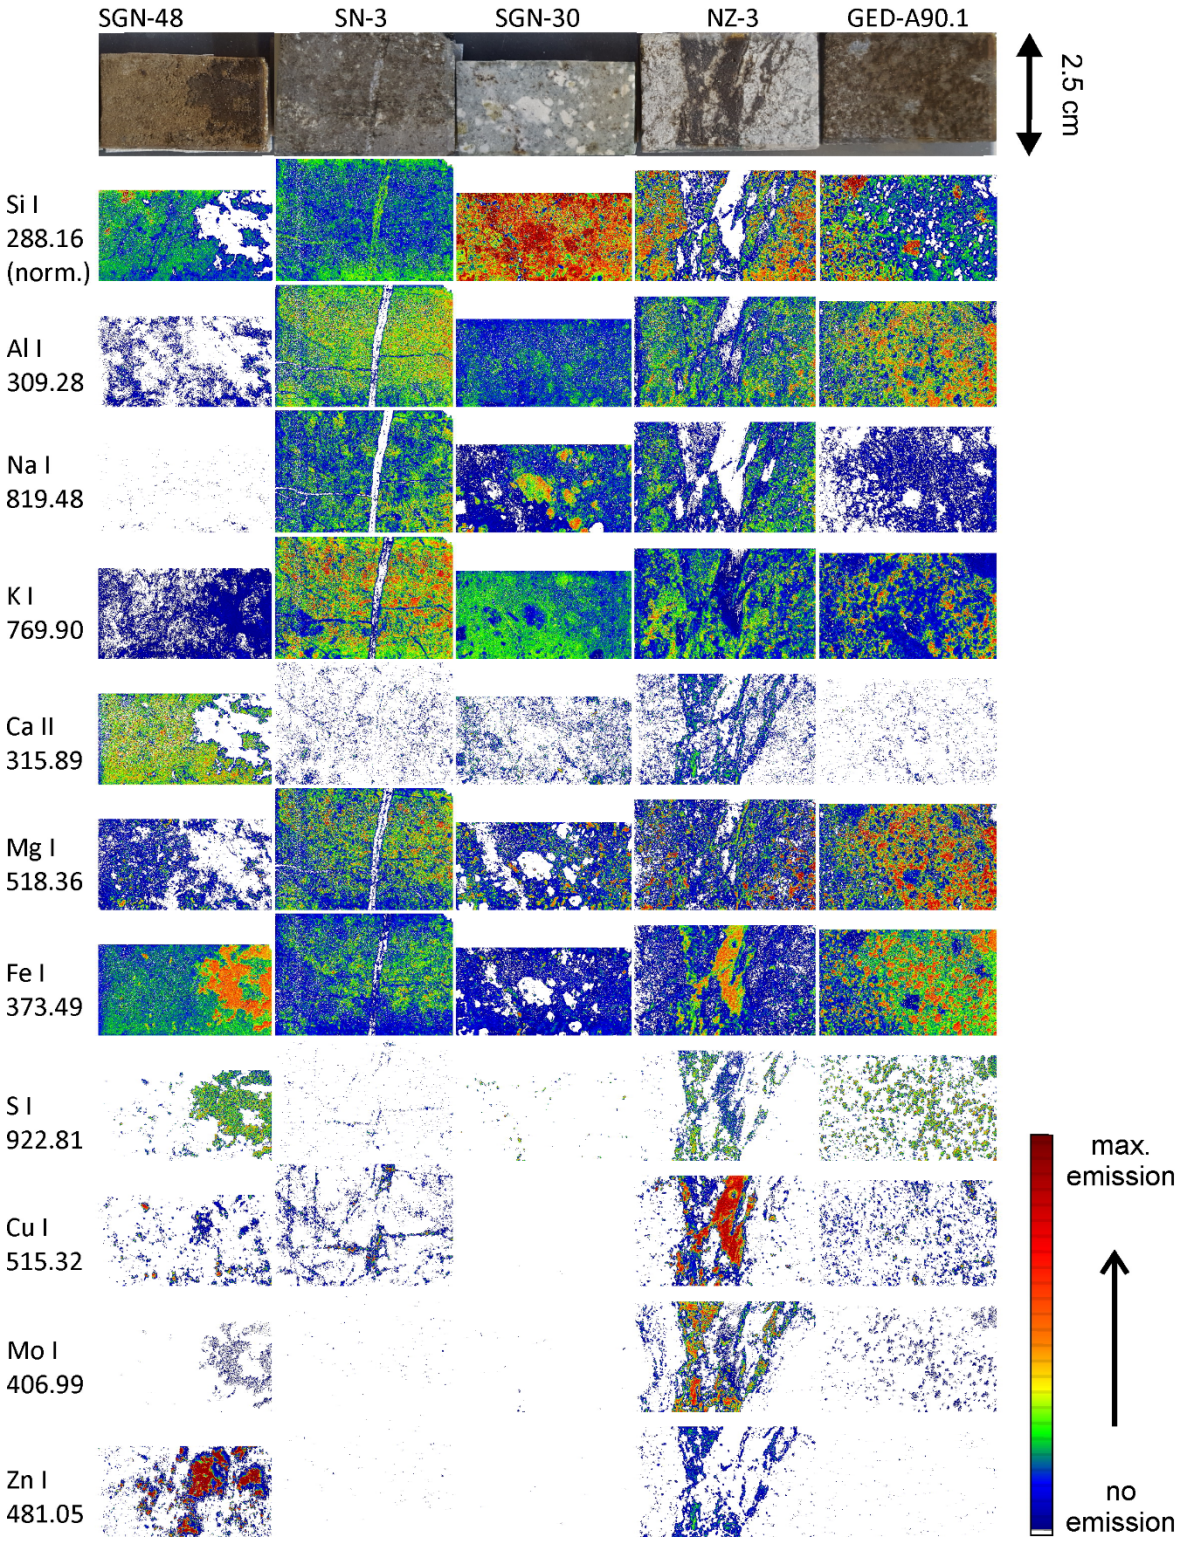

FIG 7 – LIBS-based intensity distribution images (heat maps) of characteristic emission lines of major rock-forming and sulfide-forming elements. The colour bar at the bottom right was scaled for each emission line individually according to the maximum observed intensity. Please note that the relationship between LIBS intensity and element concentration is often not linear because of the matrix effects. Left: (SGN 48) peripheral skarn, right: GED-A90.1, the potassic-phyllic zone in the centre of the porphyry.

The location of the mineralisation is clearly visible in sample SGN-48 (Zn, Fe, S, and small spots of Cu), in sample SN-3 (Cu and S in veins), in sample NZ-3 (Cu, Mo, Fe, S), and in sample GED-A90.1 (Fe, S, and small spots of Cu). Furthermore, the Cu enrichments show different Cu/Fe intensity ratios, possibly pointing to Cu minerals with different Fe content.

The heat maps for the major rock-forming elements can be used to deduce the position of specific minerals based on the presence or absence of specific elements. For example, biotite will show high emission of both Mg and K, whereas orthoclase and muscovite will show low emission of Mg and high emission of K. Calcite will show high emission of Ca only. C could not be detected in the spectra. Quartz minerals are characterised by the absence of emission lines for most elements except for Si. For automatic mineral classification, a mineral library can be built, and supervised classification algorithms applied. The methodology for imaging LIBS is described by Meima and Rammlmair (2020) and several geological applications are reviewed by Harmon and Senesi (2021).

The data in Figure 7 are in good correspondence with the microscopic results (Table 2) and results from other sensor technologies (see below). However, the LIBS-based emission intensities for the minor elements Pb, As, and Ti seem not to be consistent with the other data. With respect to Pb, small Pb-rich spots were detected in sample SGN-48 and NZ-3 with LIBS. The LIBS spectra, however, did not show any S emission at these spots, which would be expected for galena (PbS). With respect to As, the LIBS spectra show increased intensities for multiple characteristic emission lines of As in sample NZ-3, although As minerals have not been found during microscopic analysis and the presence of As could not be confirmed with XRF. With respect to Ti, not only a Ca-rich Ti phase was detected with LIBS in sample SGN-30 (which could be sphene according to Table 2), but also a very large amount of spots in sample NZ-3 show strongly increased Ti emission. These discrepancies may be explained by interferences in the LIBS spectra that could not be resolved with the applied spectrometer system. A spectrometer system with a higher resolution would be advantageous but would significantly reduce the speed of measurement. Proper calibration, eg based on a multivariate approach, could prevent such discrepancies, but could also introduce new artefacts. This example well demonstrates the advantages of a multi-sensor approach: it offers complementary information (eg chemistry, mineralogy) and offers potential for in-line quality control by automatic cross-validation of results.

X-ray fluorescence

Energy line intensities in counts per second (cps) for selected elements from the XRF analysed samples are displayed in Figure 8. The Fe Kα line shows high intensities for samples SGN-48 (>15 kcps) and GED-A90.1 (>11 kcps), medium intensities for samples SN-3 and NZ-3 (both >5 kcps) and lower intensities for sample SGN-30 (<3 kcps). Sample SGN-48 shows the highest Ca Kα line intensity (1.4 kcps) and the lowest K Kα line intensity (<10 cps) among the samples. The highest K Kα line intensity (>300 cps) is found in sample SGN-30 and may reflect the occurrence of K-feldspars (orthoclase). The Cu and Mo Kα line reach the highest intensities in sample NZ-3 (both >3 kcps) whereas the highest Zn Kα line intensity occurs in sample SGN-48 (3.5 kcps). Zr Kα line intensities are low in all samples reaching the highest value in sample SGN-30 (69 cps) coinciding with the occurrence of the mineral zircon. Ti Kα line intensities range between 100 cps and 150 cps for all samples except SGN-48 (<20 cps). The occurrence of Ti is probably related to sphene, ilmenite and rutile/anatase mineralisation.

In general, trends in the elemental distribution within the samples can be derived from the XRF measurements. Cross validation with other sensors is an important approach for improved data consistency and reliability. A site-specific sensor calibration on reference samples with known elemental compositions would further improve the information and lead to an estimation of quantitative elemental concentrations.

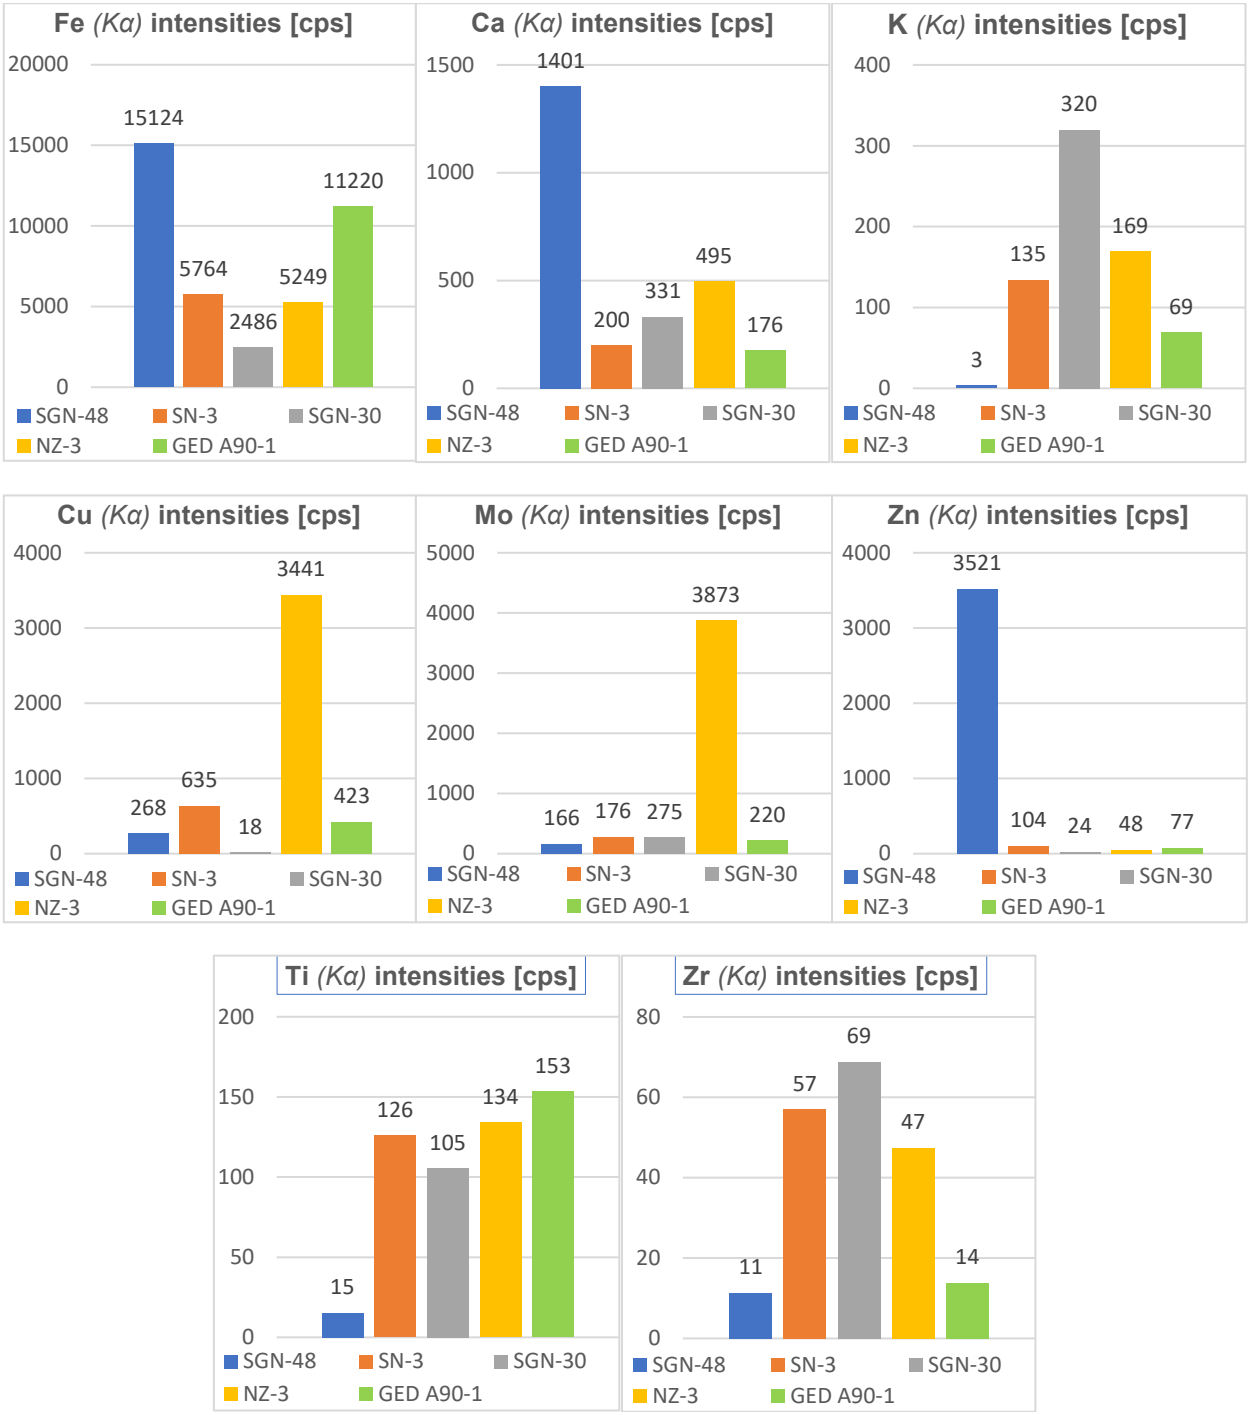

FIG 8 – ANCORELOG XRF measurements – energy line intensities in counts per second of selected elements.

X-ray transmission and computed tomography

In contrast to LIBS and XRF, DE-XRT does not reveal chemical elements but the content of groups of elements with effective atomic numbers, in our case Z_{eff} around 12 and around 29. Figure 9a and b show exemplarily the results obtained for sample NZ-3. It can be compared to the imaging LIBS results in Figure 7. This comparison shows that the low-*Z* group corresponds to Si, Al and Na, the medium-*Z* group to Fe, Cu and Zn. The same is true for ME-XRT with the difference that a third group, consisting of high-*Z* elements with *Z* around 74, is also distinguished (Figure 9d, 9e, 9f). The amount of high-*Z* elements is low and only slightly increased in the region with high medium-*Z* element concentration. A similar observation was made for sample SGN-48, where W was also observed with SEM. A search for W with LIBS to confirm the ME-XRT results will be executed in the future.

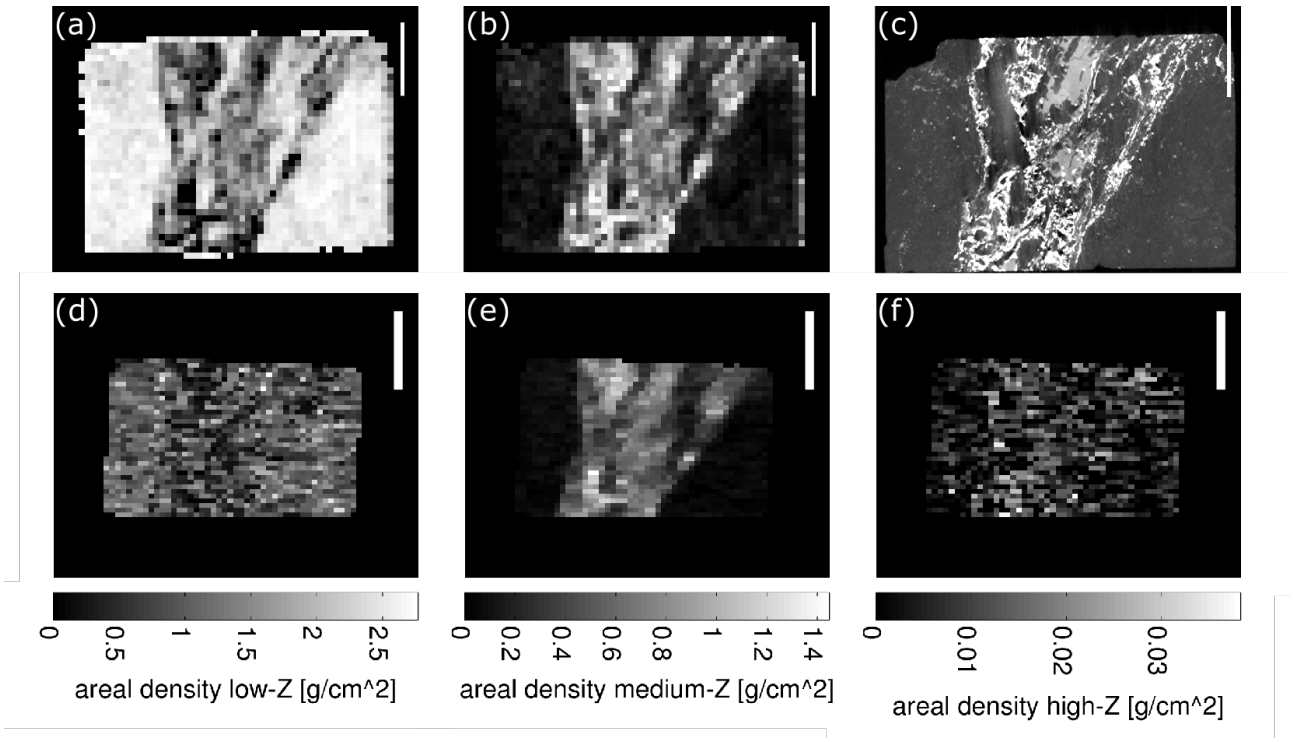

FIG 9 – (a) Low-*Z* and (b) medium-*Z* concentration for sample NZ-3 obtained by DE-XRT. Black and white correspond to concentration 0 per cent and 100 per cent, respectively. (c) Virtual cross-section through CT volume data. Areas of highest X-ray attenuation have the lightest colour. (d) Areal density of low, (e) medium and (f) high-*Z* elements obtained from ME-XRT. The meaning of the colours is indicated by the colour bars. All scale bars are 10 mm. Adapted from Bauer *et al* (2021b).

A virtual cross-section through the reconstructed CT volume allows to recognise three different grey values (Figure 9c). These correspond to elements with different attenuation. Comparison to Figure 7 shows that the darkest regions are formed of low-*Z* elements like Si, Al and Na, medium grey areas consist of Fe and Cu, the brightest regions contain highly absorbing elements like Mo.

Also for the other samples, agreement of imaging LIBS results with those obtained by DE-XRT, ME-XRT and CT was found. Figure 10 shows the medium-*Z* areal density of all samples found by ME-XRT. The comparison to the LIBS results (Figure 7) shows a similar spatial distribution of the corresponding elements. This indicates that the surface data obtained by imaging LIBS are representative for the whole volume, ie there are no relevant hidden internal structures that would only be visible with XRT or CT. The results also show that LIBS can be used to calibrate XRT and CT data. Further DE- and ME-XRT, as well as CT images of the other samples can be found in Bauer *et al* (2021b).

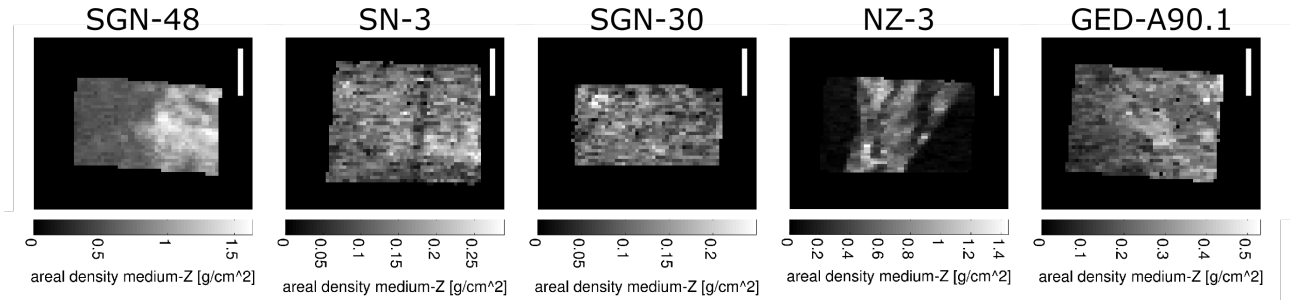

FIG 10 – Areal density of medium-*Z* elements obtained from ME-XRT. Adapted from Bauer *et al* (2021b).

The XRT and CT results can be used to estimate the fractions of the material classes with different atomic numbers Z_{eff} (Bauer *et al*, 2021a, 2021b). The results are given in Table 4. They indicate that

the content of medium-*Z* elements like Fe, Cu and Zn is highest in SGN-48 from the peripheral skarn, followed by samples GED-A90.1 and NZ-3 from the potassic-phyllic zone. The lowest content is found in samples SN-3 and SGN-30 from the phyllic-argillic and propylitic zones. The fraction of high-*Z* elements with $Z \approx 74$, like W, is low in general, which is in agreement with expectation.

TABLE 4

Fractions of material classes with different atomic numbers Z_{eff} found by DE-XRT, ME-XRT and CT. The sum of the peak areas of Fe-, Cu- and Zn-peaks of XRF spectra show approximately the same trend like the medium-*Z* elements groups found by DE- and ME-XRT.

Sample	SGN-48	SN-3	SGN-30	NZ-3	GED-A90.1
Alteration Zone	peripheral skarn	phyllic-argillic	propylitic	potassic-phyllic	potassic-phyllic
DE-XRT Median for Medium-Z Elements	26.6%	6.9%	6.5%	20.9%	17.8%
ME-XRT Median for Medium-Z Elements	20.8%	5.6%	5.4%	17.5%	13.3%
ME-XRT Median for High-Z Elements	1.1‰	1.3‰	1.2‰	3.7‰	0.7‰
CT Medium- and High-Z Elements	20.4%	7.8%	7.4%	17.5%	15.1%
XRF sum of Fe, Cu and Zn, Signal in counts per s	18 913	6504	2527	8737	11 720

The fraction of medium-*Z* elements correlates approximately to the trend shown by the total XRF signal measured for Fe, Cu and Zn. An exception are the samples from the potassic-phyllic zone NZ-3 and GED-A90.1. One reason is presumably that XRT and CT measure the whole volume, while the XRF signal was recorded only from a part of the surface.

DISCUSSION

Advantages of multisensor-based core and material scanning

The here applied methods provide useful information during exploration and mining. Moreover, they allow parameter definition for ore processing. Exploration campaigns are tightly scheduled. In remote areas, it is time consuming and costly to go back to the laboratory if information is missing. Sensor-based in-field measurements accompanied by an experienced field geologist will bring out systematic mineralogical and chemical data. Coupled with deep learning software, decisions can be made during the drilling campaigns. Ore body modelling can be successively fine-tuned. During the mining phase, in-mine measurements allow to characterise the ore feed for the plant, to anticipate dysfunction during processing related to ore anomalies (grain size, composition), and thus to define parameters for beneficiation in real time.

The multisensor approach yields complementary information, including geochemistry (XRF, LIBS), mineralogy (Raman), as well as the propagation of specific textures in 3D (XRT, CT). The here applied methods, the time-gated Raman spectrometer, LIBS, XRF and DE- and ME-XRT devices can be used in-field on mine sites on drill cores and/or crushed material on conveyor belts (moving at up to 3 m/s depending on device). Here, Raman spectroscopy, XRF and LIBS can be applied for fast line scans, while DE- and ME-XRT can image the whole sample. CT and imaging LIBS are time consuming and must be performed on selected samples which are specific objectives of the project,

based on ‘core scanner/conveyor belt’ results. The sensors can be configured and adapted to the particular ore deposits and material matrices at DMT, Essen, Germany and related companies. Imaging LIBS can be performed in the field, samples for CT measurements must be shipped to laboratories like Fraunhofer IIS, Fürth, Germany.

The ANCORELOG cross-method approach – optimising the characterisation of Cu-porphyry alteration zones

Our findings show that in-field instruments such as time-gated Raman spectroscopy, XRF and LIBS, when coupled, perfectly allow to recognise the alteration zones (here studied samples) based on prior calibration by SEM-EDS of the Niaz porphyry. The mineralised zone can be characterised in terms of volumes of samples.

Performance of Raman spectroscopy for Cu-porphyry material classification

Little studies were carried out with Raman spectroscopy on mineralogical compositions in Cu porphyry alteration zones (Abrol and Layne, 2021). These authors show that hydrous minerals such as chlorite, alunite and mica can be used to characterise hydrothermal alteration zones. Test analyses with a robust field Raman spectrometer instrument mounted on the Mars rover were performed in the Tabernas desert in Spain (Veneranda *et al*, 2021). Reliable results are reported for feldspar, carbonate, and organic compounds characterisation, in particular using point analyses on crushed material. The latter result shows the performance of Raman spectroscopy for processed materials on conveyor belts.

Our study using a time-gated Raman spectrometer shows that Raman spectroscopy is powerful for skarn-type porphyries: (1) Minerals, such as clay minerals, chlorite, hornblende, sphene and epidote can be detected. Raman is also powerful to distinguish dickite from kaolinite. This feature is particularly important to decipher hypogene argillic alteration zones (eg Chang *et al*, 2011). (2) In skarn-type porphyries, garnet (andradite) is the indicator when the porphyry is reached top-down. Raman perfectly detects this key mineral. Titanium is often a harmful element during hydrometallurgical processing (Kologrieva *et al*, 2022). Time-gated Raman allows to detect sphene, rutile and anatase to eliminate these minerals/element in the earliest stage of the processing chain. The distinction of anatase and rutile impacts the density estimation at high Ti contents. Anatase (3.79 g cm^{-3}) has a lower density than rutile (4.13 g cm^{-3}). Most importantly Raman perfectly detects molybdenite in the ore horizon. However, chalcopyrite and pyrite cannot be measured. As vector mineral by Raman spectroscopy orthoclase can be used. For efficient use of the time-gated Raman spectrometer, calibration is necessary and key spectral lines can be defined in the software.

Performance of the ANCORELOG XRF for Cu-porphyry material classification

Portable XRF is used for Cu-porphyry samples and helps significantly classifying the alteration zones and the mineralisation (eg Gray and Van Rythoven, 2020 and references therein). The ANCORELOG XRF can be particularly configured for sulfide mineralisations. In this study the skarn can be classified clearly by Fe, Ca and Zn. Cu rich, Cu and Mo rich zones are also rich in K, and can thus be clearly distinguished from non-mineralised zones. Ti-rich and poor zones can be rapidly characterised and attributed to Ti-minerals detected by Raman.

Performance of LIBS for Cu-porphyry material classification

A LIBS line scan allows to determine the spatial distribution of ore forming metal bearing phases (Cu, Mo, Zn, Fe, S) and additionally light elements (Al, Si, K, Na, Mg) to clearly locate the major silicates and carbonates (Ca, Mg). The data are qualitative or (semi)-quantitative and can also be used for identification of minerals with distinct chemistry (eg Kuhn *et al*, 2016; Meima and Rammlmair, 2020; Harmon and Senesi, 2021). Applied in core scanner or industrial instrumentation, LIBS is very fast, eg up to 1000 measurements per second are possible as shown by Rifai *et al* (2020).

Performance of DE-XRT and ME-XRT for Cu-porphyry material classification

The strength of DE-XRT and ME-XRT is that these methods allow the fast analysis of the whole volume of all samples (Bauer *et al*, 2021a, 2021b; Firsching *et al*, 2011; Wagner *et al*, 2022).

However, they do not allow the identification of elements or minerals. Thus, while they can be used to determine the volume fraction of groups of elements with similar atomic numbers, they require calibration by other methods for an assignment of these groups to elements or minerals. This calibration can be done by SEM-EDS, LIBS, Raman spectroscopy and XRF measurements on the sample surface. To ensure that the sample surface is representative for the whole sample volume, CT can be useful as it allows a fully 3D visualisation of the internal sample structure. Thus, the volume distribution of minerals in the sample can be determined. Furthermore, it allows to investigate the structural features, such as fractures.

While mapping elements or minerals on the whole surface of a sample by LIBS, Raman spectroscopy or XRF is too time consuming for a sorting application, scans along some lines or measurements of a few spots (diameters of up to 400 µm) per sample are possible. These could be combined with the XRT results to increase their accuracy. The spatial density of measurement spots necessary to obtain a realistic characterisation of the samples has to be derived from the laboratory analyses. For homogeneous samples, one or a few spots may be sufficient, but more measurements are required for heterogeneous rocks.

CONCLUSION

This study shows that a combined sensor approach is an efficient way to classify alteration zones and associated mineralisation (Cu, Mo, Zn etc). Core scanner instruments must be configured based on laboratory measurements and core-scan tests on representative samples (barren, economic, differently altered etc). Therefore, in a first phase prior to routinely material scanning, a team of instrument developers and geologists, ideally also including a process engineer, elaborate the baselines for the upcoming industrial use. Adjustments can then be performed during material scanning.

The ANCORELOG approach reduces drilling costs as drilling campaigns can be directly adapted on the results and adjacent material models (orebody, feedstock for plants etc). It also reduces operational costs during hauling, crushing, milling and further processing, as prior sorting implies that less waste material enters the processing chain. Combined or single sensors from the ANCORELOG scanner can be configured and adapted to all type of processing materials.

OUTLOOK

The ANCORELOG sensors and scanner are currently tested on VMS-type deposits and materials in southern Spain. Further materials such as bauxites (Meima *et al*, 2021; Orberger *et al*, 2022) and process materials from TiO_2 pigment production and Al-production will be tested.

ACKNOWLEDGEMENTS

The authors would like to thank the European Institute of Innovation and Technology (EIT), a body of the European Union under the Horizon 2020, the EU framework Program for Research and Innovation, for funding sensor developments in the projects ANCORELOG (Grant N°17028) and T-REX (N° 19122). The authors would also like to thank the French Iranian TRIGGER project for funds for the laboratory SEM and microprobe analyses.

ABSTRACT

Hatch has developed forecast models for predicting Life-of-Mine (LOM) circuit throughput for a number of operations worldwide. These models can be used to predict variations in future operating throughput arising from changes in ore characteristics, mine planning, blending strategies, and operating strategies, thereby improving process stability and helping to maximise profit over the LOM. In this paper, Hatch shares three case studies of throughput forecast modelling and discusses the main results, model precision, and associated challenges with the methodology, and provides a comparison of predicted plant performance with operational data.

Hatch's forecasting methodology considers the effect of ore characteristics and blast fragmentation on the entire feed particle size distribution (PSD) to the comminution circuits. Site-specific Morrell power-based models are also used to capture the key factors contributing to plant throughput. These include the proportion of each ore type in the feed blend, the characteristics of each ore type (hardness and breakage characteristics), product size targets, and equipment specifications.

Data is then collected (often during Mine-to-Mill (M2M) optimisation projects) and used to validate the power-based throughput forecast model against historical observed ore hardness and plant throughput. Outputs from site geological and geotechnical/geometallurgical block models, such as the distribution of the various ore types and their hardness, plus mine planning information are then used to predict the throughput on an annual basis over the LOM. The power-based equations that predict comminution circuit specific energy are also tuned to reflect the recommended mine and plant optimisation strategies, thus the model can reflect not only current practices, but also be used to investigate potential optimisation opportunities.

INTRODUCTION

In any operation, a certain level of variability in plant throughput is inevitable. Changes in the *in situ* ore characteristics (strength and structure) associated with different ore types or domains yield different run-of-mine (ROM) PSDs under a given set of drill and blast parameters. Changes in the hardness and breakage characteristics provide an additional source of variability once the ore reaches the plant. Differences in mineralogy and liberation characteristics may also necessitate changes in the target grind size to maintain the performance of downstream separation processes, adding yet another layer of complexity. The ability to anticipate and control the resulting variation in throughput is critical to achieving consistent, stable operation, which is a necessary precondition for process optimisation and maximising profit over the LOM.

Members of Hatch's Mining and Minerals Processing group have developed throughput forecast models to predict LOM circuit throughput for several operations globally (see Bennet *et al,* 2017; Burger *et al,* 2006; Farmer *et al,* 2021) using a methodology based on established power-based approaches, and incorporating site-specific factors and constraints. These models consider the proportion of the different ore types present in the feed blend, and where available leverage detailed ROM fragmentation models to link the blend composition to the feed size seen by the plant. Combined with ore hardness data and inputs for available comminution power and target grind size, conventional power-based models can be applied to predict the LOM throughput. With many mining companies having invested significant effort in recent decades into the development of detailed

geometallurgical models, which integrate geological, mining, and processing aspects (Alruiz *et al*, 2009), many of the required inputs can now be sourced from the one location.

Hatch's methodology is described in detail in the section that follows, with three case studies provided thereafter. While the use of similar models has been described elsewhere (Misle *et al,* 2013; Farmer *et al,* 2021), the case studies in this paper are intended to provide examples of the sort of challenges which can be encountered when applying this methodology – and the approaches needed to overcome them – as well as the flexibility of the methodology to consider future circuit changes.

METHDOLOGY OVERVIEW

At its core, Hatch's approach to throughput forecasting involves the application of power-based methods to determine the achievable throughput over the LOM, considering the available grinding power. The methodology for determining the total circuit specific energy, and the specific energy of the AG/SAG mill – proposed by Morrell (2004a, 2004b) and accepted as industry standard (Global Mining Guidelines Group, 2021) – is used to calculate the throughput over a given period, with the final forecast and the limiting grinding stage determined based on the lower of the two values. The key equations for total and SAG/AG specific energy are as follows:

$$Morrell\ Total\ Specific\ Energy\ \left(\frac{kWh}{t}\right) = 4M_{ia}\left(750^{f(750)} - F_{80}^{f(F_{80})}\right) + 4M_{ib}\left(P_{80}^{f(P_{80})} - 750^{f(750)}\right) \quad (1)$$

$$SAG/AG\ \ Specific\ Energy\ \left(\frac{kWh}{t}\right) = K\ \times\ {F_{80}}^{a} \times DWi^{b} \quad (2)$$

Where:

M_{ia}	coarse grinding work index (kWh/t)
M_{ib}	fine grinding work index (kWh/t)
F_{80}	80 per cent passing size (µm) of the grinding circuit feed
P_{80}	80 per cent passing size (µm) of the grinding circuit product
f(x)	defined functions of F_{80} and P_{80}, as per Morrell (2004a, 2004b)
DWi	drop weight index (kWh/m^3) of the ore
K, a & *b*	site-specific factors, calibrated to production data

Much of the value of Hatch's approach, however, comes from combining data from typically available sources (the LOM plan or geometallurgical model) and other models (blast fragmentation models and mechanistic process models) to best define the inputs to the power-based model, and to augment it where the impact of certain changes cannot be accurately captured by power-based approaches alone.

When developing a throughput forecast model, Hatch typically draws upon the LOM plan or geometallurgical model to provide the proportion of feed ore originating from the various ore sources or defined domains over time. The LOM plan or geometallurgical model will also contain data for the typical indicators of comminution characteristics (eg DWi, Axb, BBWi, M_{ia}, M_{ib}) for each of the ore sources, with the level of definition dependent on the maturity of the geometallurgical program at a particular site.

The proportion of the different ore types and DWi (or an equivalent parameter, from which DWi can be determined) in the LOM plan allows for a weighted average AG/SAG specific energy to be calculated for a given period. Similarly, the information within the LOM plan can be used to calculate the total specific energy via the Morrell method, provided a given feed size (F_{80}) and product size (P_{80}). While product size is a process target informed by the mineralogical and liberation characteristics of a given ore, feed size is often less well understood, particularly insofar as how it is influenced by drill and blast practices and *in situ* ore characteristics. Defining the F_{80} is critical for any power-based throughput forecasting, and it is here where detailed ROM fragmentation modelling is particularly useful, such as that completed by Hatch during a M2M study.

In a M2M study, blast domains are defined based on the *in situ* characteristics of the ore, specifically its structure (typically measured in terms of *in situ* block size) and strength (unconfined compressive strength, determined via point load testing). These two parameters respectively dictate the coarse and fine end of the ROM PSD under a given set of blast conditions. Defining these domains and conducting a controlled blast audit provides the basis for developing ROM fragmentation models, which are then used to establish drill and blast guidelines for each domain. The ultimate objective of these guidelines is to provide a ROM PSD which maximises plant throughput, while avoiding indiscriminate or unilateral increases in drill and blast cost. More energy is typically applied to harder and less naturally fractured domains, while less energy is applied in softer or more fractured domains where it is not required. The detailed fragmentation models and simulations used in a M2M study to identify the optimal blast design provide a link between ore characteristics, drill and blast practices, and ROM fragmentation, which can be captured and integrated into a forecast model. Within the forecast model this takes the form of a family of functions which together describe the ROM F_{80} in terms of drill diameter and powder factor for each of the different domains. The SAG/AG F_{80} can then be estimated in turn, based on tuned mechanistic models of the crushing stage.

Where a M2M project has not been completed, and no blast fragmentation model is therefore available, an alternative approach is required. In that scenario, data from online camera systems (eg *Ore3D*® or *Split Online*®) is often used to derive general relationships between SAG/AG feed F_{80} and blend composition.

Once the expected F_{80} is determined, the total and AG/SAG specific energy is then calculated, using Equations 1 and 2. Throughput is then calculated based on the AG/SAG and total specific energies, and the grinding power available in the AG/SAG mill and the overall circuit. By comparing the two throughput figures, a realistic estimate can be made, considering the 'rate limiting step' in the grinding process. Extending this to a full LOM forecast, useful information is provided regarding not only throughput, but also how the limiting step may shift over time, which can assist in strategic planning for long-term plant expansions or upgrades.

For a throughput forecast prepared in conjunction with a M2M study, the same blast fragmentation models used to determine ROM F_{80} also provide details regarding the increase in fines generation associated with optimised blast conditions. Mechanistic models of the grinding circuit (such as those in *JKSimMet*) and analysis of historic operating data and surveys are used to estimate the throughput increase associated with these additional fines. Of course, the effect of these fines is not captured by the power-based approaches, whether that be the total specific energy method (which considers only F_{80} as a feed size indicator) or calculations of AG/SAG specific energy, which are tuned to historic data with the 'pre-optimisation' blast conditions. When developing a throughput forecast model, Hatch incorporates the estimated impact of the added fines by applying a correction factor to the calculated throughput, linked to a toggle for the user to specify baseline or optimised blast conditions.

Where possible, validation of the increase in fines production associated with the M2M blast may help to further refine the blast model, as well as the throughput forecast. Caution should be applied, however, using online image analysis systems for this purpose, or integrating their output into the model directly. As noted by Contreras Bravo and Morales (2017), these systems are effective for measuring the F_{80} (at least when properly calibrated and maintained), however are often more prone to error at fine sizes.

Finally, an effective throughput forecast model needs to account for site specific factors or constraints, beyond those set by the feed conditions and installed power of the grinding circuit. Where such constraints are identified, Hatch's approach is to incorporate them into the model via 'constraint ON/OFF' toggle, allowing an immediate and flexible means by which to evaluate the benefit associated with relieving the issue or bottleneck. The case studies in this paper include an example where this approach has been applied.

CASE STUDY 1

Operation description

The operation in Case Study 1 is an open pit copper/molybdenum operation, with the major ore minerals being chalcocite, chalcopyrite, and bornite. Ore at this site is classified into three hardness domains (soft, medium, and hard) according to Axb and BBWi values, and six geometallurgical units, referred to as UGM 1 through 6. The comminution circuit consists of three parallel grinding lines, fed by primary crushed ore. Two of the three lines feature identical SAG and secondary ball mill circuits. The third line features a larger SAG mill, with two secondary ball mills.

SAG trommel oversize from all three lines is classified over common pebble screens; undersize from those screens reports to the ball mills in the third line, while oversize is crushed. Crushed pebbles are distributed between the two smaller grinding lines in an 80/20 split, with none of the crushed pebbles reported to the larger grinding line.

Forecast model

Hatch were engaged to complete a M2M optimisation project, and develop a throughput forecast model in parallel. Audited blasts and plant surveys were completed for the soft and medium ore types, allowing for the development of calibrated blast fragmentation models for these ores, as well as models of the crushing and grinding processes in JKSimMet. Hard ore was modelled based on the medium models, with adjustments made with reference to historical data. For the purposes of the blast fragmentation models, the soft domain was divided further into coarse and fine structural subdomains, based on the variability in *in situ* block size. Once the blast fragmentation models were developed, a range of drill and blast design conditions were simulated, with a view towards improving fragmentation in the medium and hard domains by increasing blasting intensity, while reducing operating costs and complexity in the soft domains by relaxing the blast. The prescribed blast guidelines were forecast to yield a 6 per cent increase in fines generation in the soft fine domain, 4 per cent in the medium domain, and 7 per cent in the hard domain, as well as improvements at the coarse end (reduced P_{80} and top size). In the soft fine domain, only marginal improvement in terms of fines production was possible, however some reduction in ROM P_{80} was predicted. ROM fragmentation for the simulated base cases and guidelines is shown in Figure 1.

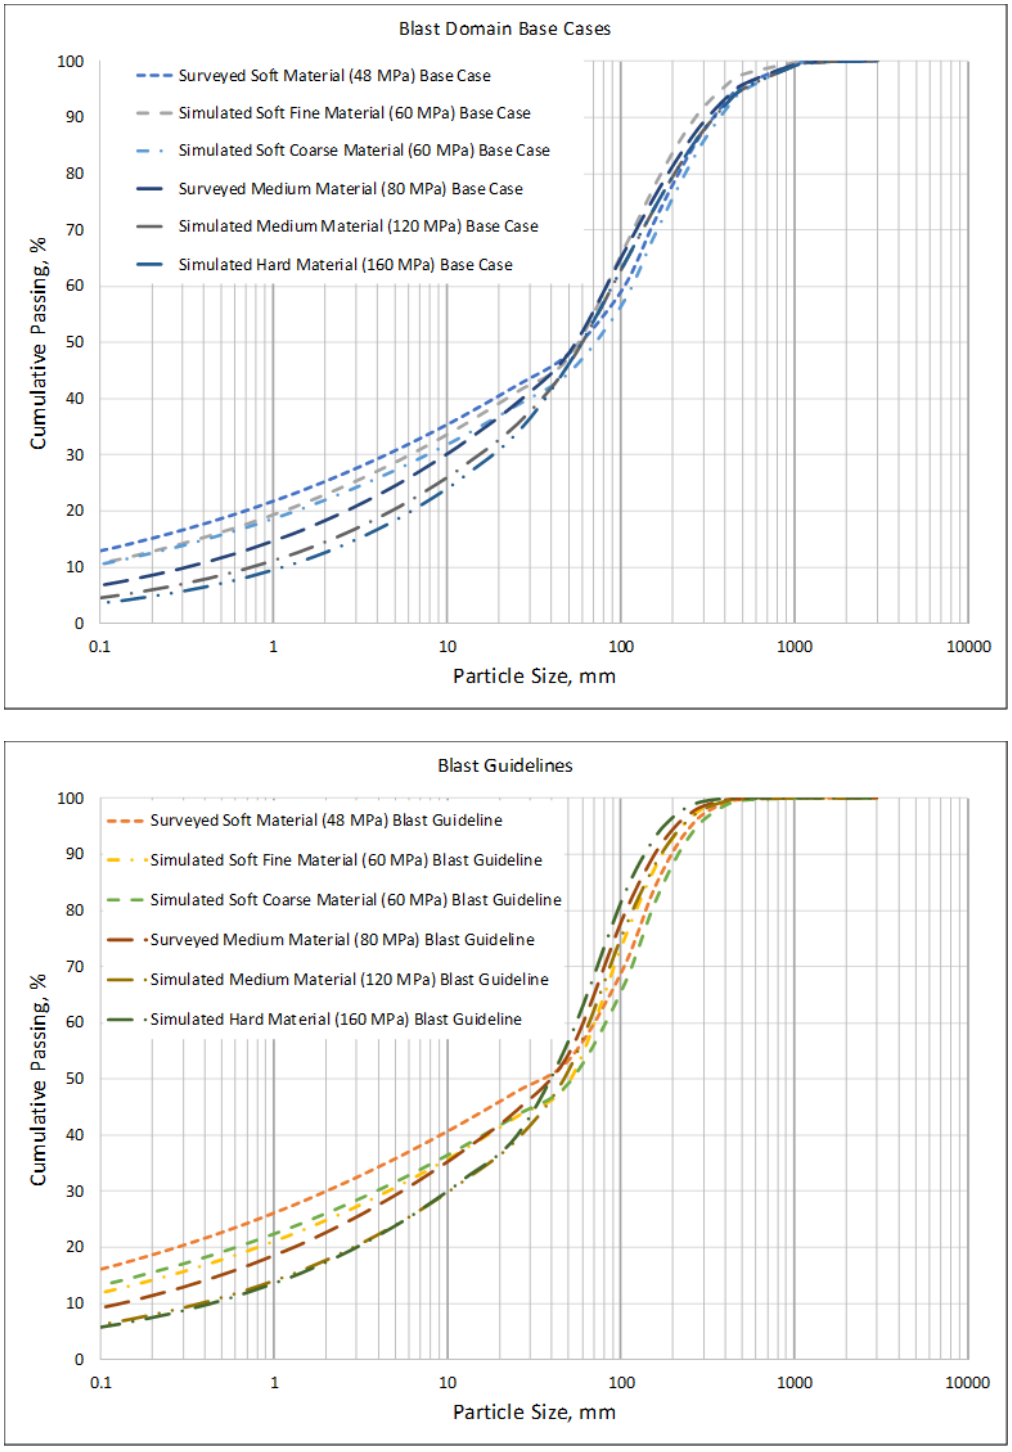

FIG 1 – ROM fragmentation for base case and optimised blast conditions in each of the blast domains defined as part of the M2M study.

Moving downstream, opportunities to optimise the crushing and grinding circuits were also identified. These included:

- improving power utilisation in the two smaller SAG mills via increasing the mill speed and ball load.
- leveraging the finer ROM fragmentation from the optimised blast by tightening the primary crusher gap, thereby providing a finer SAG feed top size.
- optimising the grate and pulp lifter designs to increase pebble production and better utilise the installed pebble crusher capacity, while simultaneously reducing the risk of slurry pooling.

The total throughput benefit of the optimised blast fragmentation and the changes in the process plant was forecast as between 10 and 12 per cent, depending on ore type. A potential opportunity to reject barren pebbles by integrating the existing pebble screens into an ore sorting circuit – and thereby free up capacity in the milling circuit, while also improving the feed grade to the downstream separation process – was also identified for further review.

Along with the M2M study, a throughput forecast model was developed. Site had an existing model, based on the Morrell power-based equations, however an updated model was required to capture the impact of the improved blast fragmentation associated with the M2M recommendations. Input data required for the LOM forecast model was drawn from sites' existing geometallurgical model. Extensive ore characterisation – including Axb, DWi, BBWi, and UCS – sits within the geometallurgical model, allowing the development of a high-quality throughput forecast. Whereas the M2M study considered the three hardness classifications, the throughput forecast was based on the six previously mentioned geometallurgical units, which provided a higher level of definition. The modelled blasting behaviour (based on the hardness domains) was captured via a correlation between F_{80} and Axb, which could then be applied to the geometallurgical domains to estimate the F_{80} to the plant for a given blend. Figure 2 shows the annual average Axb values for each UGM over the LoM. A reasonable level of variation can be seen, with values varying between approximately 40 (moderately hard) and 100 (soft) for the most part for the period out to 2036. Test work for ores to be processed beyond 2036 was not available at the time of the forecast being developed.

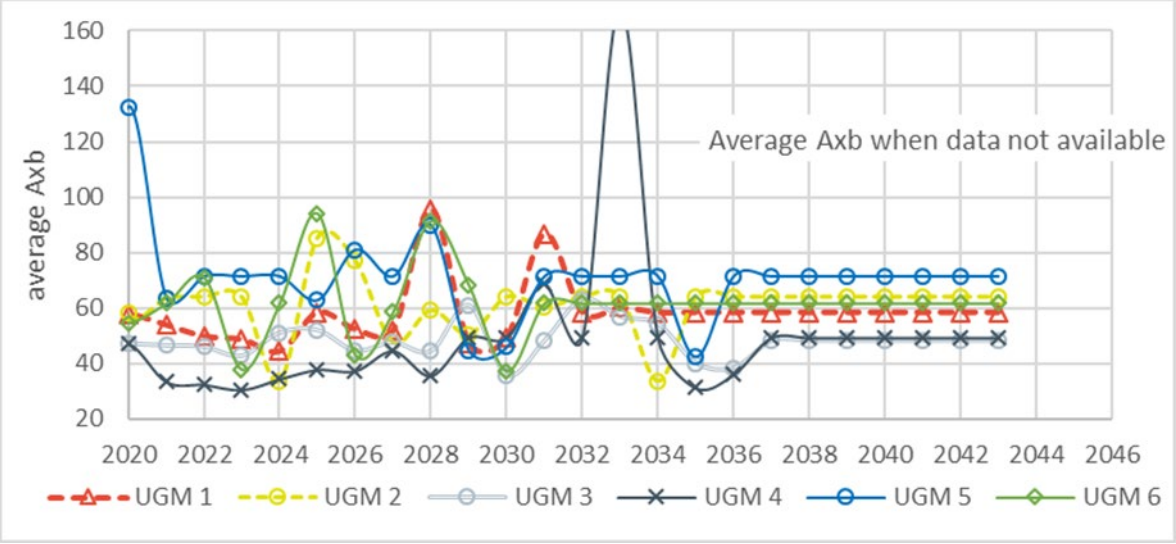

FIG 2 – Axb of the various UGMs from Case Study 1.

These data, along with the BBWi data also in the geometallurgical model, are used to calculate the M_{ia} and M_{ib} indices used in the Morrell specific energy calculations. Together with the estimated F_{80}, and the user-specified grind size target, this allows the calculation of the specific energy for each UGM. It is important to note that the specific energies used for the final throughput calculations are based on a weighted average specific energy, derived from the individual specific energies calculated for each UGM. This allows for the differing F_{80} associated with each UGM to be accurately accounted for and avoids incorrectly averaging the non-additive Axb values. Once the weighted average specific energy is calculated, throughput is calculated based on the available grinding power in each line, and the final estimate calculated by comparison against the throughput calculated based on SAG specific energy. Calibration factors were also applied to account for differences between the lines, specifically the consistent trend of lower specific energy in Lines 1 and 2, compared with Line 3.

Finally, the model features optionality allowing the user to predict ROM fragmentation for different drill and blast scenarios, being either the base case 'as is' blast design, or under conditions in line with the recommendations of the M2M study. Calculated throughput in the M2M cases is adjusted by reducing the specific energy in inverse proportion to the expected throughput gain determined from the detailed process modelling. The overall model structure is shown in Figure 3.

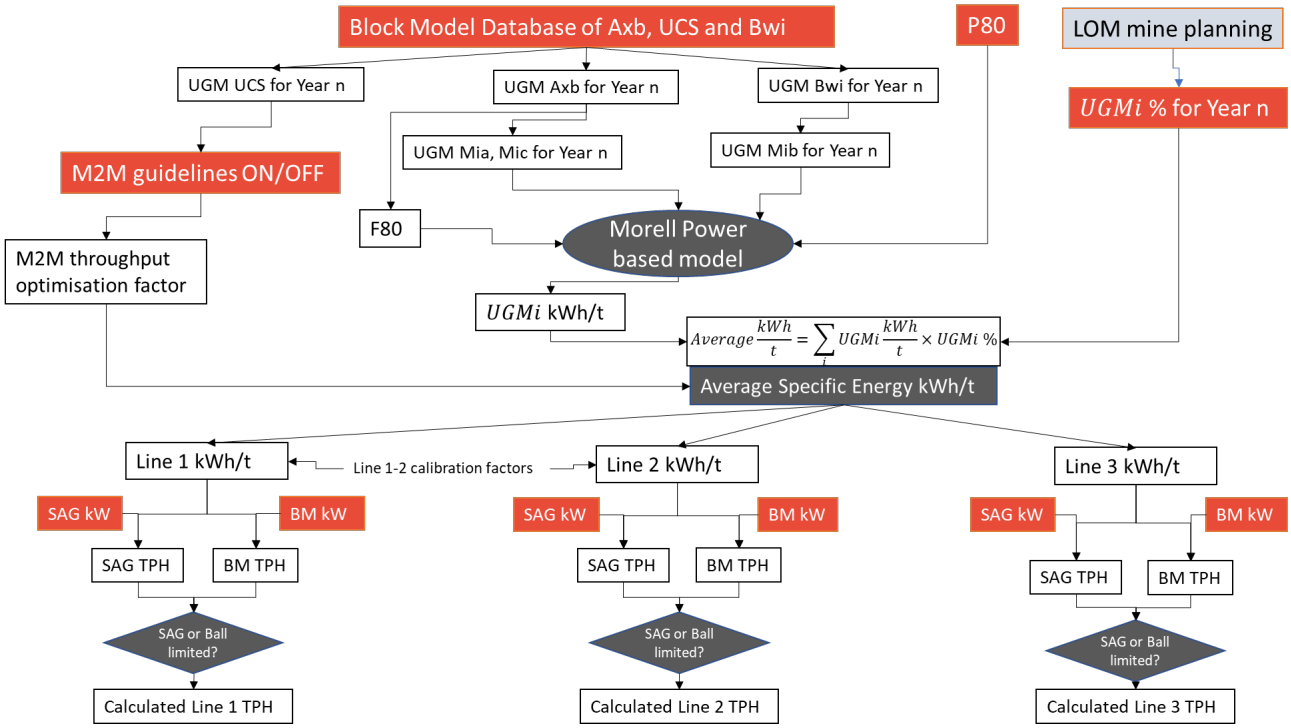

FIG 3 – Overall forecast model structure for Case Study 1. Note the on/off toggle available to the user for the M2M guidelines.

The model was validated against one years' worth of production data, covering the 2018 calendar year. Recorded power and product size were used as inputs, and the model predicted throughput was compared against the actual throughput. Model standard error equated to 9.8 per cent of the average total throughput (Line 1 + Line 2 + Line 3) on a monthly basis. Standard error for each individual line equated to 9.3 per cent, 5.8 per cent, and 11.2 per cent of the average, corresponding to confidence intervals of between 12–25 per cent of the line average throughput at a 95 per cent confidence level.

CASE STUDY 2

Operation description

Case Study 2 takes places at another large open pit copper/molybdenum operation. Copper mineralisation occurs primarily in the form of chalcopyrite and chalcocite. Recovery is via two flotation stages, with the bulk Cu-Mo concentrate from the first stage reporting to the molybdenum circuit, with the molybdenum concentrate subject to hydrometallurgical treatment also on-site. Minor silver content provides an additional by-product credit.

Comminution at the site takes place in a conventional SAG-ball-crusher (SABC) flow sheet. Primary crushed material feeds a large SAG mill in primary grinding duty. Discharge from the SAG mill is classified via a trommel and incline screen, with the circuit closed with two cone crushers. Product from the SAG circuit feeds the secondary grinding stage, consisting of two parallel ball mills, each of which is closed by two cyclone clusters. A second grinding line had been recently commissioned and was in the process of ramp-up at the time the throughput forecast model was being developed. While not the focus of this discussion, a preliminary forecast model for the new grinding line was also provided, based on the assumption that it would operate in the same manner as the existing line.

Throughput forecast model

The throughput forecast model for this operation had a similar overall structure to that described in Case Study 1, however with some key differences. As was the case in the earlier example, the LOM planning (covering the period from 2020 out to 2044) was drawn upon to define the proportion of the various ore types in the feed blend. Here, the LOM plan defined six different lithologies, five of which

occurred in significant proportion over the LOM, with the sixth being present in the plant feed in only a handful of years, and in very small proportion. The model therefore considered the five main lithologies as its basis. The proportion of the different lithologies in the plant feed over the LOM is shown in Figure 4.

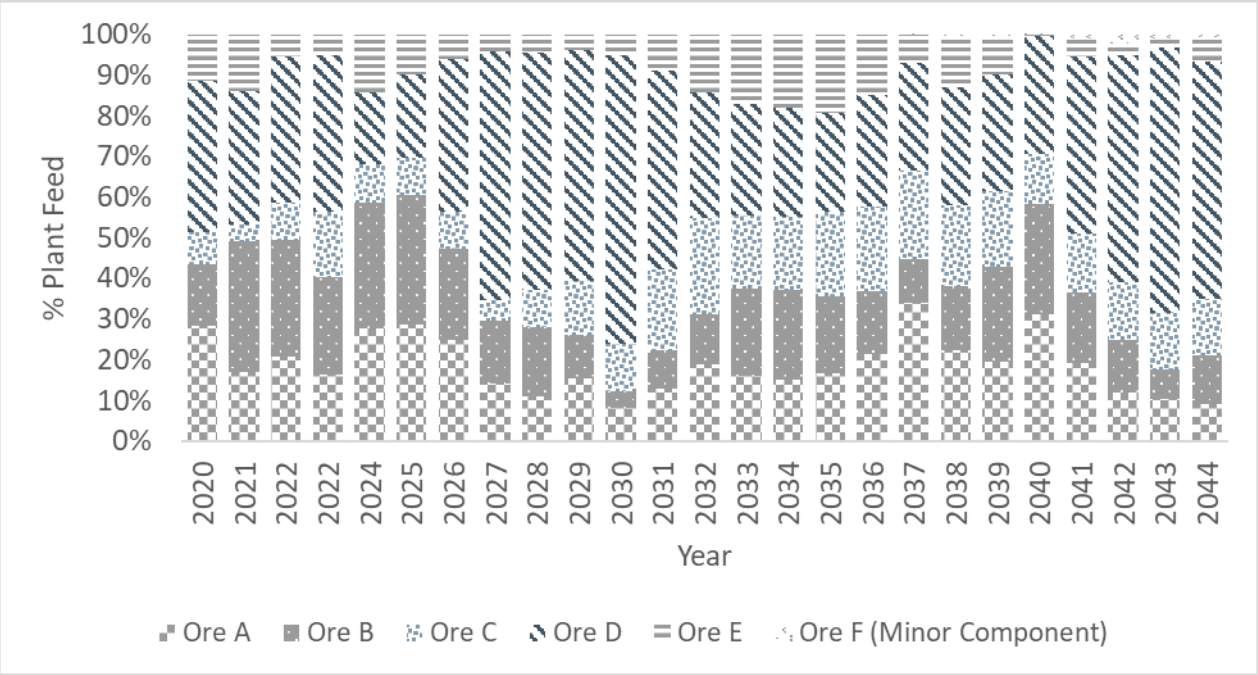

FIG 4 – Bar chart showing the proportion of each of the different lithologies in the feed blend, on an annual basis.

Where the site covered in Case Study 1 had a detailed geometallurgical model, the extent of the test work conducted at the site in Case Study 2 was much more modest. Some Macon crushability index and BBWi data was available, however the number of samples was quite limited. Based on this, a single impact hardness (DWi) and grinding hardness (BBWi) value was assigned to each lithology, with the model assuming the characteristics of the ore from each lithology will not change in future, only the proportion of the feed drawn from each. Considering this, the model was configured to allow the user to adjust the ore hardness inputs in the future, when additional test work becomes available and the variation in the hardness of each lithology is better understood. The assigned values are shown in Table 1.

TABLE 1

Assigned ore characterisation data for each of the lithologies in Case Study 2.

Ore Type	Estimated Axb	BBWi (kWh/t)
Ore A	36.7	15.28
Ore B	70.2	9.74
Ore C	50.1	13.62
Ore D	37.4	15.07
Ore E	34.7	17.60

In this case, Hatch did not have the benefit of having already completed a full M2M project for this operation. Calibrated drill and blast models to define the ROM fragmentation were therefore not available. Fortunately, the SAG feed belt at the site is equipped with an image analysis system (*Split Online).* Data from the image analysis system was cross referenced with daily production records, which provided the proportion of each ore type in the feed. Multi-linear regression was carried out,

and an equation to predict F_{80} as a function of the feed blend composition type was derived. The equation took the following form, where a, b, c, d, and e are fixed coefficients:

$$F80 = (a \times \%\ Ore\ A) + (b \times \%\ Ore\ B) + (c \times \%\ Ore\ C) + (d \times \%\ Ore\ D) + (e \times \%\ Ore\ E) + Constant \quad (3)$$

While analysis of variance (ANOVA) indicated there was a statistical significance to each of the coefficients, and that the overall regression was significant, there is a degree of scatter in the data due to operational variability and error associated with the image analysis. This is reflected in Figures 5 and 6.

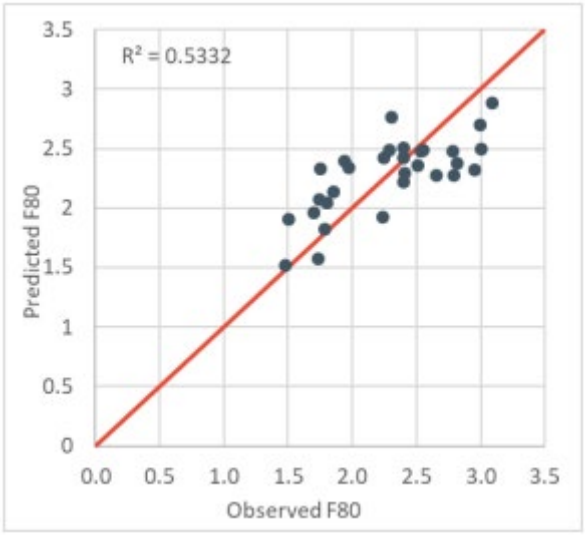

FIG 5 – Parity chart of predicted and observed (online camera) SAG feed F_{80}.

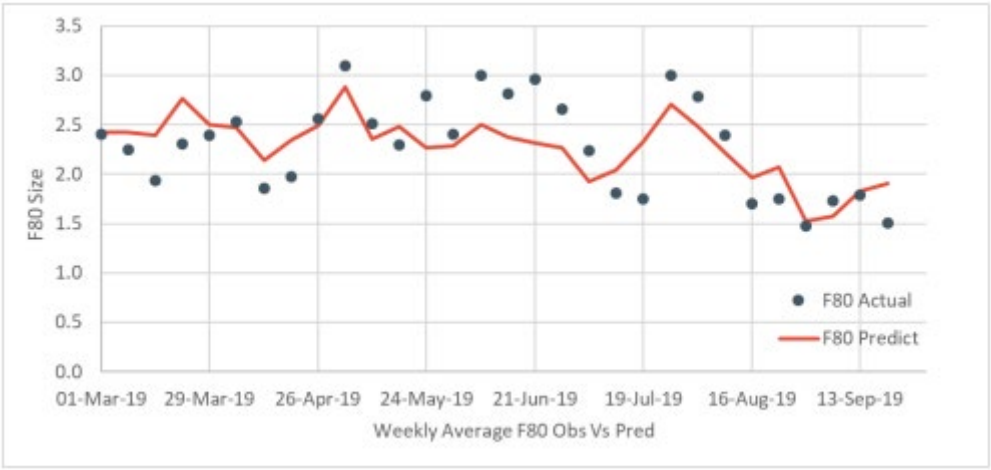

FIG 6 – Timeseries plot of predict and observed SAG feed F_{80} (weekly average).

Finally, the model development was complicated further by specific conditions which occurred when Ore B was present in high amounts. Being the softest of the five main ore types, the power-based model was predicting a reduction in the required specific energy as the proportion of Ore B increased, with a corresponding increase in the predicted throughput. The initial model, however, was shown to be systematically overestimating during these periods. Based on this, it became evident that there was an operational/practical factor at play, which was not being captured in the model.

Discussions with site indicated that this ore, along with Ore C, had been causing issues in the downstream thickener. These issues compelled the operators to manually reduce throughput when these ores were present in significant amounts. In the case of Ore B, the particularly soft nature of the ore meant that the SAG mill struggled to maintain a rock charge once the operator reduced the throughput, leading to a reduced power draw. The relationship between the proportion of Ore B in the feed and SAG mill power draw is shown in Figures 7 and 8. This relationship was incorporated

into the throughput forecast model to capture the ‘reduced SAG mill power’ operating state, with the option to disable this function once the thickener issues are resolved.

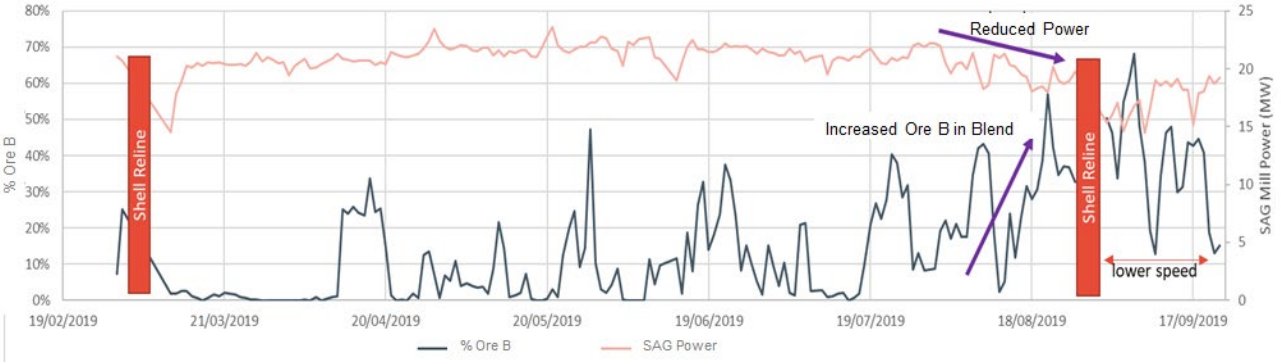

FIG 7 – Timeseries plot of SAG power alongside the proportion of Ore B in the feed blend.

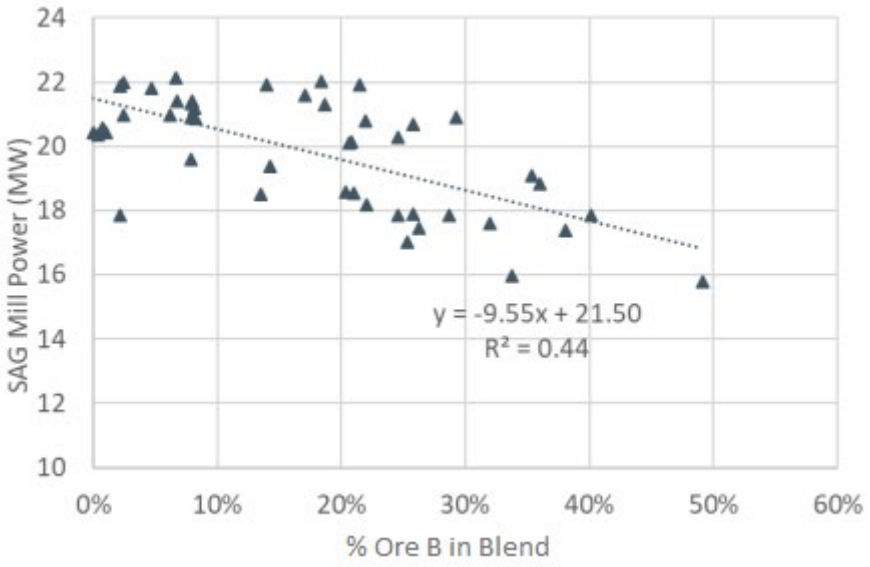

FIG 8 – Regression of SAG mill power as a function of the proportion of Ore B in the feed.

While production data covering the period from March 2019 to September 2019 was used to calibrate the forecast model (specifically, the calibration constants for SAG specific energy), data for the subsequent six months was used to validate the model predictions. Blend composition data over that period was averaged at daily, weekly, and monthly intervals, and provided as the input to the model. Figures 9–11 shows the comparison of the actual and predicted plant throughput at each time scale, with the red line separating the calibration and validation periods.

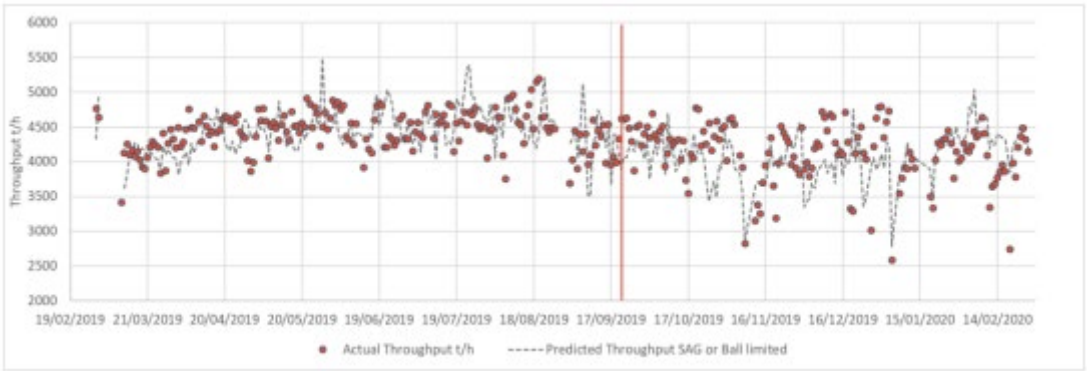

FIG 9 – Timeseries plot showing actual and predicted model throughput, on a daily timescale. Area to the left of the red line is the data used for calibration, area to the right is the validation period.

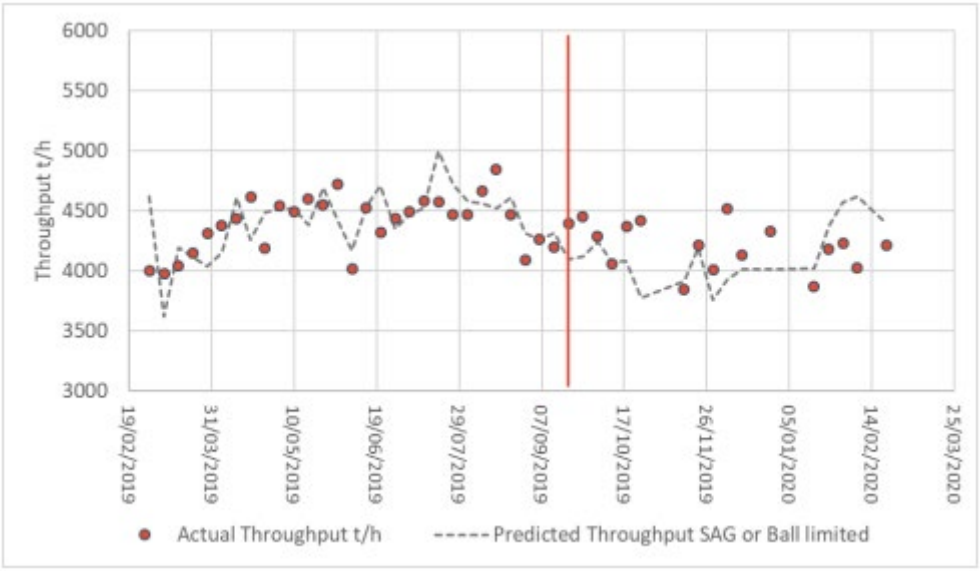

FIG 10 – Timeseries plot showing actual and predicted model throughput, on a weekly timescale.

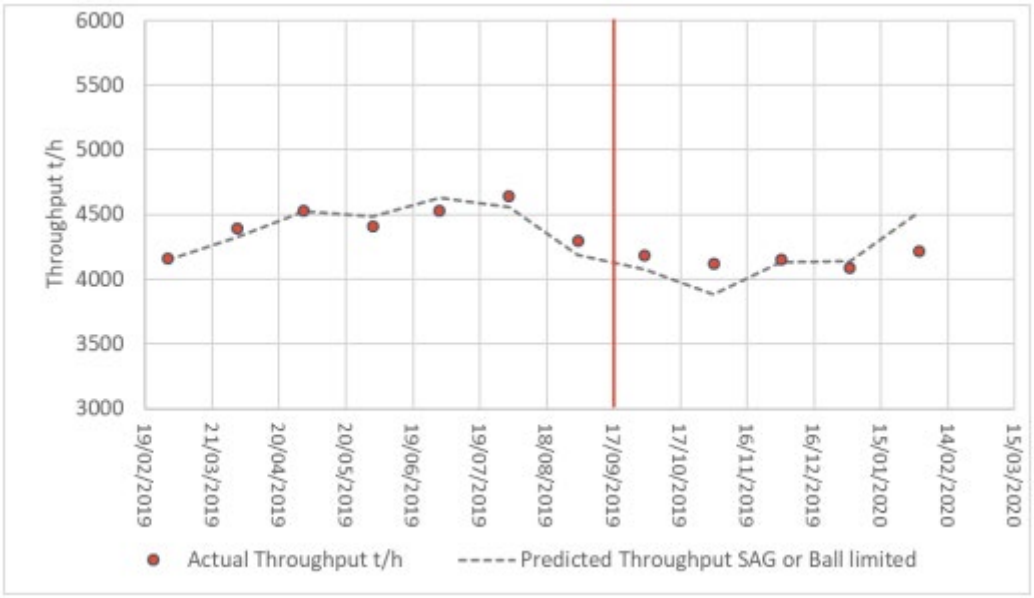

FIG 11 – Timeseries plot showing actual and predicted model throughput, on a monthly timescale.

Model standard error at each time scale was determined, along with the 95 per cent confidence interval. Standard error equated to 10.9 per cent, 7.5 per cent, and 4.4 per cent on a daily, weekly, and monthly basis, corresponding to confidence intervals of 21.5 per cent, 15.8 per cent, and 11.4 per cent respectively. While some apparent outliers can be seen in the graphs in Figures 9–11, these confidence intervals represent a good level of accuracy, particularly at a weekly and monthly timescale.

CASE STUDY 3

Operation description

Case Study 3 concerns an open pit polymetallic operation. Ore at the site is sourced from three pits, with ROM material processed first through two parallel crushing lines. The first crushing line consists of a jaw crusher receiving feed scalped over a grizzly, while the second consists of an in-pit gyratory crusher, product from which is scalped over another grizzly, with oversize reporting to a mineral sizer. Primary grinding takes place in a 34' SAG mill, which operates in closed circuit with two pebble crushers. Undersize from the SAG screen reports to a cluster of primary cyclones for pre-classification ahead of the secondary ball mill circuit. Undersize from those cyclones feeds directly

into the 24’ ball mill, along with undersize from the ball mill closing cyclones. Overflow from the two cyclone stages reports to flotation, which produces a bulk concentrate, which is sold without further selective flotation.

Forecast model

Hatch, in conjunction with the site’s explosive supplier, completed a M2M optimisation project at the site from December 2019, which concluded with the delivery of the final report and recommendations in July 2020. The M2M project identified several opportunities – including improved drill and blast practices, and optimised operating parameters of the primary and pebble crushers, SAG and ball mills, and cyclones – which were predicted to provide a 13–22 per cent uplift in throughput if implemented in full, while maintaining the product size to flotation. While the implementation of the M2M recommendations was underway, Hatch were engaged to support site in the development of a geometallurgical and throughput forecasting model.

Historically, there had been a small number of comminution tests conducted for the main lithologies in each of the three pits on-site. The test work program included impact testing conducted by external groups, and point load testing (PLT) conducted by the site geology department. A campaign of full Drop Weight (DWi and Axb) and BBWi testing was also completed shortly prior to Hatch’s engagement with site, with the same samples also subject to testing using the Hardness Index Tester (HIT) breakage device. At the time of delivering the model, a campaign of HIT tests on exploration drill core samples was underway, with the intent of further improving orebody definition and the understanding of hardness variability. HIT results representing ores to be processed in 2021 and 2022 were used to predict the throughput for those and subsequent years, with the data for later years to be updated once additional test results become available.

The model itself was based on the general structure described earlier. As in Case Study 1, a site-specific feature was incorporated to capture the impact of the increased fines (-10 mm) in the plant feed associated with the recommended M2M blasting conditions. Once again, this correction involved reducing the calculated specific energy in inverse proportion to the throughput increase predicted for the relevant domain in the M2M study.

A site-specific adjustment was also added to accommodate a proposed partial pre-crushing circuit. The model treats the pre-crushed material as a separate component in the feed with its own required specific energy in the grinding circuit, similar to how each of the different ore types are treated. To calculate the contribution of this stream to the required grinding specific energy, and therefore the overall throughput, an estimate of the pre-crushing circuit throughput and usability is required.

Model validation was completed using process data from 2020 and 2021, which was compared with the throughput forecast model predictions on daily, weekly, monthly, and annual timescales.

Partway through the period of data considered in the model validation, a change to the SAG mill internals occurred, which saw a bi-directional liner design and radial pulp lifters installed, replacing the single-direction configuration which had been in place at the time of the M2M survey. The bi-directional liners and pulp lifters were later removed. The total period for which they had been installed amounted to around 4 months, from a total of 18 months in the validation data set. While changes to SAG mill internals, and particularly the discharge assembly (grates and pulp lifters) can have an impact on mill performance, the model appears to be robust during this period. This is not entirely unsurprising, given details of these components are not inputs into the specific energy calculation. Where care would need to be taken, however, would be in a scenario where significant changes to the grate design are planned, for example to build a larger rock charge to promote fine grinding in the SAG mill and relieve the secondary circuit. In this scenario, drawn power may differ from expectations, while the calibration factors used to estimate SAG specific energy may need to be re-established under the new conditions. Alternatively, where changes are needed to alleviate slurry pooling issues, the subsequent increase in power draw may impact the assumed power draw used for forecasting, as well as the overall grinding efficiency and SAG specific energy relationship.

A second period in the validation data set saw the circuit operated under single-stage SAG conditions. The model was not designed to predict the throughput in this mode of operation and would need to be adjusted to do so. This period was therefore excluded from the validation process.

Those considerations aside, the model predictions showed good agreement with the observed throughput. The relative standard error was approximately 11.8 per cent of the average value on a daily basis, 7.3 per cent on a weekly basis, and 4.9 per cent on a monthly basis. These figures correspond to confidence intervals of 23.1 per cent, 14.6 per cent, and 10.5 per cent respectively, at a 95 per cent confidence level.

CONCLUSION

This paper has presented three case studies from recent throughput forecast projects completed by Hatch. The forecast models described provide the respective sites with a powerful tool for both short – and long-term planning, which can ultimately assist in maximising operational efficiency and profits over the Life-of-Mine. Hatch's methodology combines detailed drill and blast modelling (when available) with widely accepted power-based methodologies for grinding circuit throughput estimation, to provide a model with the flexibility required to assess trade-offs along the full value chain. While not covered here, these models also lend themselves to use alongside models of the downstream separation processes, giving an insight into the impact of changes in the drill and blast or the installation of additional comminution capacity on the overall economics of the operation.

ABSTRACT

In comminution, grindability or 'hardness' indices are used to describe ore resistance to ball milling. The most commonly used measure is the Bond ball mill work index (BBMWi). The implicit assumption underlying this test is that the distribution of mineral hardness within the sample is uniform, or at least falls within a narrow range of variation. This paper considers cases where that assumption is not valid.

In actual industrial practice, feed is subjected to multiple breakage mechanisms and several stages of classification. These may introduce biases in the hardness of material that is actually processed by the ball mill. That is, the actual hardness of feed presented to the ball mill may differ from the fresh circuit feed, especially when transition/weathered ore types are processed. Such ore types tend to exhibit variable breakage characteristics, and separation of their different hardness components is likely during different stages in comminution processes. The result is that harder minerals will tend to concentrate in the ball mill recirculating load. Another example is when crushed SAG pebbles (which are generally comprised of harder minerals) are diverted to the ball milling stage with the aim of improving SAG mill throughput. In this case, ball mills will process material which may be significantly harder than the circuit feed. In both cases, the ball milling stage may become an operational bottleneck. For these milling strategies, results from standard test work conducted on fresh ore samples should be treated with caution.

In addition to proposing a model for describing attrition breakage behaviour, this paper also tests one approach to measuring the extent and impact of ore hardness variability not reflected in standard test work protocols. It presents the results and discusses implications from a laboratory test method, developed at the Julius Kruttschnitt Mineral Research Centre (JKMRC), to investigate the distribution of hardness within samples that would each otherwise be considered 'uniform'. The results from testing three different samples characterised by standard and modified Bond ball tests confirmed that up to a 10 per cent under-estimation in evaluating ore grindability is possible. Under-estimation of ball milling feed hardness increases the risk of ball mills with limited capacity during periods of processing transitional ore domains or when a modified circuit configuration is required for debottlenecking and improvement purposes.

INTRODUCTION

Review of literature

In mining and mineral processing, particle size reduction commences with drilling and blasting operations, continuing through to the comminution circuit where rocks are subjected to different types of breakage environments. The breakage environment depends on the objectives of rock breakage, which varies from transportation in mining, to liberation in milling.

The intrinsic variability of an ore can cause instability in SAG mill throughput (Faramarzi *et al*, 2018, 2019) and inefficient classification, ultimately compromising grind size and recovery (Putland, 2006). To mitigate these risks, comminution characterisation can be undertaken to spatially model the hardness of different regions in a deposit.

In general, comminution characterisation can be conducted as single – or multi-particle test work. The former refers to tests in which individual particles are broken separately at pre-defined levels of energy; these include the JK Drop Weight (Brown, 1992, personal communication; Napier-Munn *et al*, 1996) and SMC tests (Morrell, 2004). The latter refers to tests that require batches of material to be processed in pilot or laboratory mills. Some widely-used batch test examples are the JK abrasion mill test (Leung, 1988), the Bond tumbling mill tests (Bond, 1952), the MacPherson autogenous grindability test (MacPherson and Turner, 1978), and the SAG power index test (Starkey *et al*, 2006). It is important to note that these tests usually are undertaken on 'fresh' circuit feed.

The focus of this paper is to highlight the possibility of problematic changes in ore hardness between the fresh circuit feed and the ball mill feed, that are not necessarily detected with standard testing procedures. Depending on the mineralogical composition of the ore, minerals of higher resistance to grinding would likely accumulate in the ball milling recirculating load (Maxson *et al*, 1933). However, in variable ore types, it is likely that SAG milling preferentially disintegrates softer minerals in the ore which would in turn preferentially exit the grinding circuit, further exacerbating the accumulation of hard minerals in the ball milling recirculating load. It is expected that this effect would be most prominent in weathered ores, which often exhibit the largest degrees of hardness variability in a deposit. But since standard test protocols are applied to fresh circuit feed, this phenomenon would likely remain undetected during comminution test work programs.

The Bond ball mill work index (BBMWi) is the industry-standard measurement of resistance to ball mill grinding. However, low-energy attrition events are applied to the feed during stages as early as crushing, and remain significant contributors to size reduction in both SAG and ball milling. In this context, the review of the literature focuses on the understandings gained from batch attrition test work studies, and how this impacts subsequent grindability.

Implications from attrition breakage characterisation

Previous workers have undertaken experiments to identify key variables in low-energy breakage events, often with a view to incorporating these modes of breakage into comminution models.

Bemrose and Bridgwater (1987) categorise some variables affecting attrition into particle-related and environment-related properties:

- Particle properties include size, shape, surface, porosity, hardness and cracks.
- Breakage environment properties include time, velocity, pressure, shear and temperature.

It has been observed that the rate of attrition decreases with time (Dietz, 1979; Forsythe and Hertwig, 1949). This phenomenon may be due to the initial loss of mass in the form of fines, and then gradual smoothing of particles which are less susceptible to attrition (Bemrose and Bridgwater, 1987).

The importance of this topic in mineral processing has encouraged some researchers to investigate breakage characteristics of ores at low levels of energy, conventionally called 'abrasion' or 'chipping'. Austin *et al* (1986) defined abrasion as the steady removal of relatively small progenies broken from the particle surface as it tumbles in the mill. They conducted dry tests using -63 + 53 mm material, tumbled over a period of 35 minutes in a 600 mm diameter mill. In their experiments, the undersize was screened out and replaced with the same weight of fresh feed at pre-defined time intervals. Test results were plotted as percent weight in the top size fraction versus grinding time, from which the following conclusions were made:

- At the beginning of the test, the rate of mass loss for the fresh feed is high, leading to a steep downward slope. This is probably due to initial chipping and rapid removal of asperities from particle surfaces.
- Percent mass in the oversize decreases gradually as the coarse particles are further abraded over time. This reduces the slope as the test progresses.

Tests at low-energy levels produce a bimodal size distribution that is typical of attrition. Leung (1988) conducted extensive experiments to obtain low-energy appearance functions from bimodal product size distributions by designing two types of tumbling tests (multi-particle and single-particle tumbling tests). It was observed that the product size distributions generated in either test regime were identical. Additionally, he conducted a series of low impact-energy (2.4×10^{-4} kWh/t) tests. The

results of this comparative program, applied to samples from four different mines, indicated that product size distributions from individually tumbled particles, multi-particle tumbling, and low-energy impact tests, were effectively identical.

These experiments also showed that the amount of fine product mainly depends on grind time, mass of charge and the particle size of the charge. Leung's findings formed the basis of the now-standard JK abrasion test that measures the abrasiveness of a given rock sample, expressed in terms of a 't_a' parameter (Napier-Munn *et al*, 1996).

Later, Devasahayam (2013) adopted the standard JK abrasion mill testing approach to investigate the effect of grind time and particle size on the produced bimodal product size distributions. Three kg of -55 + 37.5 mm, -37.5 + 26.5 mm, -26.5 + 22.4 mm and -22.4 + 16 mm size fractions from five different rock samples were prepared. Tests were run up to 10 minutes, and results largely aligned with the findings of Leung (1988) – specifically, that a longer grind time and a smaller size fraction produces a finer product, while the relative shape of the product size distributions remains identical. Devasahayam (2013) concluded that the shape factor of the particles was also a key parameter in abrasion, which varied with particle size and rock type.

Faramarzi (2020) argued that the current abrasion tests, being dry experiments, do not capture the likely effect of water upon attrition or low-energy breakage events that predominate in SAG milling. It is likely that water has an important role in low-energy comminution especially when milling highly altered or weathered ores, which are generally rich in aluminosilicate minerals (eg clays) that can more readily deteriorate in water. Additionally, several other testing issues were highlighted:

- The standard JK abrasion mill test is a dry procedure.
- The test scrubs the surface of the particles for a short period of time, and quantifies rock attrition with a single 't_a' value after 10 minutes of tumbling. Therefore, time-dependencies are not considered in the procedure.

Faramarzi (2020) developed an extended attrition mill testing approach with the aim of capturing the role of ore variability in ore breakage behaviour under low-energy levels in dry and wet modes. The experiments were conducted on eight rock types, and showed that different rock types exhibit different attrition characteristics in wet compared to dry environments. To an extent, this reflected the degree of alteration or weathering of the rock. Preliminary results showed that the role of water might either improve or suppress attrition, depending on the rock type. The outcomes of the attrition tests in wet vs. dry environments led to a suite of experiments that tested the hardness of actual ball milling circuit feed, which was shown to sometimes be harder than fresh circuit feed.

The point is further discussed in the following sections of this paper.

Implications from grindability characterisation

The Bond ball mill test is a batch laboratory test in which the circuit is closed with a limiting screen, to simulate the effect of hydrocyclones that are commonly used to classify ball milling discharge. It is the industry-standard measure of ore grindability, and ultimately is used in ball mill design and geometallurgical modelling. The interaction between the ball mill and classifier drives the material composition in the mill, with harder minerals accumulating in the re-circulating load. The Bond test targets a 250 per cent re-circulating load which is a typical value in conventional ball milling circuits (Man, 2002).

The Bond ball mill has smooth liners to facilitate emptying the mill after each cycle. Additionally, liner packing is avoided with the use of smooth liners. Conversely, most industrial ball mills have lifters and rotate at typical speeds ~72–76 per cent (Morrell, 1996). The charge motion inside the laboratory mill must attain a profile similar to its industrial analogues, and thus with smooth liners the test is undertaken at 91 per cent critical speed.

Blending is common practice to improve feed consistency during production. Yan and Eaton (1994) tested whether the average of grindability of different components is a reliable indicator for ore blends. They carried out experiments on samples of hard rock, soft rock and three differing blends of the two components. It was observed that ore blend grindabilities were weighted more heavily

towards the harder rocks. This suggests that the harder components were accumulating in the circulating load.

Fuerstenau and Venkataraman (1988) showed that minerals of different hardness interact with each other, with harder minerals improving the breakage rates of softer minerals, and with their own breakage rates decreasing with time. It has also been reported that in grinding multi-component feeds, the breakage rate functions of individual minerals change with variations in the composition of the mill hold-up (Fuerstenau and Venkataraman, 1988; Yan and Eaton, 1994).

Yan and Eaton (1994) asserted that in grinding a blend of hard and soft components in closed-cycle, the harder components break at slower rates and eventually predominate in the recirculating load. Accumulation of the harder components in the mill was evident during the Bond ball tests as well. They concluded that Bond ball testing may not be appropriate on ores of widely differing grindability, since the composition of the mill hold-up material may not represent the composition of the starting blend. This finding is analogous to the changes in composition that can take place between SAG milling and ball milling.

Implications from the extended attrition mill tests

Details of the extended attrition mill testing are provided in the Appendix A of this paper. The 'M10' variable (%) is the amount of material passing 1/10th of the geometric mean size of the original size interval (Faramarzi, 2020). Figure 1, shows the samples tested as well as the colour of their progenies after a comminution test; Table 1 summarises their comminution properties as a reference.

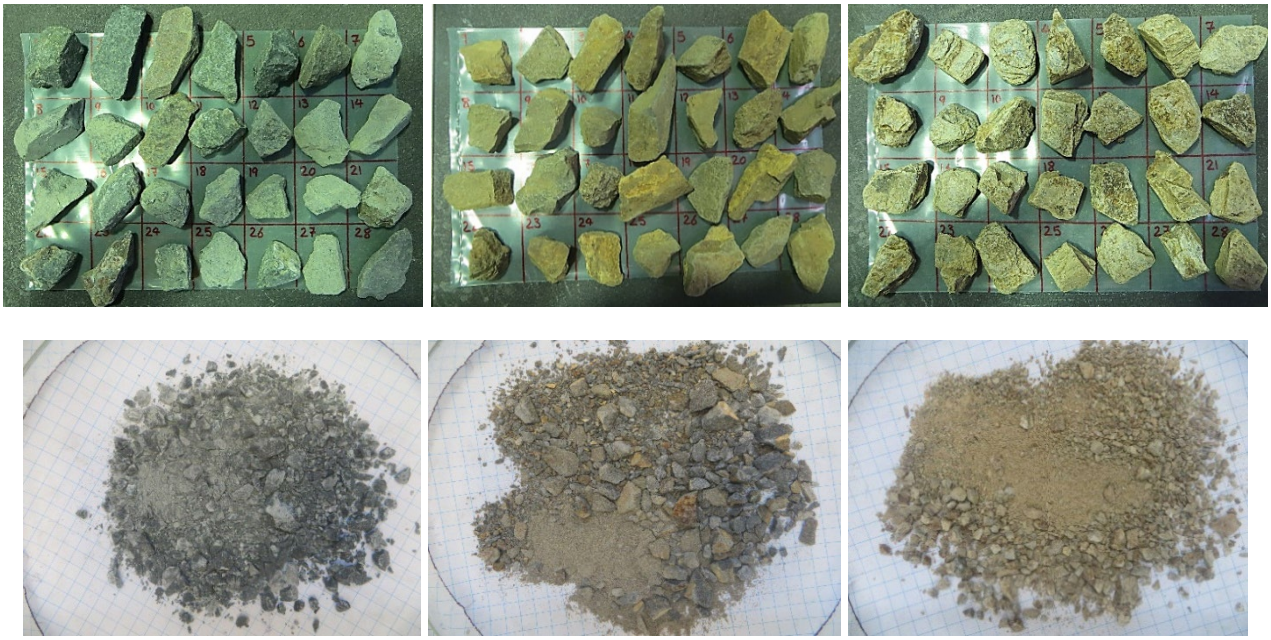

FIG 1 – Left to Right (Top): Sample A: Cadia Block Caved Gold Mine; Sample B: Maaden Gold Mine; Sample C: Weathered JK Site Rock; Left to Right (Bottom): Progenies for Samples A, B and C.

TABLE 1

Standard comminution and physical properties of tested samples.

Description	ta*	A×b	BBMWi (kWh/t)	Density (t/m^3)
Sample A	0.23	30	19.7	2.74
Sample B	0.30	30	12.7	2.70
Sample C	0.91	71	11.9	2.55

*Abrasion ore parameter.

Figure 2 shows the results of the extended attrition mill test for the three samples. The rate of mass loss for Sample A is low and is similar in both dry and wet modes. The rate of mass loss for Sample B is higher and the difference between dry and wet modes is more evident. Figure 3 shows that the rate of mass loss is very high for Sample C in both dry and wet modes.

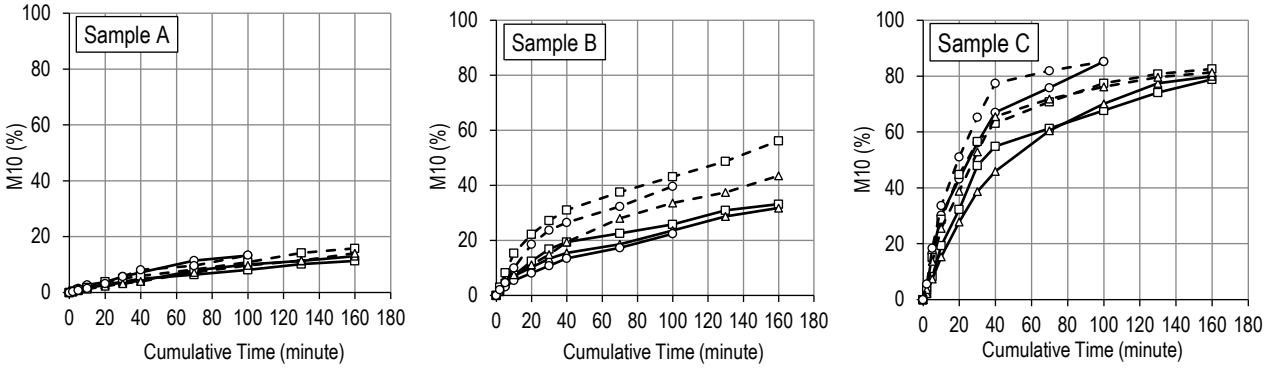

FIG 2 – Experimental results for three samples, with each sample tested three times (solid line for dry and dashed line for wet experiments).

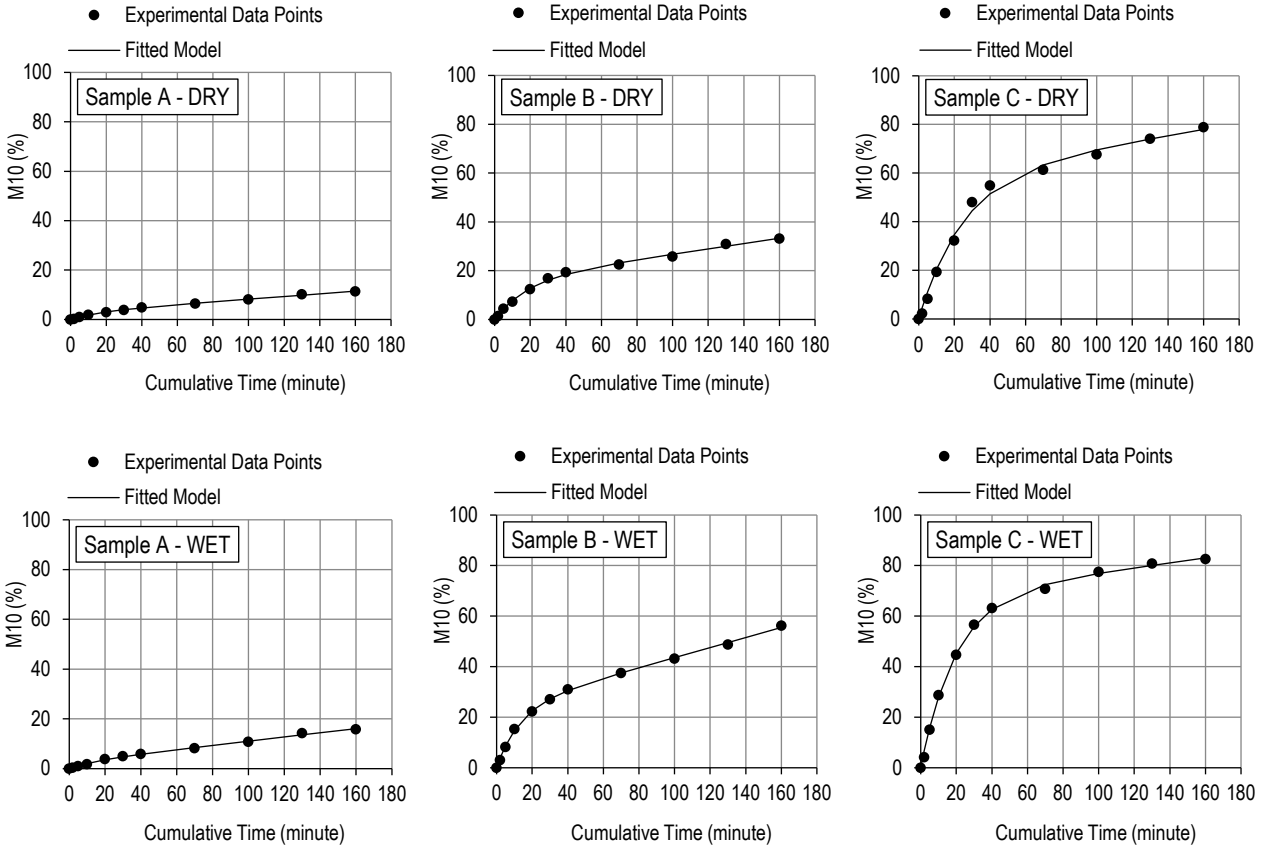

FIG 3 – Equation 2 fitted to the experimental data points of Test 1 – as an example.

The observed difference between dry and wet modes for Samples B and C may have been a consequence of their altered or weathered nature. Figure 2 shows that as expected, a rapid rounding and smoothing process occurs first followed by an almost constant rate of mass loss while the grinding environment remains more or less constant. It also indicates that water can promote the effect of low-energy breakage events.

Faramarzi (2020) used an exponential model which provided a good description of the rapid mass loss phase. However, we can combine the two relationships for a wider range estimate of M10 at time t minutes:

$$M10 = C + mt - C(1 - \exp(-Tt)) \quad (1)$$

where *m* is the slope of the linear processes, that is the rate of mass loss and *C* is the projected intercept at *t* = 0. The second term is an exponential decay which is equal to – *C* at *t* = 0. The rate of decay T controls how quickly the rounding process occurs and is the rate constant.

The model can be further simplified:

$$M10 = mt + C(1 - \exp(-Tt)) \quad (2)$$

Figure 3 shows that this model is a good match to the measured data. Tables 2 and 3 show the derived parameters and the standard error of the model fit or the estimate.

Observations based on the model parameters

Sample A which is appreciably harder than samples B and C shows very similar parameters for wet and dry attrition. The intercept C at 2.7 per cent suggests that only a small amount of rounding and smoothing occurs.

The grinding rate *m* for Sample A is much lower than for Sample B. Surprisingly *m* for Sample C is lower again. However, that may be because with a *C* value of 58 per cent, the intensity of the grinding environment will have been substantially reduced.

Sample B has a much lower *C* value of 15.9 per cent and should enjoy a more constant grinding environment. However, an *m* which correlates better with mill performance may need to be normalised with an estimated or measured mill power draw.

The Bond test overcomes these issues by using a well-controlled ball charge and restoring the ore loading before each cycle.

The initial rapid wear phases enjoy a much more similar grinding environment and should offer more valid comparisons. The two harder ores A and B have similar dry rate constants *T*, but the altered Sample C has a much lower value. As noted earlier, fresh ore Sample A shows similar parameters, but oxidised/altered Samples B and C show appreciably increased rates of initial loss and intercept when milled wet.

Overall, this model provides a way to estimate M10 over time and to compare how quickly and how much rounding will occur. However, as noted earlier, the *m* parameter may need to be normalised against power draw to be useful for prediction of attrition in other environments.

As the Bond test is based on grams of new product per revolution, the presence of or absence of -106 µm material in the feed sample makes little difference.

The modified feed does allow a little more of the new volume for grinding – about 25 per cent, but as the volume of feed is matched to the interstitial ball space, it does not make much difference.

Concluding remarks on attrition breakage behaviour

The rounding of Sample A is just that and does not imply a multicomponent feed. This is consistent with the C value of 2.7 per cent wet and dry, which suggests that ore A is also highly uniform with respect to hardness. The measured work indices overlap at less than two standard deviations.

Samples B and C have much broader distributions of hardness losing around 30 per cent of the soft feed hardness distribution as -425 µm. Hence the remaining feed material should be harder on average than the standard feed as suggested by the C values of 16 and 58 per cent respectively for Samples B and C. Their measured work indices do not overlap at two standard deviations.

Some other key observations during the test work were:

- The slow rate of attrition for the hard rock samples in dry and wet modes, producing more rounded particles. The colour of the product after each cycle was similar to the final product in both the dry and wet modes.
- The fast separation and disintegration of the soft components (likely to be clays and oxides) from the hard components (probably quartz) during the early stages of tumbling, particularly when wet. This was especially the case for Sample C (see Figure 2).
- Changes to the colour of the product in dry and wet modes. For example, in the case of Sample C, as the test proceeded the product colour changed from dark brown to light brown, ending with an almost white, silica-rich material.
- Decreasing viscosity of the slurry product in the wet tests, probably due to further removal of the clay minerals from the original sample after each cycle. This was particularly the case for Sample C.

The outcomes from this suite of experiments formed the basis of the hypothesis in the next section.

Statement of problem

The results of the extended attrition mill test in dry and wet modes lead to the following question and hypothesis:

- When a typical SAB or SABC circuit processes a transition ore type, a considerable amount of the softer material grinds out the SAG mill and reports directly to the hydrocyclone overflow; consequently, the harder (and coarser) material with a truncated particle size distribution (PSD) is introduced to the ball mill which accumulates in the recirculating load and ultimately constrains milling capacity.

  This potentially results in a change in BBMWi between the fresh circuit feed hardness, and the actual hardness introduced to the ball mills (see Figure 4).

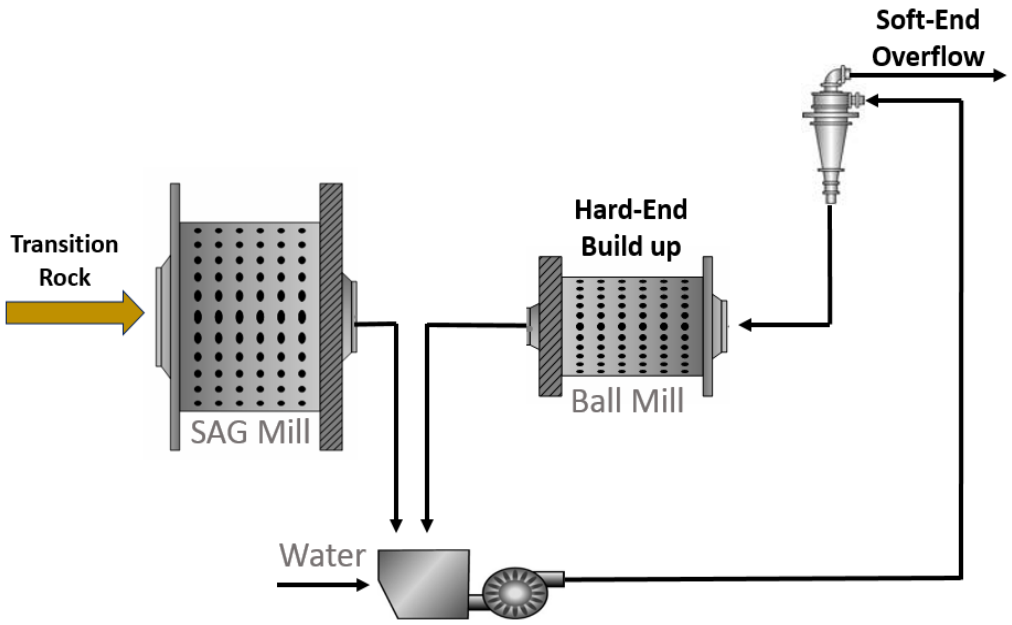

FIG 4 – Typical SAG – ball milling circuit configuration.

EXPERIMENTAL DESIGN

A test work program was designed to mimic the effect of attrition of rocks prior to introduction into ball milling circuits. It was assumed that scrubbing the material in a wet environment would remove some soft minerals in the feed, similarly to what occurs inside SAG mills. Additionally, a classification stage was introduced to mimic the duty of a hydrocyclone and generate a 'truncated' feed size distribution. The sample preparation process was as follows:

1. Material was crushed to -3.35 mm.
2. 4000 g of -3.35 mm material was fed to the JK abrasion mill (300 mm diameter × 300 mm length with four 10 mm lifter bars).
3. 1.5 L fresh water was added to the mill.
4. The mill was operated for 20 minutes at 53 rev/min.
5. The mill was emptied, and the product wet-sieved on a 425 µm screen.
6. The +425 µm material was oven-dried, and the undersize discarded.
7. After drying, the +425 µm material was re-sieved on a 425 µm screen to ensure good separation of fines.
8. This process was repeated several times to collect sufficient -3.35 mm + 425 µm material.
9. The standard Bond ball mill test was undertaken on the prepared samples.

For each ore type (shown in Figure 1), three samples were prepared based on the modified approach and three samples were prepared with the standard Bond procedure.

The closing screen sizes for Sample A were 106 µm for four experiments, and 150 µm for the other two which is reflected in a coarser product PSD for 'modified tests 1 and 2' shown in Figure 5. All experiments on Samples B and C were conducted with a closing size of 150 µm. The feed and product PSDs show good consistency in the experimental work.

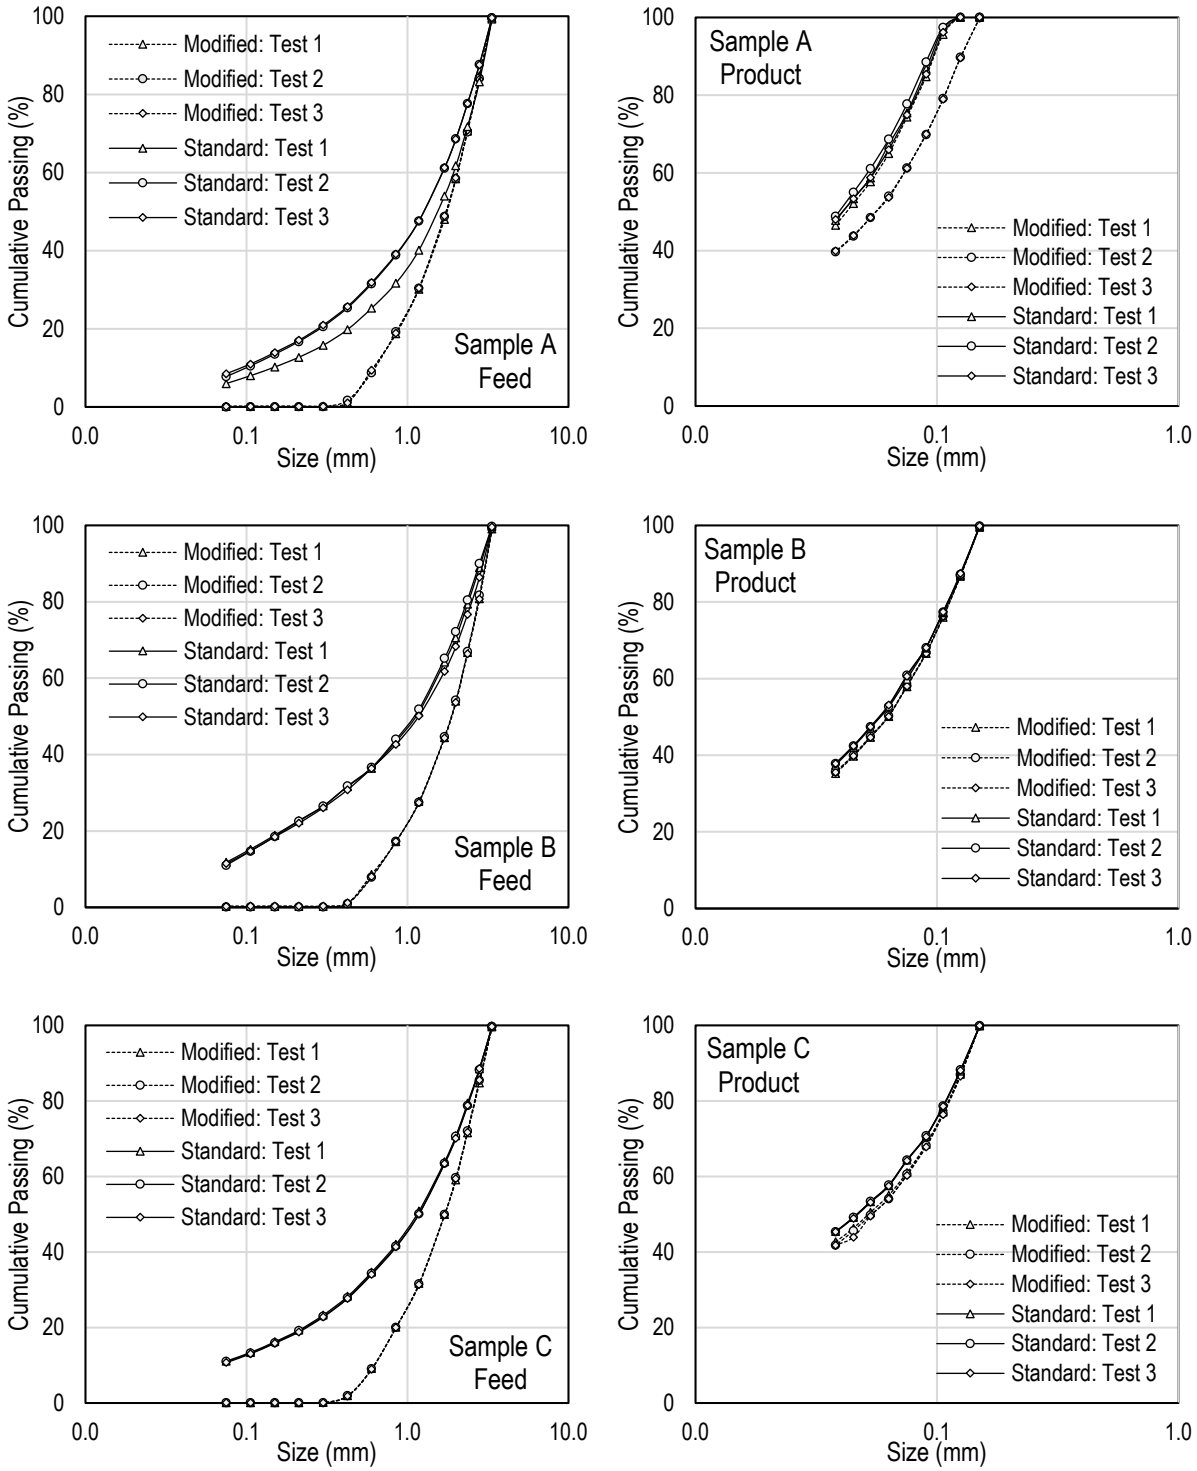

FIG 5 – Feed and product size distributions for all Bond ball mill tests.

RESULTS AND ANALYSIS

The Bond ball mill experiments (Standard versus Modified sample preparations) were undertaken three times on each sample. The measured BBMWi values as well as confidence limits (CL) are reported in Table 4.

The BBMWi values measured by the standard and modified Bond ball experiments are illustrated in Figure 6.

TABLE 4

Summary statistics of Bond ball mill tests (Standard versus Modified sample preparations).

Type of Test	Bond Ball Mill Test (Standard Sample Prep)			Bond Ball Mill Test (Modified Sample Prep)		
Measurable	BBMWi (kWh/t)			BBMWi (kWh/t)		
Sample	Sample A	Sample B	Sample C	Sample A	Sample B	Sample C
Test 1	19.8 (CS=106um)	12.8 (CS=150um)	11.9 (CS=150um)	20.6 (CS=106um)	14.0 (CS=150um)	13.1 (CS=150um)
Test 2	19.7 (CS=106um)	12.5 (CS=150um)	11.9 (CS=150um)	20.7 (CS=150um)	13.9 (CS=150um)	13.0 (CS=150um)
Test 3	19.6 (CS=106um)	12.7 (CS=150um)	11.9 (CS=150um)	21.0 (CS=150um)	13.9 (CS=150um)	13.4 (CS=150um)
Mean	19.7	12.7	11.9	20.8	13.9	13.2
SD	0.10	0.15	0.00	0.21	0.06	0.21
95% CL	0.25	0.38	0.00	0.52	0.14	0.52

SD: Standard Deviation, CL: Confidence Limit, CS: Closing Screen.

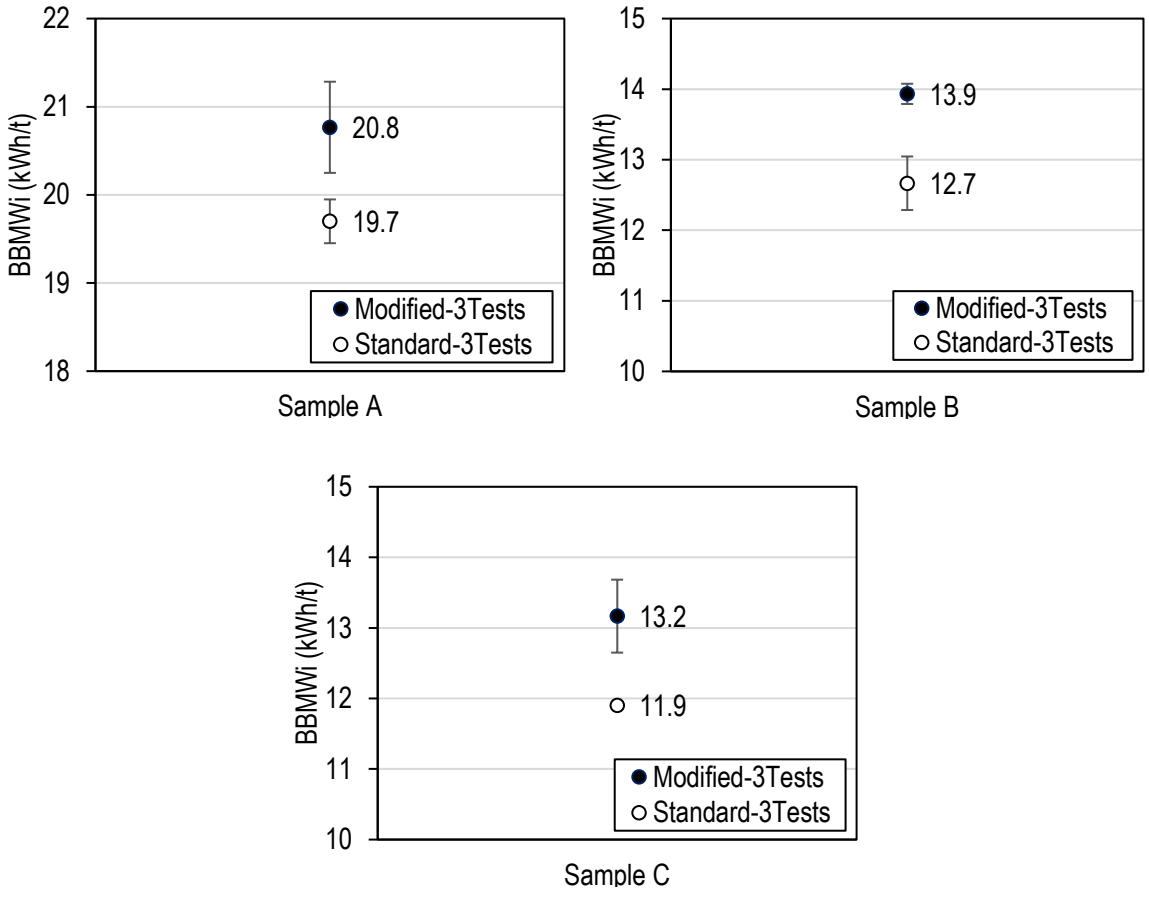

FIG 6 – Comparison of standard and modified BBMWi values.

In each test, the modified procedure resulted in 'harder' BBMWi results. While the magnitude of this change differed between each sample, all increases in BBMWi from the baseline standard procedure to the modified procedure were statistically significant.

The differences in the BBMWi values between the standard and modified testing procedures are likely to be driven by ore mineralogy and texture, and to some degree the removal of the -425 µm fines. That is, in the case of variable ores, the feed prepared through the modified sample preparation is concentrated in harder minerals following the removal of softer minerals. However, the circulating load in the BBMWI test is truncated as the closed-circuit size as part of the standard test. This factor will reduce the sensitivity to using a truncated feed.

Figure 7 compares the grindability of all samples during the experiments. For Sample A (a fresh, competent, less heterogeneous rock type) it was difficult to differentiate between grindability rates of the standard (Mean = 0.863 g/rev) and modified (Mean = 0.876 g/rev) experiments. However, Sample B (a competent but more variable rock type) shows a significant difference in grindability between the standard (Mean = 1.547 g/rev) and modified (Mean = 1.785 g/rev) tests. Sample C (a weathered, soft and variable rock sample) shows similar patterns between the standard (Mean = 1.629 g/rev) and modified (Mean = 1.864 g/rev) tests.

As shown in Figure 7, the grindability rates for Sample A show no significant difference between standard and modified tests, which is characteristic of a competent ore type. It is interesting to note that for Samples B and C, standard and modified feeds resulted in significantly different grindability rates at all stages. A possible reason would be the presence of higher concentrations of hard minerals in the modified feed. That is, the attrition process in wet environments results in preferential disintegration and separation of 'softer' minerals from the initial feed. Mineralogical analysis is required for confirming possible changes in composition in these ore samples, which should be considered in future investigations.

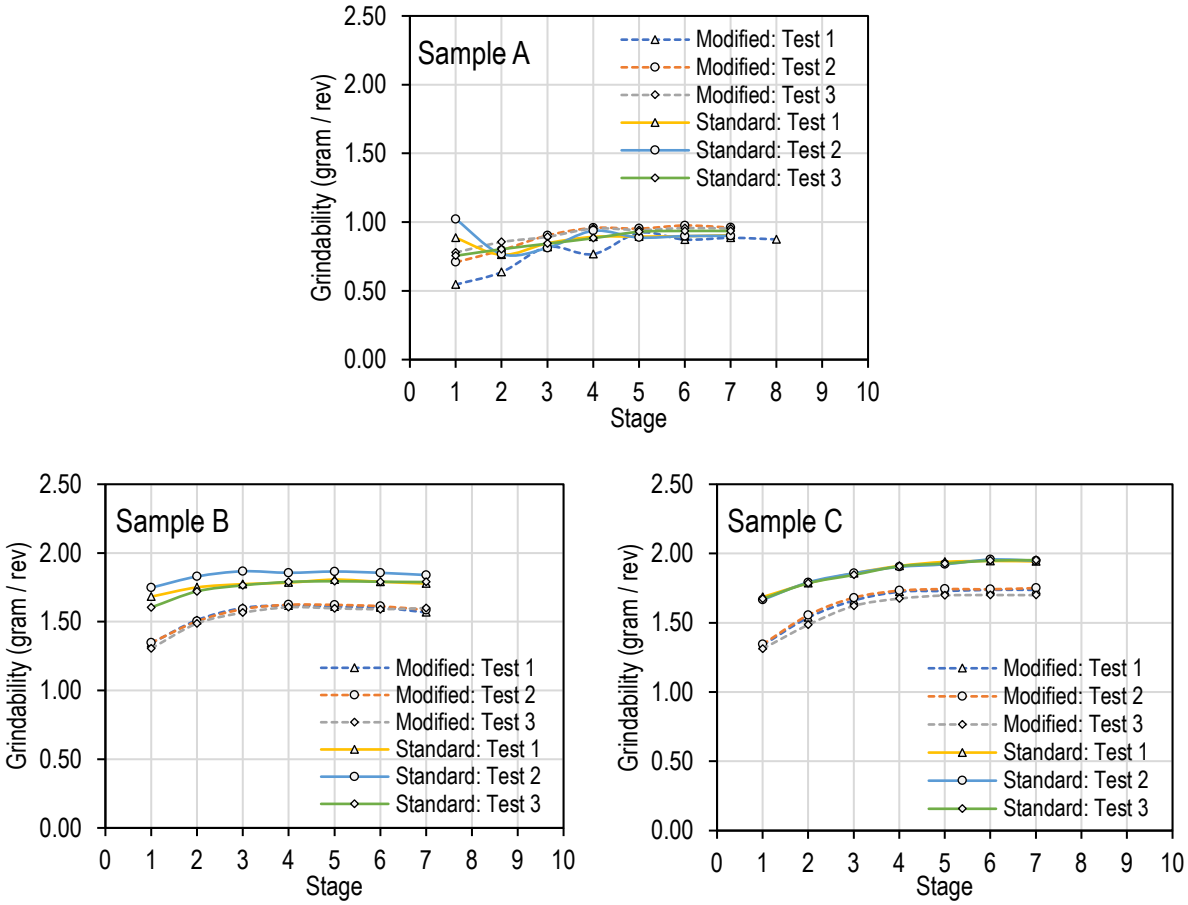

FIG 7 – Grindability rate per stage for all Bond ball mill tests.

DISCUSSION

A simple model of the process has been developed. The model parameters provide quantitative characterisation of the rounding phase and the more uniform rate of attrition phase after removal of asperities and altered material.

To further understand the implications of ore variability, the possibility of hardness/grindability changes through the comminution-classification process was examined by developing a suite of novel laboratory experiments. The outcomes are considered indicative and should assist future investigations in improving ore testing procedures.

Although standard 'average-based' comminution tests provide indicative measurements of ore hardness properties, not accounting for possible changes in material hardness at different stages of

a flow sheet could render standard test outcomes as misleading. At worst, this may result in the selection of a ball mill which is too small.

The attrition tumbling mill testing approach in dry and wet modes characterises the amenability of rock samples to attrition. The difference between wet and dry attrition parameters to some extent indicates the degree of alteration or weathering of the rock (eg clay-rich samples). The indications from these experiments suggest that it would be beneficial if standard testing methods are improved to obtain more information on ore breakage behaviour on a stage-by-stage basis, particularly before and after classification steps where removal of fine particles from the circuit could bias the composition of recirculating loads towards harder minerals.

The results of this study suggest that it is likely that comminution characteristics (ie BBMWi) of fresh, competent ore types (eg Sample A) remain largely consistent through the milling process. That is, the BBMWi of fresh feed will be representative of ball milling feed. Conversely, for weathered samples where soft minerals are susceptible to rapid deterioration in the presence of water (eg Samples B and C), size reduction and classification processes might bias ball milling feed grindability towards harder minerals.

It is worth noting that this effect can, in other ways, offset the benefit of strategies that are otherwise intended to improve circuit performance. One example is when crushed SAG pebbles (which are generally comprised of larger percentages of hard minerals when compared to fresh feed) are diverted to the ball milling stage with the aim of improving SAG mill throughput. This can overload ball mills with material that may be significantly harder than the circuit feed.

Overall, the results of this study suggest that depending on the ore characteristics, ball mill feed hardness could increase by 10 per cent compared to fresh circuit feed, which is otherwise tested in conventional test work programs. This difference might be exacerbated with different circuit configurations, and should be investigated in future research.

CONCLUSIONS

The standard ore hardness test work procedures assume reasonably homogeneous feed. The test work approach detailed in this paper provides a way to quantify variability arising from non-homogenous feed. High variability will most likely increase the required ball milling power compared with traditional design techniques. Hence one way to reduce risk associated with high variability would be to increase contingency in ball mill selection.

The novel tests undertaken in this study showed that, depending on the degree of alteration/weathering of an ore, the rates of attrition in dry versus wet environments could differ, due to the preferential breakage (and removal from the grinding circuit) of soft minerals prior to ball milling. This has implications for the subsequent grindability of these types of rocks, as measured with Bond work index testing.

Key conclusions from this study are as follows:

- The results from this initial suite of experiments suggest that, depending on ore properties, up to a 10 per cent difference in hardness between circuit feed and the actual ball mill feed is possible. However, the difference may become more pronounced for highly variable ore types.
- Higher BBMWi values for samples prepared with the modified procedure are likely to be driven by ore mineralogy.
- Therefore, for orebodies of highly variable mineralogy, the standard Bond ball mill results should be treated with caution; for design purposes, higher risk factors should be considered when sizing mills.

Future experiments could compare Bond test results on circuit feed samples versus samples obtained from the hydrocyclone underflow of a full-scale production plant. Correlating these differences with mineralogical data will help operations better refine production strategies when dealing with highly variable/multicomponent ore types.

APPENDIX A

The testing procedure is illustrated in Figure A1. The extended attrition mill testing approach steps are as follows (Faramarzi, 2020):

- A 300 mm diameter × 300 mm long tumbling mill with four 10 mm lifter bars.
- The mill speed is 53 rev/min.
- Sample requirement is 4000 ± 30 g.
- Particles suitable for this testing approach can be in either of -63 + 53 mm, -53 + 45 mm, -45 + 37.5 mm, -37.5 + 31.5 mm and -31.5 + 26.5 mm or a combination of two successive size fractions. However, it has to be noted that the experiments were conducted by using 4000 ± 30 g particles in the size range of -63 + 45 mm (2000 ± 15 g of -63 + 53 mm and 2000 ± 15 g of -53 + 45 mm). It was aimed to use very coarse particles, assuming that they should contain more elements of intrinsic variability.
- Accumulative grind time is 100 minutes. It includes time intervals/cycles at which tumbling stops to measure mass loss at a defined size criterion. In this study, the accumulative grind time was extended to 160 minutes for several experiments to further investigate the effect of time on attrition behaviour of the tested samples.
- The testing approach includes two separate experiments in the wet and dry modes. In the wet mode, 1.5 litre fresh water is used in the first cycle as well as each of the time intervals.

The measurable is mass loss at a certain size criterion at the end of each cycle. Therefore, two 'characteristic' sizes were chosen as size criteria as below:

- M2 size: It is used to separate the product at 1/2nd of the geometric mean size of the upper and lower apertures of the original size interval. All the particles smaller than M2 size are removed and coarser particles will be present in the next cycle.
- M10 size: The M10 variable expressible in percent is the amount of material passing 1/10th of the geometric mean size of the upper and lower apertures of the original size interval. This variable is used in the modelling.
- Additionally, mass of the particles that are still falling in the original size range is measured in each cycle. This variable shows percentage of mass loss within the original size range after each cycle.

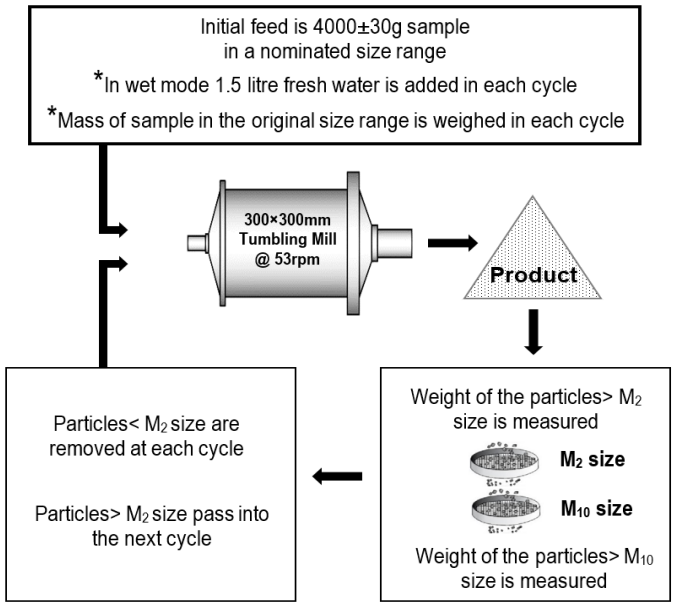

FIG A1 – The extended attrition mill testing approach procedure (Faramarzi, 2020).

Digitalisation of conveyed ore flows and using real time composition data to improve process performance

H Kurth[1]

1. Chief Marketing Officer, Minerals Consultant, Scantech International Pty Ltd, Underwood Qld 4119. Email: h.kurth@scantech.com.au

ABSTRACT

Advanced sensing technologies are used to measure conveyed flow composition in real time in many commodities to provide data for improved process control. The most reliable data is supplied by continuous, fully penetrative sensing techniques that representatively measure material in timely increments. Parameters measured in conveyed flows include elemental content, moisture and mineralogy using different methods. Quantitative techniques include high specification Prompt Gamma Neutron Activation Analysis (PGNAA) proven to provide multi-elemental content at high precisions, Magnetic Resonance (MR) proven to measure a range of minerals, and microwave transmission proven to be effective for moisture measurement. These techniques are largely independent of particle size, belt speed, segregation, dust, or matrix effects. Other techniques have generally proven to be qualitative by sensing only parts of the surface of conveyed material. These provide less compositional certainty due to high sampling error. Measuring conveyed flows over short time increments provides high selectivity as each decision can be made on a relatively small mass. This higher resolution provides opportunities for ore and waste separation between the mine and mill to upgrade ore and reduce waste entering the process. The higher measurement precisions also provide greater confidence in responses to the data. Data can be customised to suit ore tracking, ore blending, bulk diversion (bulk sorting), ore reconciliation, feed forward control, and metal accounting. While proven in many of these applications in the case studies outlined in the paper, further benefits are available through increased use of advanced analytics and digital twin modelling to relate composition fingerprinting to process performance. Process performance improvements can be modelled and implemented as each ore type is received for processing. Geometallurgical parameters that affect process performance are used at multiple stages in processing to optimise performance and examples are provided.

INTRODUCTION

It seems obvious to say that measurement is a requirement for quality management and process improvement, yet few mining operations implement proven, representative measurement technologies early in the bulk material flows between the mine and processing operations. The opportunity to improve many aspects of the operations using this data is therefore commonly overlooked. These opportunities include the digitalisation of the ore and waste quality to provide high precision, real time data considered by many sites as essential to manage and improve their performance (Arena and McTiernan, 2011; Balzan *et al,* 2016; Kurth and Balzan, 2017; Matthews and du Toit, 2011; Patel, 2014). Applications include:

- feedback of actual mined material quality to the mining and geology teams for reconciliation,
- active grade (quality) control through ore blending and/or bulk diversion (bulk sorting),
- feed forward of ore quality data to process operations to enable responses to process impacting parameters, and
- metal accounting to help processing operations reconcile metal content in feed with product and discard flows.

The paper discusses some of the representative sensing technologies that have been proven for conveyed flows and how the data they produce, presented via case studies, can benefit existing mining operations.

Conveyed flows provide continuous movement of materials in relatively predictable configurations which are ideal for sensor applications. Existing measures of flow variability via belt scales or

volumetric flow measurement are utilised as inputs to penetrative sensing systems to enable representative measurement through tonnage weighted compositional data.

HETEROGENEITY

Segregation is common in mining and most ores and waste materials display obvious heterogeneity due to mineralogical characteristics that include; density variation, brittleness, predisposition to break with preference for finer fractions where material is friable, or larger particles if massive and competent. It is common for the grade by size analysis to show preferences for fines to be higher grade in some commodities and lower grade in others. Every orebody is sufficiently different in composition and structure that few can be considered the same when it comes to application of sensing technologies for broken rock measurement. The segregation is further complicated by bulk material handling processes which may mix materials and therefore early measurement is essential to take advantage of quality variability. Heterogeneity is always present at some scale despite multiple handling stages (see Figures 1 and 2). This affects which technologies can be considered. Process feed variability has a major effect on process performance (Goodall, 2021) and should therefore be measured and managed. A ten percent reduction in metal recoveries due to increased feed quality variability can be the difference between profit and loss for a mining operation.

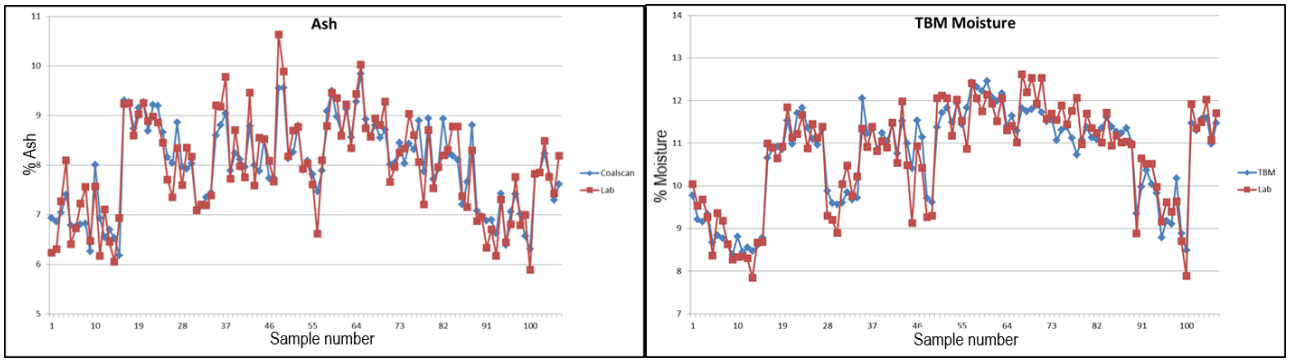

FIG 1 – Typical heterogeneity of ash and moisture content in coal.

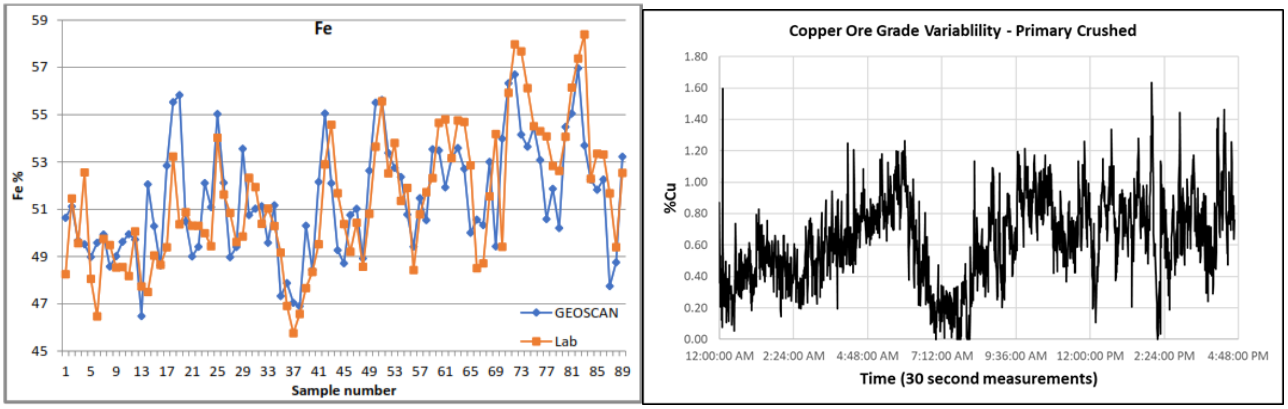

FIG 2 – Typical heterogeneity in iron ore and porphyry copper-gold run-of-mine ore.

The impact of plant feed quality variability has been studied by many companies when major changes in process performance needed to be explained retrospectively. Figure 3 is an example of the impact on metal recovery where variable feed quality was present but with the same average grade. A reduction in metal recovery of 15 percent is financially disastrous for any operation, but can be avoided through better ore quality management.

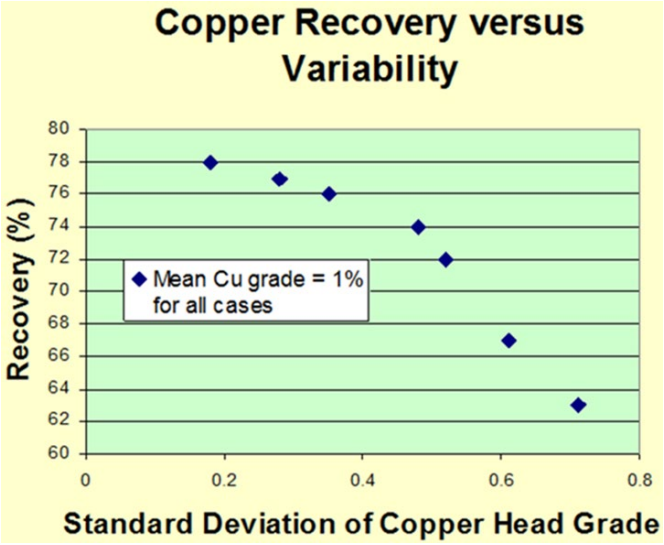

FIG 3 – An example of the effect of ore quality variability on metal recoveries (Codelco, 2007).

SENSING TECHNOLOGIES

The focus of the paper is on technologies providing timely, representative measurement. There are not many commercially available technologies for ore and waste measurement that have proven to provide unbiased results when evaluated against intensive sampling and sub-sampling of a measured interval or increment.

Representative measurement

Representative measurement occurs when the data generated is unbiased, which requires that all material has an equal probability of influencing the measurement outcome without preference to any specific component. It implies that any characteristic of the material that prevents this will result in a bias in the measurement. The heterogeneity of materials will change at some scale through handling. Heterogeneity between particles increases as they are reduced in size and ultimately reaches its maximum when all minerals are liberated, usually after fine grinding. The mineralisation style will influence how heterogeneous the particles may be in a flow. What has been clear through decades of measurement experience with Scantech analysers is that all commodities exhibit heterogeneity including coal, iron ore, bauxite, phosphate rock, porphyry copper-gold and many more, some of which appear to be considered more homogeneous due to the disseminated nature of the minerals, but which at smaller scales (several tonnes) are shown to contain significant variability.

To be considered representative the sensing should be transmissive through the full material depth and not biased by any physical characteristics such as particle size, movement speed, physics of the sensing technology, segregation of material, matrix effect changes, effect of the conveyance type, or other aspect. There is not a single technology that can provide every parameter of interest for a complete solution for elemental (chemical) content, moisture, mineralogy, particle size distribution, ore texture, mineral form (crystallography), hardness, abrasiveness and other parameters that influence processing performance. It is therefore appropriate to utilise whichever sensing techniques can be applied to provide representative analysis and to use further data as proxies, where strong correlations exist, for parameters that can’t be directly measured.

Techniques that have proven to provide representative measurement include high specification prompt gamma neutron activation analysis (PGNAA) for elemental analysis, microwave transmission for free moisture measurement, and magnetic resonance for mineral sensing. Magnetic resonance (MR) can be applied to conveyed flows to measure the response of certain minerals, but each analyser can only be configured to measure one mineral, so if there are multiple minerals of interest then multiple units are required or assumptions need to be made, which introduces errors. The MR is fast and penetrative, making it representative, though somewhat limited in its application as few sites are fully dependent on only one mineral for their overall process performance. Grade is calculated from the direct measurement of one mineral only, hence this technique has numerous limitations.

The through belt moisture (TBM) transmission microwave technology is effective in measuring free moisture content in conveyed flows utilising the dielectric properties of the material relative to those of water. Attenuation and group delay in microwave signals penetrating the full conveyed flow continuously indicate the amount of free moisture present, when proportioned to the mass flow provide a percent free moisture content.

High performance PGNAA for high precision, multi-elemental analysis over conveyed increments of 30 seconds to two minutes uniquely provides representative analysis of conveyed composition irrespective of the atomic arrangement of the elements contained in the flow. The chemical analysis can be reported in the form of total by element typical for metal content, or as common oxides of elements, or as elemental ratios, or in the form of mineralogy depending on how the stream of digital data is intended to be utilised. PGNAA utilises a small neutron source, typically Californium-252, to expose the conveyed material to the neutrons at a rate of over 100 million neutrons per second. Elemental nuclei capture neutrons and emit unique prompt gamma signatures which are detected allowing a combined spectral response to be accumulated over each analysis time increment. The finger print of each element's response is used to identify the proportion present in the spectral response and any variation in mass flow is used to weight the responses over the measurement time interval.

PROCESS PERFORMANCE BENEFITS

Representative moisture measurement is useful for dry tonnage determination for ore reconciliation and metal accounting, management of dust, filter and dryer control, and provides information on material handling impacts for some ore types. Changes in moisture content can reflect changes in mineralogy, for example clay content. The continuously measured moisture content replaces the moisture factors commonly applied for mill feed. The factors are determined through one-off reconciliation exercises and applied continuously irrespective of ore sources, weather conditions (rain) and seasonal changes.

Barrick's digital transformation program at Cortez (Bozbay and Moyo, 2019) included process objectives to address:

- reduction of manual tasks that pose a high risk to employees (specifically sampling from conveyor belts in hazardous areas such as reclaim tunnels),
- collecting field data that would lead to process optimisation (availability of timely data), and
- targeting best operating practices (not stopping conveyors to take samples and interrupt production).

An increase in ore throughput of three percent was achieved within two months of implementing a moisture analyser (Figure 4). This ensured compliance with the site's dry tonnage processing permit and increased the value of contained gold in plant feed by USD 75 million per annum based on USD 1500 per ounce.

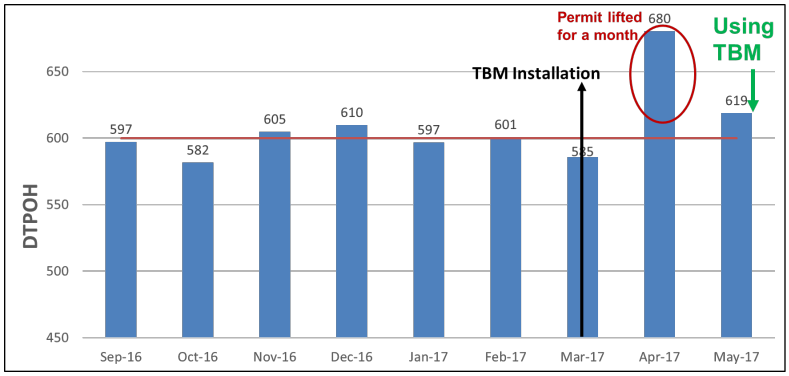

FIG 4 – Benefit of moisture measurement over moisture factor on ore feed (after Bozbay and Moyo, 2019).

The high specification PGNAA technique has proven highly reliable for 30 second measurement intervals and has enabled high confidence in diversion (bulk ore sorting) decisions and minimised misallocation of material evident in lower specification systems and unrepresentative measurement technologies. Kurth (2022) showed that the magnitude of the difference between sensing system precisions is significant in metal recovered to the mill feed using a copper bulk ore sorting example. Analyser precision directly affects material allocation efficiency. The additional contained metal recovered to the ore stream when using more precise measurement in operations processing 1000–1500 t/h is valued at tens of millions of dollars per annum.

Figure 5 shows a mobile ore sorting plant configuration incorporating a high specification PGNAA GEOSCAN analyser that measures each 30 seconds of conveyed flow with a precision of about 0.03 per cent Cu. Anglo American (2019) was quoted in International Mining in July 2019 saying that:

> *at El Soldado, we are sorting in four tonne packages. …. Being able to remove an orebody above the cut-off grade alongside waste tonnages and upgrade the latter has led to an effective lift in head grade. It has been enabled by new sensing technology with a particular type of neutron sensor. What we have seen in early results has surprised us on the upside. We thought we would see a 5% uplift in head grade, but in fact we have seen about 20% – to qualify that, it's in its early stages.*

FIG 5 – GEOSCAN analyser in a copper ore bulk sorting plant at El Soldado, Chile (source: Hillyer, 2019).

The benefits accumulate as bulk sensing of a conveyed flow provides a set of digital measurements that can be used immediately for active control of the quality by means of bulk diversion but also by feedback to adjust ore blends where that flexibility exists from stockpiles or mine sources. The same data can be used to feed forward to the process operators to warn of quality changes and also to adjust process settings. These include adjustments to mill feed rate based on ore quality and other process impacting parameters such as ore hardness, clay content etc (Kurth, 2018). Changes in ore type or quality can also be used to adjust reagent addition, particularly where variations in deleterious content can lead to contamination of concentrate if not addressed. Many of the characteristics of the ore can be measured, calculated or determined from the composition measurement before processing. Sepon process operators utilised the real time data for copper ore blending, pyrite proportioning to feed a ferric leach process, and determination of acid consuming gangue content and moisture for pH control (Balzan *et al,* 2016). They also achieved a 0.4 per cent metal accounting error.

Benefits of real time, high quality elemental and moisture measurement data in iron ore are exemplified through the applications at Assmang Khumani (Matthews and du Toit, 2011) where a detailed understanding of the ore types at multiple mines feeding a beneficiation plant have realised many benefits. This application is seen as a successful implementation of operation geometallurgy.

Ore chemical composition enabled different categories (Table 1) to be defined and utilised through conveyed material sensing. Material considered ‘on-grade’ on the overland conveyors is determined to be of product quality not requiring beneficiation through the jig plant and increments meeting these compositional criteria are diverted to bypass the jigs. The five million tonnes per annum bypassing the plant saves upwards of AUD 6 million per annum in beneficiation costs alone and represents 30–35 per cent of total product.

TABLE 1

Algorithms used for run-of-mine classification (after Matthews and du Toit, 2011).

	%Fe	%Al_2O_3	%K_2O+%Na_2O	%SiO_2	%Estimated yield
On-grade	>=65.3	<=1.8	<=0.25	<=2.5	>91
Just barely off spec	>=65.3	>1.8 & <=2.2	>0.25 & <=0.35	>2.5 & <=4.5	>80
Off-grade high	<65.3 & >60	>2.2 & <=3.2	>0.35 & <=0.40	>4.5 & <=6.5	>60 & <80
Off-grade low	<65.3 & >60	>3.2	>0.40 & <=0.54	>6.5 & <=12	>45 & <60
Waste1	<60 & >=39		>0.54	>12	
Waste2	<39				

Material classified as ‘off-grade’ continues to the plant to be processed. There are multiple ore types and each has a target upgrade quality which is used to optimise recovery using analysers installed on jig feed and jig product conveyors. Discard and three product types are also measured as is the train load out from each of the product stockpiles. The application of analysers throughout the plant allows for high confidence in production reporting and effective real time elemental balance to be determined.

Benefits of sensor fusion

Combining data from multiple sensor types is a proven way to increase the knowledge of plant feed material as there are no single sensors that can provide all the necessary information required to completely characterise plant feed in real time at full production rates. Ash and moisture measurement for coal was used in the 1980s to help power stations determine the energy value for conveyed coal feeding boilers. Different coal sources were blended to achieve optimal and consistent feed quality. Elemental analysers were used from the 1990s with moisture measurement to provide more precise energy value determination and further improve efficiencies in power station performance. In minerals processing, operators mostly rely on offline ore characterisation and ore tracking methods to determine which material is in plant feed and how to best process it based on prior metallurgical bench scale test work. Ore tracking is the real time component of the system, rather than any online analysis from a sensor on conveyed feed which started to occur in the 2000s. There had been systems in place for decades on slurry sample measurement but these did not help the plant decide which ore to process and how to proactively manage blends from different ore sources and ore quality feeding the stockpiles and mill.

The relatively recent development and application of representative measurement technologies has enabled the combination of elemental and moisture data with qualitative fragmentation and mineralogy data derived from surface sensing. The processing power of data from geological and chemical assay databases and the integration of plant performance data has resulted in greater predictability and better management of process plant performance to maximise metal recoveries and product quality and consistency. Operational geometallurgy uses real time sensing data to promptly identify ore type changes, variation in deleterious content in plant feed and trends in ore quality that cannot be predicted with high confidence from geological block model and mine planning data.

Each site needs to assess the potential benefits of multiple sensors and their data, whether it is representative, qualitative or indicative to determine synergies (Scott *et al,* 2020). Sites that benefit

most are those with a comprehensive understanding of their ore and waste types, their process characteristics, process sensitivities, and the ability to collect useful, timely data to optimise their recoveries and process efficiencies.

CONCLUSIONS

Utilising high performing representative measurement technologies for conveyed flows in plant feed can provide multiple benefits. Mining and processing operations with a detailed understanding of ore and waste characteristics and sensitivities of the process plant to these and their variability will derive immense benefits and very short paybacks when implementing suitable sensors and combinations of sensor technologies appropriate to their orebody and flow sheet.

The paper has discussed some key representative technologies suitable for elemental and moisture measurement and given examples of process performance improvements achieved when high quality sensor data are timely and successfully integrated into mining and processing operations. There are many more benefits to be achieved as geology and mineral processing professionals develop a better understanding of the benefits of real time data from digitalising the material flows between the mine and the mill.

ABSTRACT

Quantification of submicroscopic gold is one of the critical ore characteristics in evaluating the refractory degree of gold ores. This is because submicroscopic gold cannot be leached until the sulfide carriers have been oxidised. The variation of the submicroscopic gold in different types of pyrite has challenged the quantitative evaluation for the gold industry. Although previous studies have proved the relationship between morphological types of pyrite and the amount of submicroscopic gold, the classification was conducted under optical microscopes by experienced mineralogists.

With the automated mineralogy system development, high-resolution scanning electron microscope and multiple factor particle categoriser have become a new tool for classifying gold carriers. This paper is a case study of quantifying the ore characteristics inhibiting gold leaching and investigating the correlation between gold and arsenic for various ore domains at KCGM. Diagnostic leaching tests showed that most of the un-leachable gold was locked in sulfide phases. The mineralogical study quantified the distribution of gold locked in sulfides, including submicroscopic gold, Au (Ag) and Au-Te inclusions, combined with the grain size distribution of gold inclusions, explaining the different leaching performance of each sample. High-resolution SEM scanning indicated that arsenic mainly occurred as micro arsenopyrite inclusions (1–5 μm) or crystal lattice replacement in pyrite rather than coarse arsenopyrite. Au-bearing pyrite has been classified into four morphological types by automated mineralogy categoriser tools in TIMA. LA-ICP-MS measurement showed that submicroscopic gold concentration gradually decreased from pyrite with micro – arsenopyrite inclusions, to porous pyrite, to fine-grain pyrite, to coarse pyrite and arsenopyrite. The positive correlation between arsenic and gold concentrations in pyrite was verified in this study, which aligned with the previous study by other microprobe analyses. The Au/As ratio was recommended as one of the geometallurgical indexes to estimate the gold leachability for flotation concentrates in the Fimiston ore system. The objective and high-speed classification method by automated mineralogy could benefit more gold projects.

INTRODUCTION

Submicroscopic gold, named as invisible gold (Bürg, 1930), is identified as solid-solution and colloid gold locked in sulfides and iron oxides (Chryssoulis and Cabri, 1990; Zhou, Jago and Martin, 2004) because it is invisible under the optical microscope and scanning electron microscope (SEM). Due to the rare probability of being exposed to the cyanide solution by the ultrafine grinding process, the quantification of submicroscopic gold became the critical ore characteristic in evaluating the refractory degree of gold ores and selecting pre-oxidation techniques. However, the analytical method was challenged by the inhomogeneous amounts of gold among sulfide particles.

The quantitative submicroscopic gold study method based on secondary-ion mass spectrometry (SIMS) analysis and morphological classification as coarse pyrite, porous pyrite, fine-grained pyrite and microcrystalline pyrite was reported by Cook and Chryssoulis (1990) and Zhou, Jago and Martin (2004). The morphological classification and statistics of pyrite were usually conducted under optical microscopes by extensively experienced mineralogists.

The morphological classification is necessary because of the various amounts of submicroscopic gold in sulfide particles, changing from less than one ppm to ten thousand ppm. As the most common gold carrier, the morphological features of pyrite pertaining to gold were studied on various types of gold ores, referring to solid-solution gold is strongly enriched in the fine-grained sulfides (Cook and

Chryssoulis, 1990; Arehart, Chryssoulis and Kesler, 1993; Simon *et al*, 1999; Reich *et al*, 2004; Zhou, Jago and Martin, 2004).

This paper is a case study of the refractory degree of ores from Kalgoorlie Consolidated Gold Mines (KCGM) in Western Australia. KCGM operations include the Fimiston open pit (Super Pit), Mt Charlotte underground mine and the Fimiston and Gidji Processing Plants. The Super Pit is Australia's largest open pit gold mine processing refractory gold in which most of the gold is locked in sulfides. The processes undertaken in the Fimiston processing plant include crushing, grinding, and flotation. The flotation concentrate is then transported to the Gidji Processing plant for ultrafine grinding and carbon-in-leach (CIL). This study focused on the features of flotation concentrate affecting the following CIL.

METHODOLOGY AND SAMPLES

A series of quantitative mineralogical studies were conducted on flotation concentrate samples, including the mineral abundance, locked microscopic gold study and submicroscopic gold study. Scanning electron microscopy (SEM) with an automated mineralogy system (TIMA: TESCAN Integrated Mineral Analyzer) was used for mineral composition and microscopic gold scanning. The specific sulfide morphological categoriser for KCGM ore was developed through high-resolution SEM scanning and the TIMA system to provide objective classification results. A new type of gold-bearing pyrite was identified in this study, which enriched the highest gold among all the categories. Laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) was applied for the *in situ* gold and arsenic analysis on various types of pyrite and arsenopyrite. Agilent7700 ICP-MS and ESL NWR213 laser were used for submicroscopic gold measurement, with spot size 10 μm, repetition rate 10 Hz, laser energy 3.6 J/cm^2.

Sixteen flotation concentrates were studied by the same method, with eight of them from different domains of the metallurgical feasibility study for deposit S and another eight from the current Fimiston flotation concentrate. Samples of flotation concentrate collected prior to processing at the Gidji Processing plant were selected where they subsequently achieved a 90 per cent gold recovery in August, and compared against those that achieved a 95 per cent gold recovery in July (Table 1).The metallurgical tests results for Deposit S samples proved the high refractory degree of several domains, such as FS-03, FS-06, FS-07 and FS-09 (Table 1). All of the leaching results were processed on ultrafine ground concentrates.

RESULTS AND DISCUSSION

Bulk mineralogy

The flotation concentrates were composed of 30–61 per cent sulfide and 37–68 per cent non-sulfide minerals (Table 1). Sulfide minerals included mainly pyrite, with a trace amount of pyrrhotite and arsenopyrite. Most of the arsenic occurred as the impurity in pyrite, including isomorphism and micro arsenopyrite inclusions (1–5 μm). Au leaching recovery of Deposit S samples came from metallurgical tests, while the recovery of plant samples was the average recovery of the operation day. All of the leaching results were processed on ultrafine ground concentrates.

Locked microscopic gold study

Microscopic gold is one of the main gold occurrences in Fimiston ores. The designed flotation concentrate targets a P80 passing 180 μm. As exposed gold in the concentrates is leachable, this study paid attention to the characteristics of locked gold. Mineral speciation is one of the mainly mineralogical factors affecting gold leachability because some gold-bearing minerals known to have a slow kinetic leaching rate. The grain size of locked gold is another parameter since the <4 μm grains reduced the probability to be exposed by the ultrafine grinding at P80@11 μm. Microscopic gold was measured through high-resolution, bright phase searching tools in TIMA with a pixel size of 0.5 μm. High-resolution gold scanning was conducted on one resin block per sample, and a totally of 822 enclosed gold grains were observed, 98 per cent of which grains were locked in pyrite.

Gold minerals observed in KCGM samples are native gold, electrum, calaverite ($AuTe_2$), petzite (Ag_3AuTe_2) and sylvanite ($(Au,Ag)_2Te_4$). Because gold tellurides were reported as slow leaching minerals, the microscopic gold inclusions were sorted into gold-silver alloy (Au(Ag)) and gold telluride (Au-Te). Table 2 shows the relative gold distribution in the two types of microscopic gold inclusions. Most of the microscopic gold inclusions in the current Fimiston flotation concentrate occurred as native gold or electrum, with various amounts of gold telluride. Some samples from Deposit S contained a high component of gold tellurides, especially FS-07, which affected the leaching performance. Whilst other occurances of lower than expected recovery could not be explained by the presence of telluride minerals.

Since the flotation concentrates will be ground to 11 μm before the leaching process, the exposing probability of gold inclusions was controlled by the grain size, in which +7 μm grains would have more chance to be exposed to cyanide solution based on industry experience. Figure 1 shows the grain size distribution of locked gold inclusions in concentrates. Most of the locked microscopic gold in Deposit S samples was smaller than 10 μm. Especially in FS-03, FS-06 and FS-09, more than 85 per cent of the locked gold grains were smaller than 4 μm, which challenged exposure by grinding. On the other hand, the locked gold was much coarser in the current plant ores from July and August, with 52 per cent and 50 per cent smaller than 10 μm individually. Aligning with the excellent leaching performance in July (Table 1), the results indicated that the grain size of locked microscopic gold was one of the crucial factors for the refractory degree.

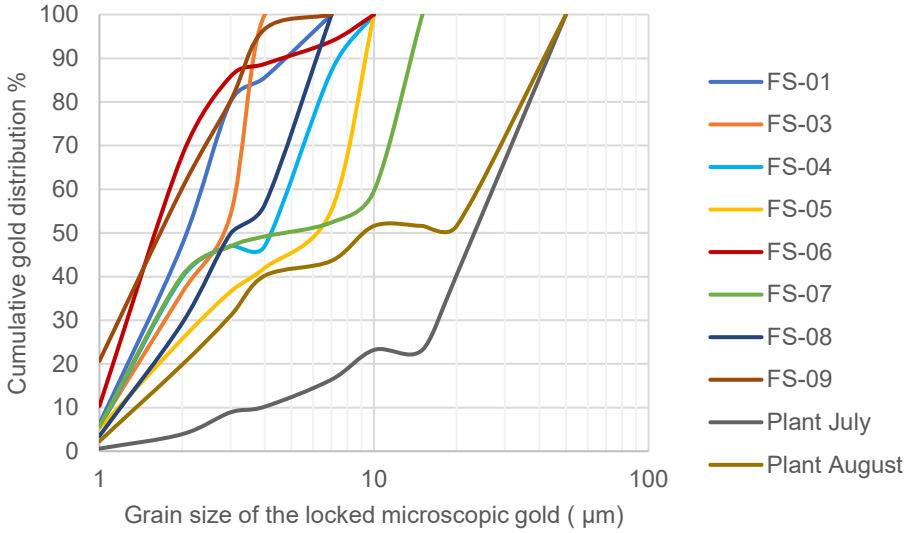

FIG 1 – Grain size distribution of the locked microscopic gold.

Submicroscopic gold study

Submicroscopic gold usually occurs as a solid-solution or colloidal gold. Solid-solution gold refers to gold atomically distributed in the crystal lattice of sulfide minerals like pyrite and arsenopyrite, which is non-leachable without oxidation of sulfides. Colloidal gold is a submicron gold inclusion in sulfide minerals, with a size between 5–500 nm, which is able to be detected by SIMS (Chryssoulis, Cabri and Salter, 1987) and imaged and analysed by high-resolution transmission electron microscopy (HR-TEM) (Bakken *et al*, 1989). However, the possibility to expose the colloidal gold in natural pyrite by ultrafine grinding is very low. LA-ICP-MS was used in this study to measure submicroscopic gold with the laser spot at 10 μm, so the results included solid-solution gold and colloidal gold.

Morphological identification and classification of pyrite

The morphological classification of pyrite was conducted by 1 μm pixel size SEM scanning and particle categoriser tool by TIMA system. A specific type of pyrite was identified and sorted in this study which is pyrite (Py) with micro arsenopyrite (Apy) inclusions. The detectable arsenopyrite inclusions were 1–5 μm locked in the crystal zone of pyrite (Figure 2e) or in the centre of the particle (Figure 2d). This type of pyrite was proved as the most robust submicroscopic gold carrier in the Fimiston ore deposit (Table 3). Therefore, the morphology of pyrite pertaining to gold was classified into four types for Fimiston ore deposit, including pyrite with micro arsenopyrite inclusion, porous pyrite, fine-grained pyrite and coarse pyrite (Figure 2 and Table 3).

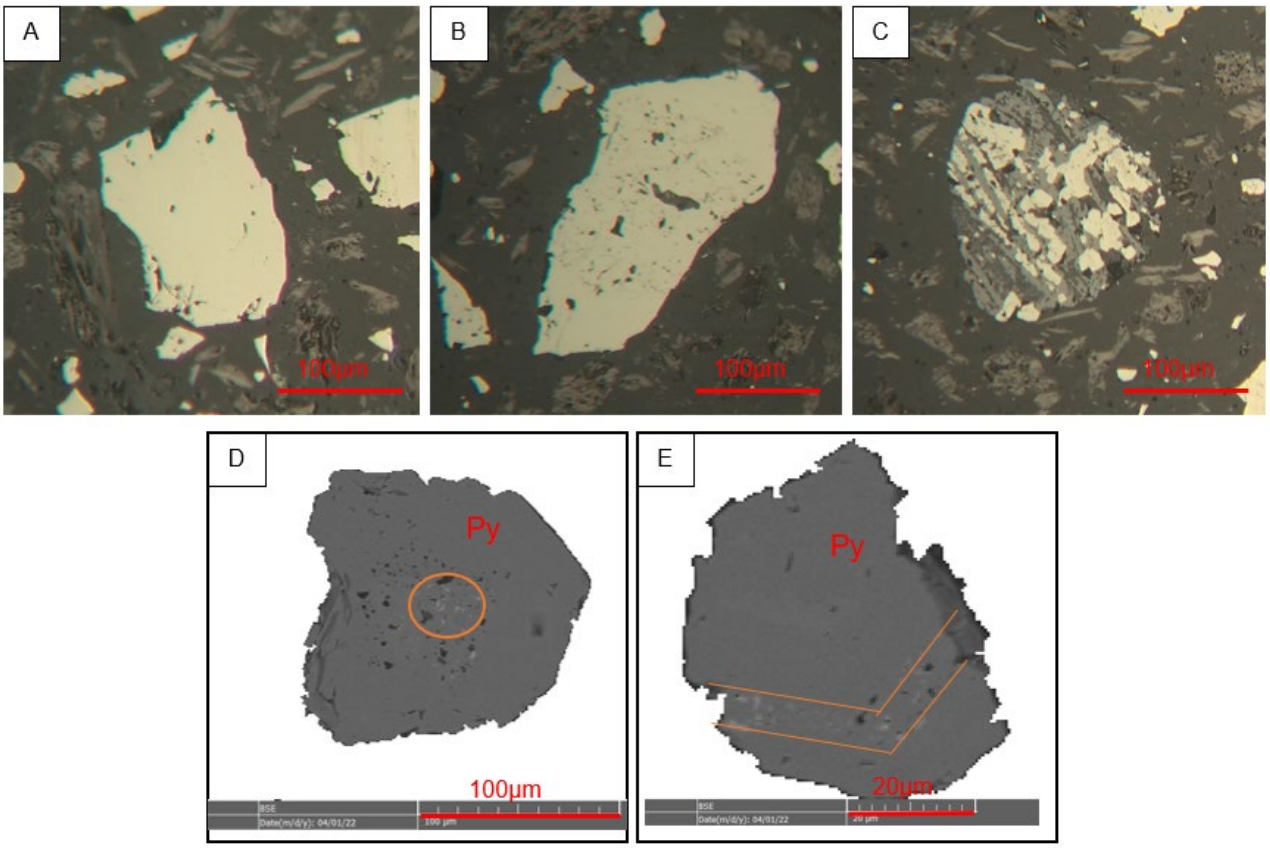

FIG 2 – Pyrite morphological types for submicroscopic gold study. A, B, C are reflective optical microscope images; D and E are SEM BSE images. A: coarse pyrite; B: porous pyrite; C: fine-grained pyrite D: Py with micro Apy inclusions hosted in the middle of the grain (bright spots in the orange circle); E: Py with micro Apy inclusions hosted in the growth zone (bright spots between the orange line).

The morphological sorting results show (Table 3) that pyrite from current plant ores was mainly coarse pyrite, secondly porous pyrite, with a minor amount of fine-grained pyrite and pyrite with micro arsenopyrite inclusions. For Deposit S samples, the mass of fine-grained Py and Py with Apy inclusions (Table 3) increased with the arsenic abundances in the samples, such as samples FS-03, FS-06 and FS-09. For plant July and plant August samples, only the mass of Py with Apy inclusions particles increased in August samples, while the mass of the other three types of pyrite stayed at the same level (Table 3).

Gold concentration in various types of pyrite particles

The concentration of submicroscopic Au in different morphological types of pyrite (Table 3) was measured by LA-ICP-MS. Totally 153 pyrite and seven arsenopyrite particles were measured in this study. The counts over time graph (Figure 3) of each particle showed S, Fe, As, Au concentrations with the depth profile during 30 seconds acquisition time. The particles with stable counts of gold contents (Figure 3 left) were used to quantify submicroscopic gold, while the graph with plateaued S, Fe and As but strongly disturbed Au curve (Figure 3 right) indicated that gold inclusions were detected under the surface, which was not used for the submicroscopic gold statistic. So 45 pyrite and seven arsenopyrite from Deposit S samples, 32 pyrite particles from Fimiston plant July and 41 pyrite particles from Fimiston plant August were applied to calculate the concentrate of submicroscopic gold in various morphological types of pyrite.

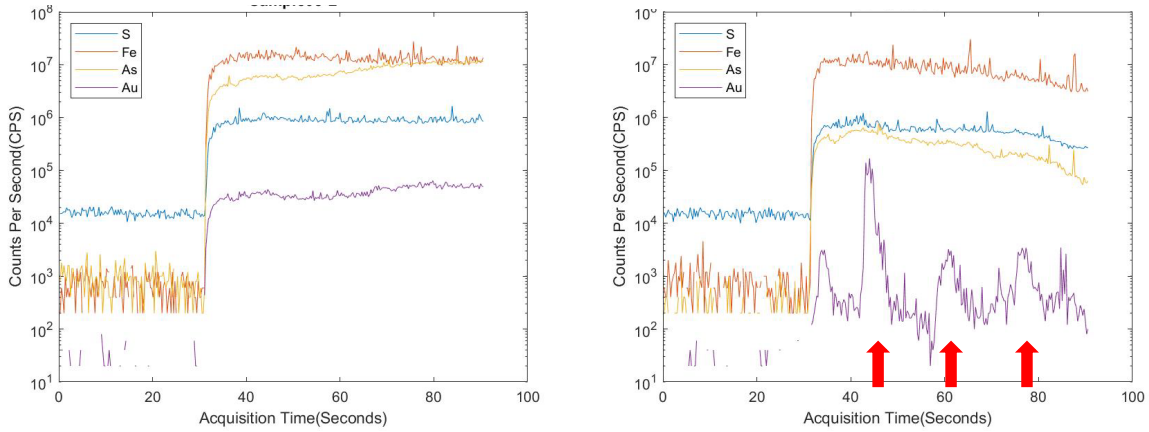

FIG 3 – LA-ICP-MS counts over time graph.

Generally speaking, submicroscopic gold was typically strongly enriched in the pyrite with arsenopyrite inclusions, secondly in fine-grained pyrite or porous pyrite, traced in coarse pyrite or coarse arsenopyrite (Table 3). The gold concentration hosted in Py with Apy inclusions was 14.4–29.3 ppm which can be identified as high gold carriers, while it was usually 0.8–11 ppm in porous Py, 1.9–6.1 ppm in fine-grained Py and only 0.1–0.2 ppm in coarse Py.

Quantification of submicroscopic gold

Submicroscopic gold was quantified based on the mass% of different pyrite types and the average gold concentration in each type (Table 3).

For samples from plant July or plant August, the gold concentrations in fine-grained Py were greater than that in porous Py. However, the high mass of porous pyrite (18.15–24.61 per cent) contributed more submicroscopic gold to the sample than that from fine-grained Py. Relatively higher mass of Py with Apy inclusions and the increasing of gold concentration in Py with Apy inclusions, porous Py and fine-grained Py in plant August samples were the crucial features for submicroscopic gold compared to July samples, which affected the leaching performance.

Several samples from Deposit S displayed various refractory related characteristics. Obviously, more high gold pyrite carriers, such as Py with Apy inclusions, were observed in the lower recovery samples, such as FS-03, FS-06 and FS-09. The abundance of fine-grained Py and porous Py also increased.. Moreover, the gold concentrations in the three types of pyrite except coarse Py were higher than that from the current plant samples. Extremely high gold contents in porous Py particles with the mass of this type provided more than 70 per cent of the submicroscopic gold in the Fimiston south samples. The abundances of arsenopyrite were less than 0.2 per cent (Table 1), which occurred as coarse particles and micro inclusions in pyrite. The average gold concentration of seven coarse arsenopyrite was 0.1 ppm, which indicated that the submicroscopic gold was not enriched in coarse arsenopyrite particles. However, the total amount of submicroscopic gold (Table 3) did not show a linear relation with the gold recovery.

The parameters that can be used to estimate the refractory degree will be discussed below.

DISCUSSIONS

Correlation between as and submicroscopic gold in pyrite particles

The positive correlation between arsenic and gold concentrations in pyrite was recognised early in the course of routine determinations of solid-solution gold in pyrite by SIMS, in which the solubility of gold was found as a function of arsenic content in pyrite, and the function was various among different ore types (Chryssoulis and Cabri, 1990; Reich *et al*, 2004).

In this study, arsenic and gold were measured by LA-ICP-MS at the same time for each particle. The correlation of submicroscopic gold and arsenic on 118 pyrite particles in four morphological groups was displayed, overlapping the gold versus arsenic plot for pyrite that was modified from Reich *et al* (2004) (Figure 4). The results from this study were located in the same area as the previous study,

with most of the spots sitting in the solid-solution gold area, which verified the reliability and high quality of the method in this study and also proved the positive correlation between arsenic and submicroscopic gold in pyrite particles.

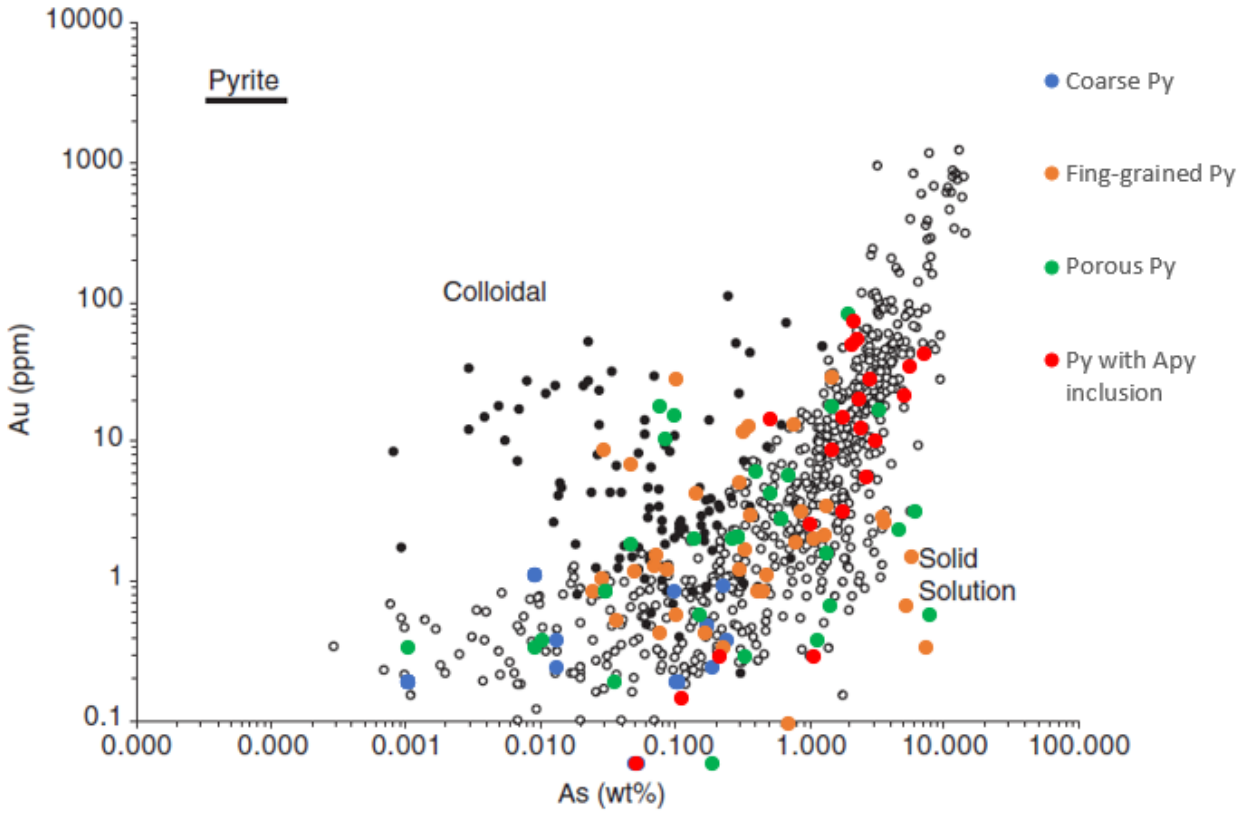

FIG 4 – Correlation of submicroscopic gold and arsenic in the morphological types of pyrite (colour spots from this study), modified from Reich *et al* (2004) (solid-solution gold (○) and colloidal size gold (●)).

Py with Apy inclusions type (Figure 4) hosted the highest gold concentrations (10–100 ppm), most of which were solid-solution gold. This type of high gold carrier in the Fimiston gold deposit has not been detected previously. Fine-grained pyrite (Figure 4 orange spots) contained 0.03 per cent-8 per cent arsenic, with mainly solid-solution gold and minor colloidal gold. Porous pyrite (Figure 4 green spots) carried a wide range of As and Au, including both types of submicroscopic gold as well. Coarse pyrite (Figure 4 blue spots) usually carried less than one ppm solid-solution gold with arsenic less than 0.3 per cent.

Geometallurgical factors evaluating the refractory degree

Although it is known that the increase of arsenic content negatively affects the gold leaching recovery, it is not a linear relationship between arsenic abundance and gold. To evaluate the refractory degree, understanding the refractory gold ore-forming process is necessary.

Based on an Au versus As plot of over 1000 microprobe analyses of pyrites of all morphological types (Figure 4), Reich *et al* (2004) found that the maximum solubility of gold in pyrite in epithermal and mesothermal gold ores was calculated as a function of arsenic content in pyrite as:

$$C_{Au} = 0.02\ C_{As}$$

Where C is the concentration of As, Au in mol%. When gold abundance in the ore-forming fluid was more than the maximum solubility, gold would occur as colloidal gold, micro gold inclusions, and even coarse gold minerals. The more gold exceeded the solubility, the lower the proportion of refractory gold in the ore. Therefore, the refractory degree of gold ore was determined by the relative amounts of arsenic and gold in the same ore deposit, regardless of other detrimental elements, such as tellurium and antimony. Figure 5 showed a good correlation between As/Au ratio and the gold leaching recovery of the samples in this study which can be explained by the theory of refractory

gold ore-forming studies until now. Therefore, As/Au ratio would be recommended as one of the geometallurgical factors to evaluate the refractory degree for KCGM and to understand the leaching performance affected by arsenic. Another important detrimental factor that affects gold leachability is tellurium. The significant presence of gold telluride, especially in FS-07 (Table 2), will result in slow leaching kinetics and explains the decrease in gold recovery for some samples. As the samples in this study were limited, research on more samples will be required to develop an accurate geometallurgy index for refractory degree estimation.

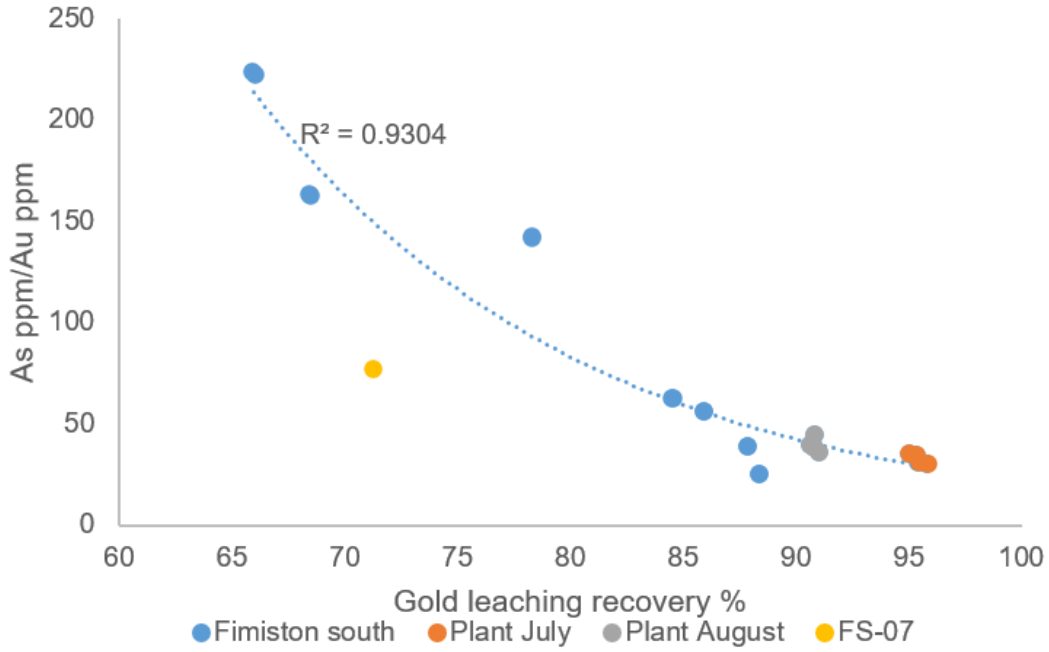

FIG 5 – Correlation between submicroscopic gold and As/S ratio.

CONCLUSIONS

High-resolution SEM scanning and automated mineralogy software (TIMA) combined with LA-ICP-MS were applied for the refractory gold deportment study for KCGM samples. The ore characteristics affecting the gold leachability were studies on flotation concentrates with various leaching performances. The morphological classification of pyrite was successfully conducted by an automated mineralogy categoriser tool. The pyrite with arsenopyrite inclusions was identified as a new pyrite type which was identified as the most vital gold carrier type in Fimiston and Fimiston south deposits. The arsenopyrite inclusions indicated that arsenic was oversaturated in pyrite under the ore-forming condition and generated high gold solubility in pyrite, resulting in the refractory nature of the ore. Most Py with Apy inclusion type particles hold more than 1–10 per cent As and 3–100 ppm Au, in which the gold occurred primarily as solid-solution gold. The amounts of this type of pyrite increased obviously with the rising arsenic content in the samples. The relatively high arsenic content also generated more fine-grained pyrite particles or porous pyrite particles, which were significant gold carriers as well. The positive correlation between arsenic and gold concentrations in pyrite was verified in this study. The Au/As ratio was recommended as one of the geometallurgical indexes to estimate the gold leachability for flotation concentrates in the Fimiston ore system.

ACKNOWLEDGEMENT

The authors thank AXT PTY LTD and KCGM, Northern Star Resources Limited, for permission to publish this paper. The first author is also grateful to Mr Joe Zhou for his assistance in the study of pyrite morphological classification. LA-ICP-MS analysis was conducted at Bureau Veritas Perth.

ABSTRACT

Like many data sets, test results generated from geometallurgical test work inevitably contain outliers. There are many causes for outliers. A common practice during any model development is to exclude outliers to avoid a biased or skewed model. Outlier removal is a critical step in geometallurgical model development since the decision we make at this stage has significant impact on final output. Will deleting all outliers result in a better prediction?

All data tells a story – a small group of data points behaving significantly different from the majority doesn't necessarily mean they are erroneous and quite often they are telling us something that we don't already know. This paper uses examples at Olympic Dam to describe how outliers in the flotation tails leach acid consumption model triggered us to review the compositional variability of the chlorite group of minerals in the deposit and the way we cluster them. This exercise led to improved understanding of how different subtypes of the mineral chlorite have distinct behaviours during tails leach and that chlorite mineral composition varies widely across the deposit, which was also linked to another 'abnormal' ore behaviour in tails leach process. Understanding the spatial distribution in mineral characteristics supported our decision to retain the data points that were initially classified as statistical outliers but were, in fact, genuine test results. As we sampled and tested those areas more, the number of 'outlier' results increased, hence suggesting they were not outliers. A different case study is uranium leach extraction where early samples showed unexpected extraction results but as more samples from the same area were tested they started to show a new trend. This approach enabled us to group data more sensibly and make better predictions for plant production.

INTRODUCTION

The Olympic Dam iron-oxide copper gold (IOCG) deposit is hosted by the 1.6 billion year old Roxby Downs Granite. Mineralisation is associated with intense, texturally destructive hematite and sericite alteration and brecciation of the primary host rock units, including Roxby Downs Granite, bedded clastic facies rocks, and mafic-ultramafic dykes (Ehrig, McPhie and Kamenetsky, 2012). The vast majority of the rock mass (>90 per cent) is comprised of gangue minerals with less than 10 per cent of deposit mass as sulfide minerals. While the recovery of the sulfide minerals and uranium is obviously critical, the behaviour of the ore through the concentrator and hydrometallurgical circuit is controlled by the gangue mineralogy and therefore its characteristics and abundance are important in a geometallurgy context.

Ore is mined using a sublevel open stoping method underground. Ore from different stopes are mixed on the run-of-mine stockpiles on the surface. There are 5 to 10 stopes online at one time and about 60 stopes are mined each year. Ore is then treated in the fully integrated processing plant to produce copper cathode, uranium oxide concentrate, and gold and silver bullion. Ore is milled in one of the two autogenous grinding mills to expose sulfide minerals from gangue minerals. Bulk sulfide flotation separates the copper sulfide concentrate from the tailings stream. The copper sulfide

concentrate is leached using sulfuric acid to further reduce uranium, fluorine and a portion of hematite gangue. The leached concentrate is smelted in the copper smelter before electrolytic refining to produce copper cathode, Anode slimes are sent to the gold room to produce gold and silver bullion. The majority of the uranium reports to flotation tailings stream which is treated in an atmospheric sulfuric acid leach then concentrated by solvent extraction. About three quarters of the revenue are from copper, with the remaining 20 per cent from uranium and 5 per cent from gold and silver.

Geometallurgy

The driver behind geometallurgy at Olympic Dam is to reduce the technical risk to the current operations and future expansions caused by unexpected mining and process performance issues due to variable ore properties (Ehrig, 2017). The following three objectives of Olympic Dam geometallurgy:

- Develop metallurgical performance predictors that reliably describe the process performance of different ore types and spatially distribute these into the resource block model for use as a fundamental input into mine planning.
- Identify any ores which may be 'problematic' to the current plant, and provide variability data of suitable quality for process plant design and future plant optimisations.
- The chemical, mineralogical, physical property, and 'recovery models', collectively called the geometallurgical model, provide the data required to support the JORC Code 'modifying factors'.

Since the beginning of geometallurgy program in 2006 over 2000 samples have gone through extensive metallurgical tests, all of which carries sufficient information to tag them back to a spatial location in the orebody. Each head sample is assayed for more than 50 elements, and analysed for mineralogy via both Mineral Liberation Analysis (MLA) and quantitative X-ray diffraction (QXRD). Other tests include specific gravity by pycnometer, comminution, flotation and tailings leach conducted on flotation tails generated from flotation. As Liebezeit *et al* (2020) pointed out even though this is a data-rich set from the metallurgical viewpoint, the sample support is far too low to allow the use of traditional geostatistical estimation techniques in Olympic Dam's 20-million block resource block model. Therefore, each geometallurgical relationship (ie metallurgical performance predictor, for example tailings leach acid consumption) is expressed as a function of variables geostatistically estimated in the block model (eg elements, minerals calculated from elements and density). Hence metallurgical performance is predicted on every block in the resource model.

Tailings leach

Flotation tailings are thickened and pumped to a series of leach tanks and the slurry flows through them by gravity. Sulfuric acid and sodium chlorate are added to maintain targeted levels of free acid and oxidation-reduction potential. As an essential reagent, part of the required acid is produced in the acid plant from smelter off-gases and sulfur, and additional acid requirements are transported by road to Olympic Dam. Therefore, prediction of acid consumption is critical to manage the acid balance on-site and manage acid import requirements. Since the main purpose of tailings leach is to extract uranium from flotation tailings, uranium extraction has direct impact on downstream uranium production.

Outliers

As with any data set, we regularly encounter outliers during the geometallurgy test work and in the process of model development. Depending on the underlying reason for their classification as outliers, they should be treated differently. However, how the outliers are handled can have significant impact on the final outcome. According to Napier-Munn (2014):

> *Outliers are values which appear to stand apart from the rest of a dataset in some way. If some mistakes can be identified in the way the outlier(s) were collected then of course they should be excluded because they will unreasonably distort the properties of the data. If not then careful consideration should be given to whether or*

not they should be excluded, because it is possible that they are conveying useful information and are a legitimate part of the data.

This paper includes three case studies from the Olympic Dam tailings leach circuit where outliers were not caused by mistakes, and in fact they were telling us something that we didn't already understand. Hence outlier rejection needs to be investigated so that potentially valuable information is not lost.

CASE STUDY 1 – TAILINGS LEACH ACID CONSUMPTION MODEL

Tailings leach acid consumption model

The primary acid consuming minerals at Olympic Dam include chlorite, sericite and carbonate (ie siderite, with lesser amounts of ankerite and dolomite). The geometallurgy acid consumption model inputs are simply the concentrations of those minerals. Since acid consumption is also a function of the solubility rates of the minerals and tailings leach conditions, coefficients for those minerals varies. Table 1 contains the gross acid consumption model based on mineralogy derived from different methods (ie QXRD, MLA, calculated) for tails leach operated at 70°C for 10 hours at a free acid concentration of 12 gpl and oxidant addition of a minimum of 1 kg/t sodium chlorate. This is the standard leach condition in the geometallurgy program and will be referred to as LFT in this paper. It includes the acid remaining in the liquor at the end of the leach and the acid required to convert sodium chlorate oxidant.

TABLE 1

Summary of the latest acid consumption models under LFT condition.

Model input	Model format	R^2_{adj} (%)	Total # of data used	# of outliers
QXRD*	acid consumption (kg/t) = 28.9 + 19.5 *%chlorite + 4.7 *%carbonate	97	1389	102
MLA*	acid consumption (kg/t) = 28.9 + 18.1 *%chlorite + 5.8 *%carbonate	95	1639	127
Calculated mineralogy	acid consumption (kg/t) = 15.2 + 12.7 *%chlorite + 5.4 *%siderite + 0.6 *%sericite	93.5	1520	144

*QXRD: model input mineralogy measured by quantitative X-ray diffraction.

*MLA: model input mineralogy measured by Mineral Liberation Analysis.

All three models have reasonably good predictive ability but there are some samples that the model statistics show just couldn't predict their acid consumption correctly (outliers in Table 1). This could be caused by:

1. Actual acid consumption for the leach test could be wrong due to operation error or equipment failure
2. Model input for those samples were incorrect. In this case measured or calculated mineralogy might not be accurate
3. There is something else that influence acid consumption but is not explained by the model

The first and second causes could be combined together since they are both caused by errors during the data collection process and if that is the case those sample results should be excluded from model development until the affected test was repeated correctly. On checking all the related information and if all of them are correct, then those data points might deserve extra attention since they are telling a story.

Chlorite measurement

In the original MLA results there are 61 minerals in total and this is referred to as the ungrouped mineral list. For various purposes minerals that behave similarly for the process of interest are grouped together to create a simplified mineral list for that particular purpose and they are referred to as the condensed mineral list. In the ungrouped mineral list there are three types of chlorite. They all belong to the chlorite group but with different endmembers. Chlorite2 is the Fe-rich endmember. Chlorite3 is the Mg-rich endmember and chlorite1 is in between chlorite2 and chlorite3. The nominal chemical formula for each chlorite type can be found in Table 2, although there is still considerable compositional variation.

TABLE 2

chemical formula for different types of chlorite.

Mineral	Formula
Chlorite1	$(Mg,Fe,Al)_3(Al,Si)_4O_{10}(OH)_2$
Chlorite2	$(Fe,Al)_3(Al,Si)_4O_{10}(OH)_2$
Chlorite3	$Mg_2(Al,Fe)_3Si_3AlO_{10}(OH)_8$

Chlorite content represented in the resource block model is calculated from drill core assays and we don't have the ability to differentiate different types of chlorite. Chlorite measured by QXRD is also the total of all types of chlorite.

As more and more samples from new mining areas have undergone geometallurgy testing, we started to see more Mg-rich chlorite samples and this triggered us to investigate how different types of chlorite will affect acid consumption during tails leach. It was also noticed that Mg-rich chlorite samples are all sourced from a localised area (refer to as Area A in the rest of this paper) in the orebody and that area was included in the mine plan for the first time in 2016.

Figure 1 compares predicted acid consumption by MLA model during standard LFT with actual acid consumption. Orange colours are for samples with chlorite3 >4 per cent. The MLA model tends to over predict acid consumption for samples with high chlorite3. In other words, those samples with high chlorite3 consume less acid than predicted by the model. The MLA acid consumption model is based on all geomet samples and the vast majority of them have no or very low chlorite3. The handful of new samples with dominant chlorite type being chlorite3 have been excluded from model development because they don't behave the same as the bulk of the samples so not meet expectation. Also, the model uses the condensed mineral list so all three types of chlorite are aggregated into one.

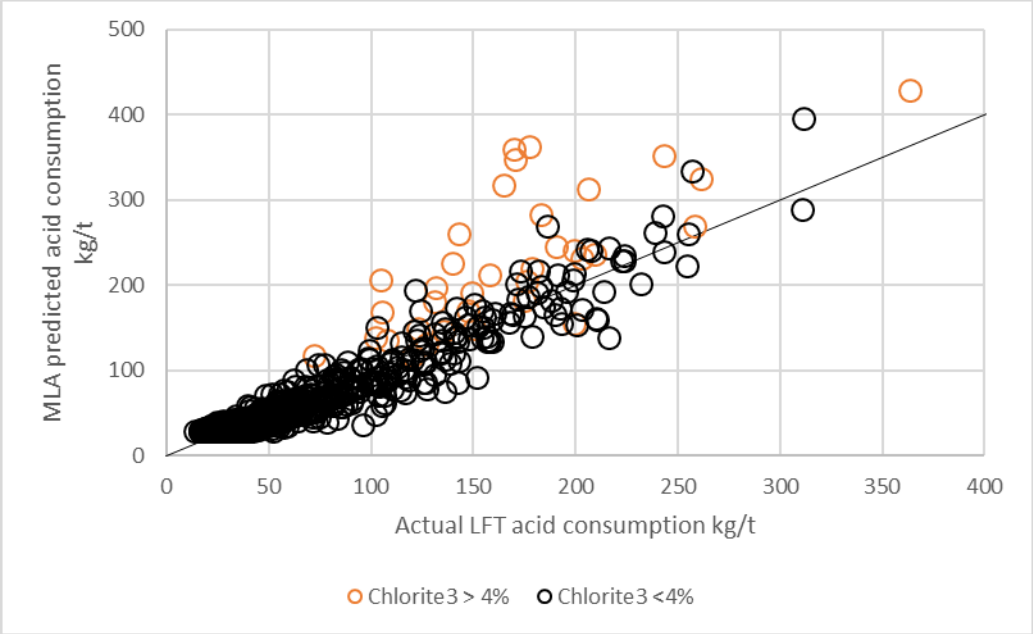

FIG 1 – MLA predicted acid consumption versus actual acid consumption.

In order to understand how chlorite3 consumes acid differently, MLA acid consumption models for Area A and all areas were created using the ungrouped mineral list. As shown in Table 3 both the area specific model and general model suggested that chlorite1 and chlorite2 consumes nearly double the amount of acid chlorite3 consumes. Please note Area A doesn't contain any carbonates so carbonates don't appear in the model.

TABLE 3

LFT acid consumption models using ungrouped mineral list.

LFT acid consumption model	**Model format**
Area A model	Acid consumption (kg/t) = 30 + 19.7 *%Chlorite1 + 20 *%Chlorite2 + 10 *%Chlorite3
All area model	Acid consumption (kg/t) = 29.4 + 15.5 *%Chlorite1 + 20.4 *%Chlorite2 + 12.8 *%Chlorite3 + 9.5 *%Carbonate + 5.6 *%Siderite

Another way to look at this is to group the samples according to their head total chlorite content by 1 per cent intervals and then separate samples with similar total chlorite by dominant chlorite type. For example, if more than 50 per cent of total chlorite is chlorite1 then the sample was classified as a 'chlorite1 dominated' sample. Figure 2 plots the LFT acid consumption kinetic curve for samples with total chlorite at different levels. It shows chlorite2 dominant samples consume more acid than samples with similar total chlorite but dominated by chlorite1 or chlorite3. Chlorite1 dominated samples consume slightly higher or similar acid to clorite3 dominated samples depending on the total chlorite group. Charts for total chlorite at all levels were created but not included here. They all show very similar trend.

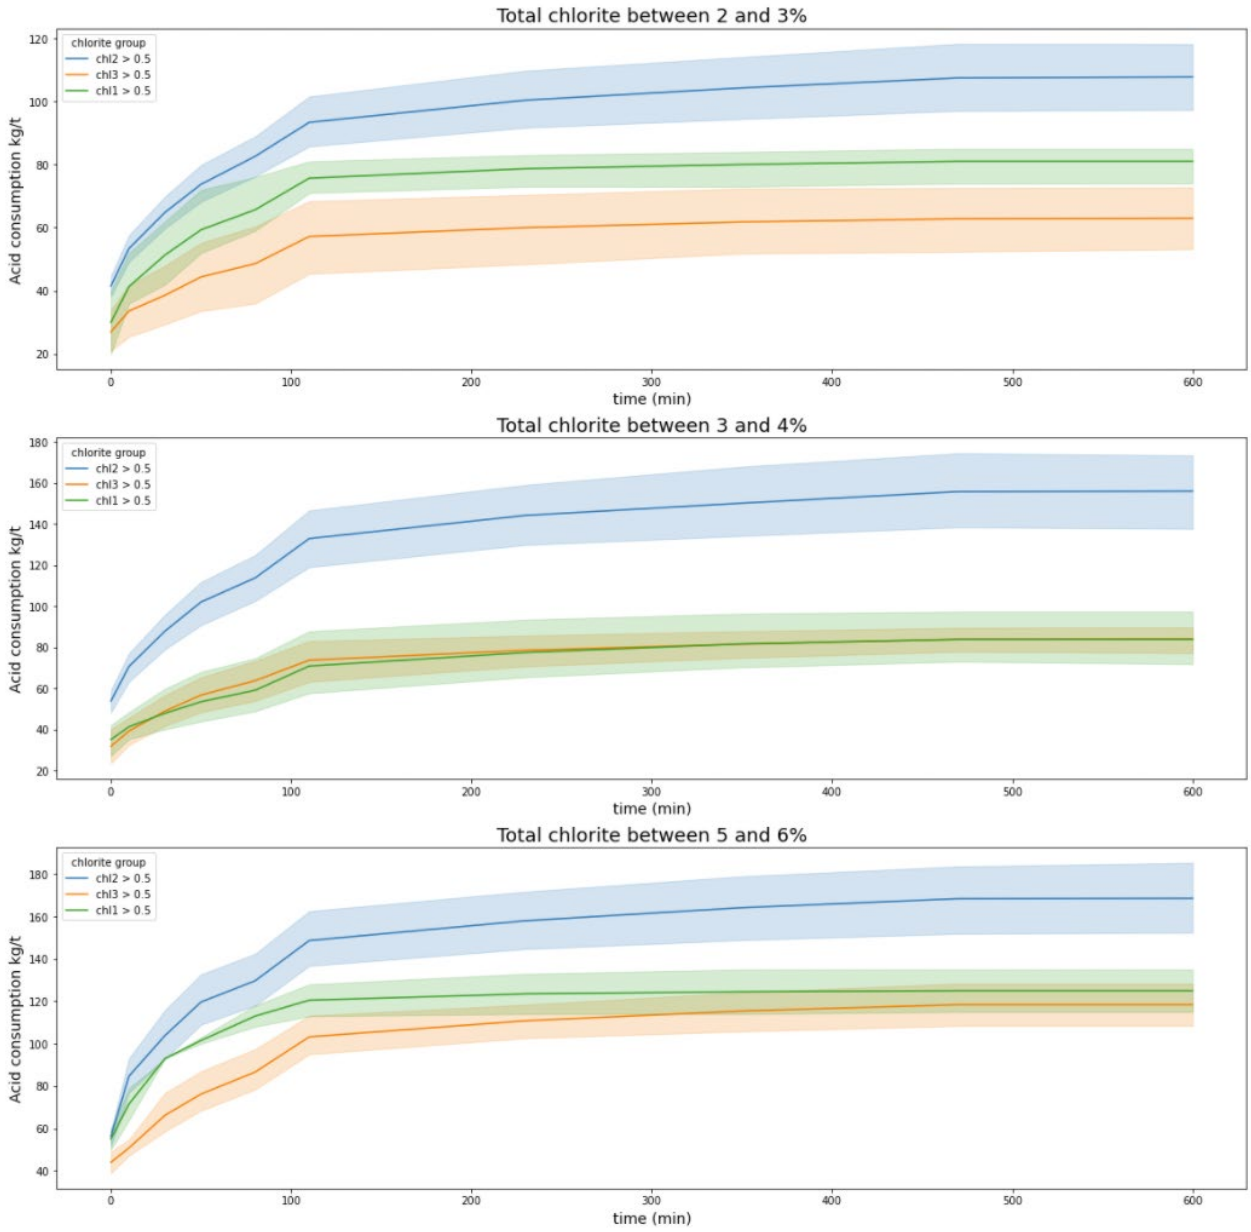

FIG 2 – LFT acid consumption kinetic chart for samples with various total chlorite. Solid line for average, shading represents range of results.

This discovery didn't result in updating the current acid consumption model with ungrouped mineral list at this stage because the current acid consumption based on the condensed mineral list is fit for purpose. There are limited geometallurgy samples (~5 per cent) with head chlorite3 greater than 3 per cent and it will not have material impact on the final model. However, it is used to modify the local estimates of acid consumption for stopes in Area A, which means that this effect is accounted for in short to medium term predictions. However if more chlorite3 rich material became mill feed in the future, this discovery will explain why actual acid consumption is not aligning well with modelled value and the model can be modified accordingly.

CASE STUDY 2 – GELLING POTENTIAL REVIEW

Chlorite content versus gelling

The first gelling event in OD happened on 1st May 2004 when the tailings leach process came to a halt as the easy-flow slurry in the tailings leach tank turned into a gel that could not be pumped nor dewatered. Gelling occurs when silica in solution (sourced from the leaching of chlorite) forms long chain polymers, instead of remaining in solution or precipitating (Ehrig *et al*, 2019). A gelling event

could have a profound impact on uranium production, and if not controlled in a timely manner, it could stop the production of the whole plant and have significant financial implication on the business. Ehrig *et al* (2019) stated mitigating the potential to gel is the primary reason why OD continues to support an ongoing geometallurgy program.

Apart from being a significant acid consumer, numerous studies have demonstrated that chlorite is the main cause of gelling from source material's point of view. As a risk mitigation measure, a chlorite concentration limit of less than 2–3 per cent is placed on the ore sent to the processing plant. Leach conditions also affects the probability of gelling with the same ore more likely to gel under high intensity conditions than a low intensity leach.

Gelling potential against chlorite content was analysed and is plotted in Figure 3. Low intensity leach (LIL) test conditions are 60°C for 10 hours at a free acid concentration of 8gpl and oxidant addition of a minimum of 1 kg/t sodium chlorate. Unlike LFT, LIL test is not conducted on all samples in the geometallurgy program but selected ones. So the LIL data set is smaller than LFT but all samples with a LIL result also has a paired LFT test. Under LFT conditions, gelling starts at 2 to 3 per cent chlorite while LIL tests have slightly higher gelling onset at 3 to 4 per cent chlorite. For both types of leach tests, gelling potential rises with the increase of chlorite concentration for sample with medium to high chlorite then drops for samples with over 8 per cent chlorite. The drop in gelling potential for high chlorite samples was attributed to the small number of leach test conducted on samples in those groups and was not considered a likely behaviour in the plant.

	0	>0 & <=1	>1 & <=2	>2 & <=3	>3 & <=4	>4 & <=5	>5 & <=6	>6 & <=7	>7 & <=8	>8
LFT	0.1%	0%	0%	9%	38%	46%	69%	63%	67%	33%
LIL	0%	0%	0%	0%	16%	18%	27%	60%	80%	50%

FIG 3 – gelling potential for each chlorite group under LFT and LIL.

Table 4 lists the total number of LFT and LIL tests conducted in each chlorite group and it is evident that the number of leach test reduces with the increase of chlorite content. There are several hundred leach tests conducted on samples with no or less than 1 per cent chlorite and only a handful of tests in the >8 per cent chlorite group but is small sample number really the cause of the problem here?

TABLE 4

LFT and LIL sample numbers in each XRD chlorite group

XRD chlorite%	Total # of LFT sample in each chlorite group	Total # of LIL sample in each chlorite group
0	670	269
Between 0 and 1	311	153
Between 1 and 2	112	74
Between 2 and 3	56	45
Between 3 and 4	53	51
Between 4 and 5	26	22
Between 5 and 6	16	15
Between 6 and 7	8	5
Between 7 and 8	6	5
Above 8	9	8

High chlorite = gelling?

Due to the importance of gelling behaviour, gelling is recorded for each geometallurgy sample during laboratory leach test. Technicians observe the settling and thickening status of the slurry throughout the test and record their observations in the data file as ‘gelling rank’. Since visual observation can be subjective to the technician’s experience, the geomet team conducted a series of yield stress measurement during leach tests using a Haake Viscometer 550 to quantitatively measure gelling. Yield stress measurements were compared with gelling results derived from traditional observations. The good comparison indicates gelling results based on visual observations are valid. The use of yield stress measurement does add time and cost to the leach test, and could compromise the uranium extraction result since the slurry does change temperature during the yield stress measurement when it is removed from the hotplate. Therefore yield stress measurement is just used to validate visual observation for gelling rank and has not been part of the standard leach protocol.

For the yield stress measurement work, a range of samples with different chlorite levels and gelling behaviours were selected to have a good representation of existing samples. In the sample selection process, it came to our attention that there are some samples with elevated chlorite (up to 15 per cent) but the gelling rank based on visual observation indicates they didn’t gel. Considering that tailings leach (in the plant) starts gelling at 2–3 per cent chlorite and the laboratory leach observation showing similar gelling onset levels, our previous experience meant we thought it was almost impossible for have a sample with confirmed 15 per cent chlorite and no gelling. To our surprise, yield stress test work on those samples confirmed the visual observation and those samples didn’t gel.

It is unclear what is preventing the high chlorite material from gelling. One hypothesis is that there are some natural occurring substances (eg minerals, or cations/anions) in those samples that can prevent gelling from happening. A composite sample was created by mixing a high chlorite non-gelling sample with an equally high chlorite gelling sample. Yield stress measurement results on the composite sample show the blended composite sample did gel. Chlorite in the non-gelling sample will contribute to gelling when mixed with other gelling samples from other areas.

Unusual gelling behaviour of chlorite3

Further investigation showed all the high chlorite3 non-gelling samples came from a localised area (area A) and they are high in Mg-rich chlorite3. So it was hypothesized that chlorite3 is less likely to cause gelling than the other types of chlorite at the same concentrations.

Figure 4 plots different types of chlorite versus total chlorite for all samples with both LFT and MLA data. Open circle indicates sample didn't gel during LFT and triangle represents gelled sample during LFT. Blue are for samples from Area A while black is for samples from the rest of the orebody. Samples that are high in chlorite2 are most likely to gel (top right chart) while samples that are high in chlorite1 are slightly less likely to gel than high chlorite2 samples (top left chart). Samples with a high amount of chlorite, all as chlorite3, are much less likely to gel under the same condition (bottom left chart). This chart also confirmed that all samples containing chlorite3 (blue symbols) are sourced from Area A.

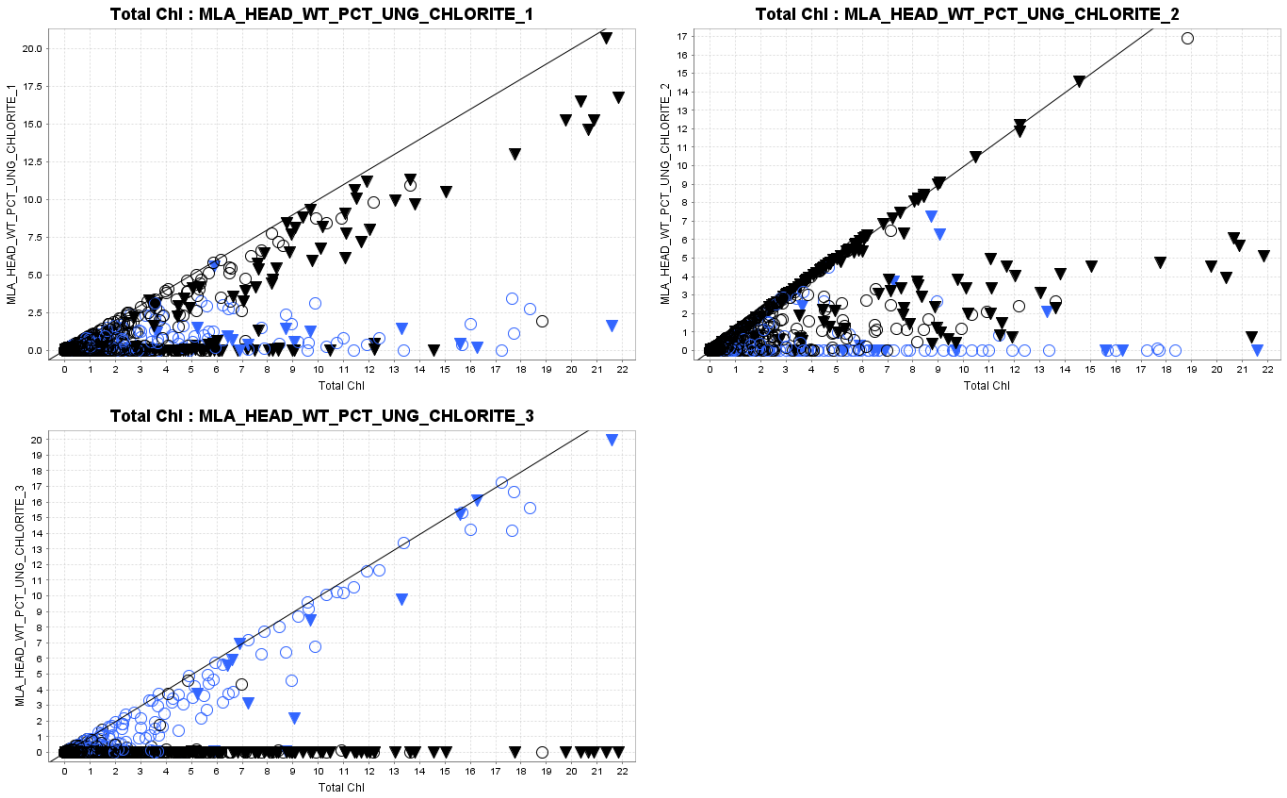

FIG 4 – different types of chlorite versus total chlorite.

This observation ties in nicely with the Case 1 observation. Chlorite3 consumes less acid at a slower rate, which suggests it slowly releases less silica into the leach liquor and hence it is less likely to cause gelling than the other two types of chlorite at the same abundance. It also explains why gelling potential dropped for samples with total chlorite >8 per cent in Figure 3. Actually 80 per cent of the non-gelling samples with chlorite >8 per cent are chlorite3 rich samples with more than 90 per cent of chlorite being chlorite3.

But is that all?

There are some samples containing only chlorite3 which gelled, even though they were a small proportion of the chlorite3 sample population. Are the results just inconvenient that should be ignored or is there something else that we don't know yet? We further extended the analysis to understand why two samples with the same type of chlorite and chlorite content had completely different gelling status by examining different types of chlorite by abundance with all other minerals in the head sample. Particular attention was paid to the minerals which the literature (Tan, Skinner and Addai-Mensah, 2013) has identified as playing a role in gelling. Figure 5 plots head chlorite3 versus fluorite and it shows samples with high chlorite3 (>4 per cent), none of them with fluorite below 2 per cent gelled. Samples with high chlorite3 (>4 per cent) and fluorite >2 per cent have a much higher chance of gelling. This is indicating that chlorite3 on its own without fluorite (or very little fluorite) is very unlikely to result in gelling.

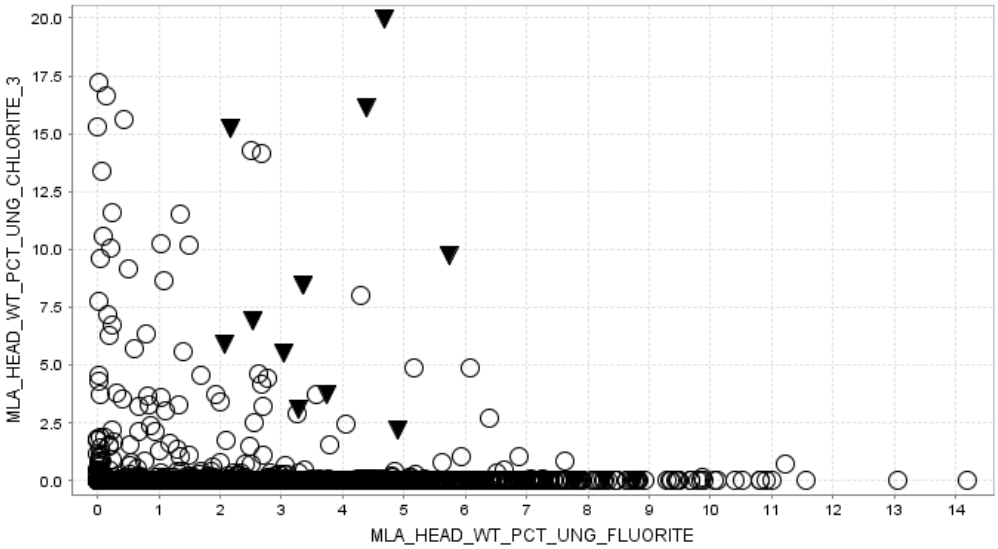

FIG 5 – Head chlorite3 versus fluorite for all samples. Triangle: gelled during LFT; Circle: didn't gel during LFT.

To further verify this theory, leach residue fluorite versus leach feed fluorite are plotted in Figure 6 and samples with head fluorite >2 per cent and chlorite3 >4 per cent were highlighted by different colours depending on if it gelled or not. Gelling samples are orange and non-gelling samples are green. Regardless of head fluorite and chlorite3 contents, gelling samples have a higher amount of fluorite dissolved in liquor during leach than non-gelling samples with triangles located further away from the parity line while circles closer to y=x line. This indicates that fluorine in leach liquor is key for high chlorite3 (and only chlorite3) samples to gel.

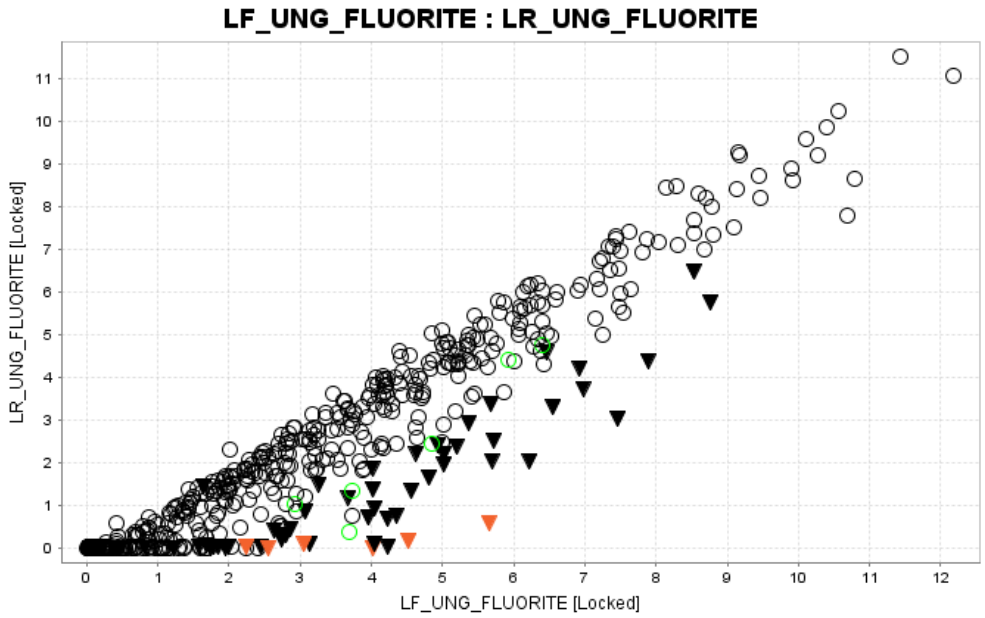

FIG 6 – leach residue fluorite versus leach feed fluorite.

Currently this observation cannot benefit plant production since mill feed is a blend of multiple stopes plus a small portion of development on any given day and fluorite content is well above 2 per cent all the time. However, it does provide direction for further research into the gelling phenomenon in tails leach.

CASE 3 – URANIUM EXTRACTION

As a critical production metric, uranium extraction during tailings leach and uranium grade in leach residue is measured in all geomet samples. As the first results became available in 2006, the leach

residue uranium grades were compared with plant data. At that time plant leach residue U_3O_8 grade was around 150 ppm. The first geomet sample had leach residue under the same leach conditions with more than double the amount of U_3O_8 at 370 ppm. The next couple of samples dropped slightly to about 300 ppm but still much higher than what the plant was getting. Figure 7 shows the leach residue box and whiskers chart of plant and the first 30 geomet samples. It is obvious that the distribution of those two populations are markedly different from each other.

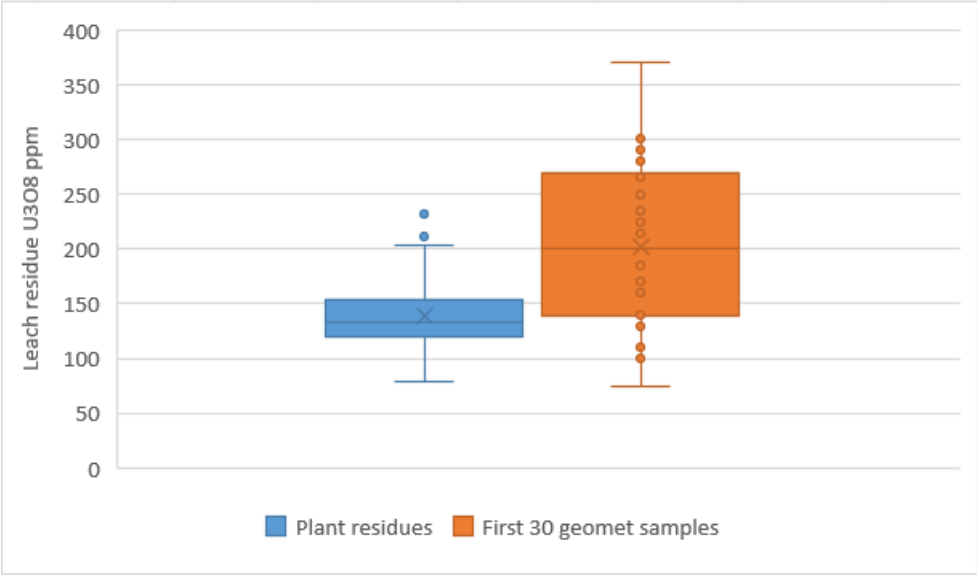

FIG 7 – comparison of leach residue U_3O_8 grade between plant data and the first 30 geomet samples.

There was clearly something going on with those results and the following actions were taken to trouble shoot the issue:

- Leach residue samples were split into several subsamples and sent to different laboratories for assaying. They came back on the same level as original results
- Plant material was leached under the same conditions by the same laboratory and the same leach residue grade as plant was achieved
- Leach test under the same condition on the same sample was conducted by a different laboratory and the same leach residue as the original laboratory was received

Those check results gave us high confidence in the data by eliminating the possibility of sample splitting error, assay error and test error and also confirmed that the leach test is a good representation of plant operation. Since there was no mistake in the data generation process, we cannot remove them just because they are dramatically different from what we expected or where the bulk of the samples are. The unusually high leach residue uranium grade must be associated with the sample itself. The geomet team continued on testing new samples with the same method while investigating the root cause of low uranium extraction during tailings leach. It turned out that all geometallurgy samples at the beginning of the geometallurgy program were sourced from the Southern Mine Area (SMA) as future material, but the processing plant had only processed ore from the Northern Mine Area (NMA) up to that time. It happens that the relative proportions and absolute concentrations of the uranium minerals in the SMA are significantly different from the NMA. The SMA ores have a smaller proportion of the easy leaching uraninite as illustrated in Figure 8. Liebezeit *et al* (2020) explained the leach characteristics for various uranium minerals in more detail.

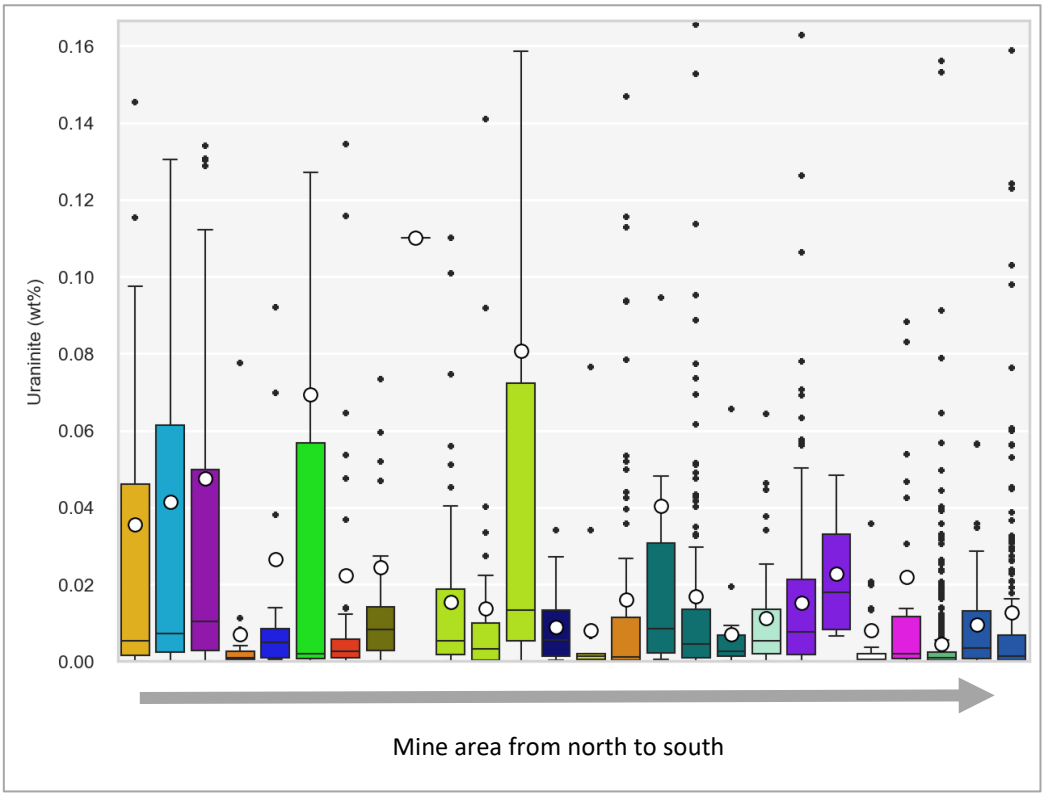

FIG 8 – weight percent of uraninite in head from north to south.

This is an excellent example of the reason for geometallurgy – that future material doesn't necessarily have similar behaviour as past material. Geometallurgy tests on future material enables us to predict potential processing issues that the plant would face in the future and allows time to make adjustments accordingly to avoid any negative impact on production. Those 'anomaly' geomet samples informed us of increase in leach residue uranium and drop in uranium extraction for SMA ores and equipped us with the right information to adjust our prediction of uranium in leach residue when SMA material came online. Figure 9 plots the plant feed and leach residue U_3O_8 since 2006 and the dotted line indicates when the plant started processing SMA ores. Straight away there was an upward shift in leach residue uranium grade. Since we forecast this would happen due to the different composition of SMA uranium mineralogy, it was not a shock when leach residue uranium grade jumped as SMA ores hit the mill. This actually validated our prediction.

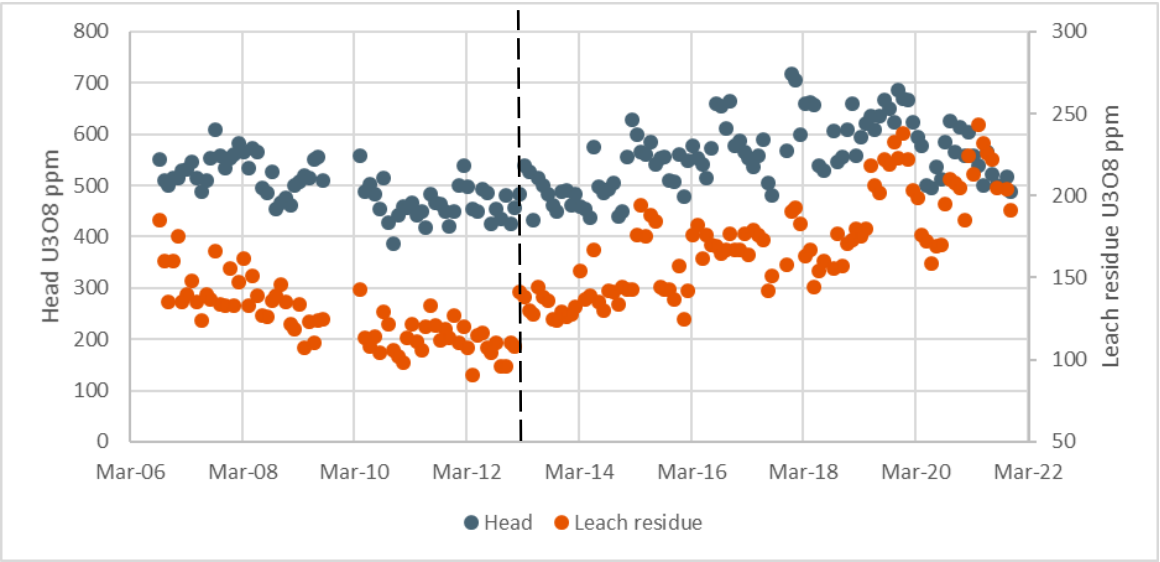

FIG 9 – Plant feed and leach residue U_3O_8 grade since 2006.

CONCLUSIONS

Outliers are inevitable during data collection and model development but they shouldn't be excluded just because they returned unexpected results or are minorities that sit outside the 'normal' range. Thorough investigation should be conducted to rule out the possibility of any mistakes during sample preparation. If they are caused by mistakes or errors during the test process then they should be removed from the data set since including them will unavoidably skew the data set. However, if there is high confidence in the results, 'outliers' may deserve extra attention as they are trying to tell a different story and further investigation quite often broadens our knowledge on the subject.

ACKNOWLEDGEMENTS

The authors appreciate the support from BHP Olympic Dam to publish this paper.

ABSTRACT

The development of geometallurgical programs for the prediction of future ore performance (recovery) can be a complex balancing act. Significant front end engineering and assumptions on future revenue streams rely on geometallurgy study programs. The scope of these study programs are frequently dictated by financial constraints that affect both the number of samples and the amount of test work that is able to be completed. This paper provides practical insights for those working in mass-mining operations on key aspects of predictive geometallurgy to make the most of these samples including:

- sample selection methodology – grade profiles, mineralogy, host rock lithology
- sample number requirements – development of orebody specific sample selection methods
- metallurgical test work flow sheet development
- primary variable determination and analysis
- integration with geology and mine planning departments
- integration with financial modelling for life-of-mine.

Practical examples are presented on the methodologies used. The intention is to leave the reader with an informed starting point when embarking on a future ore test work program.

INTRODUCTION

Orebodies, by their very nature, are rare and are required to be assessed on limited data capture. Conversion of discoveries to projects requires careful planning of resource definition (res-def) drilling that is most often carried out in a way that is aligned to meeting JORC geology reporting standards.

The definitions around the requirements of metallurgical assessment lags a long way behind geological assessment, however this is likely to change in coming years with many companies taking steps to ensure the projects they have coming online in the near term are compliant with the standardised metallurgical assessment requirements.

This paper considers the sampling methods used by the lead author for mass-mining (large scale developments) to ensure adequate sample coverage. The development of appropriate test work programs with a view to the end user requirements (mine planning) is discussed. Data usage in Life-of-mine (LOM) systems and the inherent risks and errors associate with this is also considered.

What is Geometallurgy? According to Wikipedia…..

> *Geometallurgy relates to the practice of combining geology or geostatistics with metallurgy, or, more specifically, extractive metallurgy, to create a spatially or geologically based predictive model for mineral processing plants.*

The practical reality of working as a geometallurgist involves working within multi-disciplinary teams (geology, processing, mining and environment). Future ore studies work is generally managed within the mining department (mine planning or mining studies). The primary deliverable of a geometallurgical study is typically ore processing plant recovery models for valuable metals in future ore sources. To ensure compatibility with mine planning systems, simple, head-grade based models that are spatially discrete (within a mine planning block model) are required. Final models should be developed around variables that are measured consistently across the orebody and with sufficient data density to ensure propagation of error does not cause issues. Secondary deliverables include

mill throughput forecasting (utilising hardness test work data); the impact of grind size on recovery (using targeted test work at multiple P80s), concentrate grade forecasting, consumables optimisation for OPEX evaluation, and tailings management (including cyanide detox requirements).

Geological domains do not necessarily correlate with observed metallurgical performance and determining a definitive 'geometallurgical domain' cannot be undertaken by either geology or metallurgy in isolation. The process of developing a site specific geometallurgical system involves defining amongst the entire team (geology, mining and metallurgy) the domains that are meaningful to performance, not geological formation alone. Key questions requiring consideration:

- Do the geological domains correlate to metallurgical domains?
- Do the chosen domains separate key mine planning requirements?
- Are the domains easily identifiable using either, or a combination of:
  - spatial location (can the orebody be zoned?)
  - lithological properties
  - head grade (of one or more elements) or
  - mineralogically driven.

Host rock lithology types do not necessarily drive the recovery of target payable elements, different lithology types can report similar metallurgical performance. To successfully determine relevant recovery domains, mineralogy is key for success, and textural changes in the ore should be part of the mineralogical assessment process. In order to relate mineralogical measurements to the *in situ* properties of the ore, a coarser size class is required for analysis (as opposed to mill discharge sized material).

Ore samples are characterised using detailed mineralogical methods and hardness testing. Ore performance is assessed on the response observed using a standardised hydrometallurgical (flotation and/or leaching and/or gravity etc) test work procedure. This procedure should provide a meaningful reflection of anticipated performance of a processing route at the full plant scale (testing for each major unit operation).

When performed correctly, geometallurgical characterisation of ores allows a profile of expected ore performance to be developed across an orebody for use in long-term forecasting and planning. The type of test program discussed here is not intended to be used for short-term production planning, but is suitable for determining long-term economic assessment and planning. This paper will discuss the methods developed to gather and interpret primary sampling and data types for use in long-term modelling of ore performance of large deposits (>200 Mt) or ore zones (50–200 Mt). Details of ore specific recovery modelling will be presented in a subsequent paper.

SAMPLE SELECTION

Appropriate sample selection is critical for successful modelling of key metallurgical variables. Traditionally geological lithology types are used in conjunction with the grade distribution of target elements within the block model. The number of samples required and the spatial distribution of these samples is often dependent on the level of study the results are being used for. Typically, in a desk top or pre-feasibility study there will be limited drill holes available to select from and the generated data is used for a high-level overview assessment of anticipated performance. If the ore performs well on these samples, then a targeted drilling program (geomet drilling) is undertaken to ensure coverage of ore types and grade distributions. To have a successful geomet campaign there are a number of key questions to consider:

- How many host rock lithologies are there?
- How does the grade vary of recovery targets?
- Variations in the presence of deleterious elements (possible preg robbing, smelter penalty elements etc)?

- Will mineralogical domain sampling be used (eg. high pyrite versus low pyrite; bornite versus chalcopyrite, tellurides, which depends on the nature of the orebody)?
- Differences in application of processing routes.
- Metallurgical sample size requirements.

The sampling method used is dictated by the size and style of deposit. In large scale mass mining operations where hundreds of millions of tonnes are expected to be mined, the application of a traditional approach can result in an economically crippling number of samples required to be metallurgically assessed to meet corporate orebody evaluation guidelines and 'matching' of statistical distributions of the grade of target elements with the distributions of these elements within the ore reserve block models. In addition to this statistical matching, the samples must be spatially distributed across the ore zone to ensure all regions are covered and there are no 'blind spots' for estimation of recovery forecasts. Figures 1 and 2 shown the distribution of two key elements within an ore deposit using data from the block model. Both elements are payable and require recovery forecasting to LOM. For the purposes of the discussion here these two target elements will be known as X and Y. Typically, the distribution of these elements in the head grades of metallurgical samples should be as close as possible to the distributions within the block model.

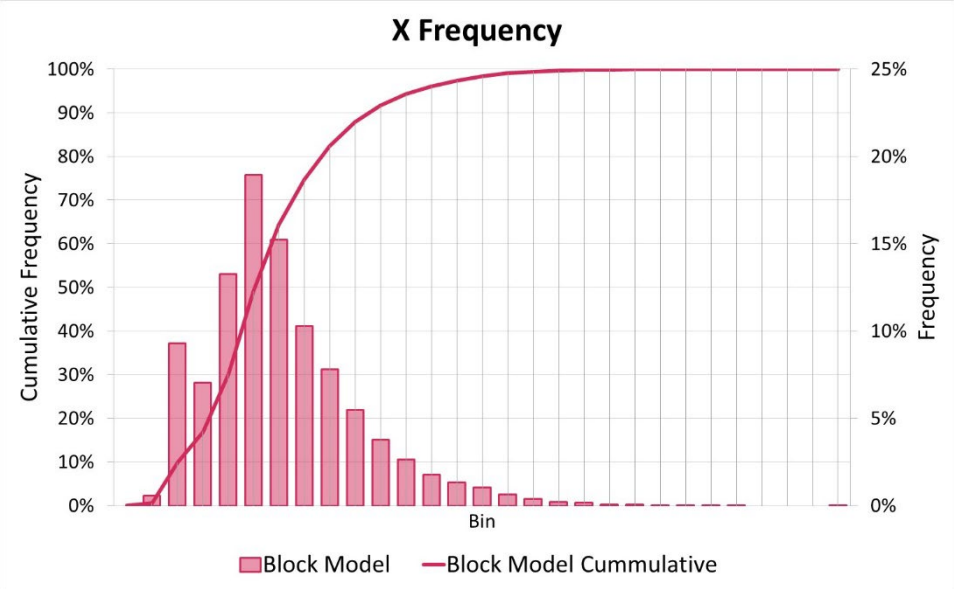

FIG 1 – Distribution of element X within the block model.

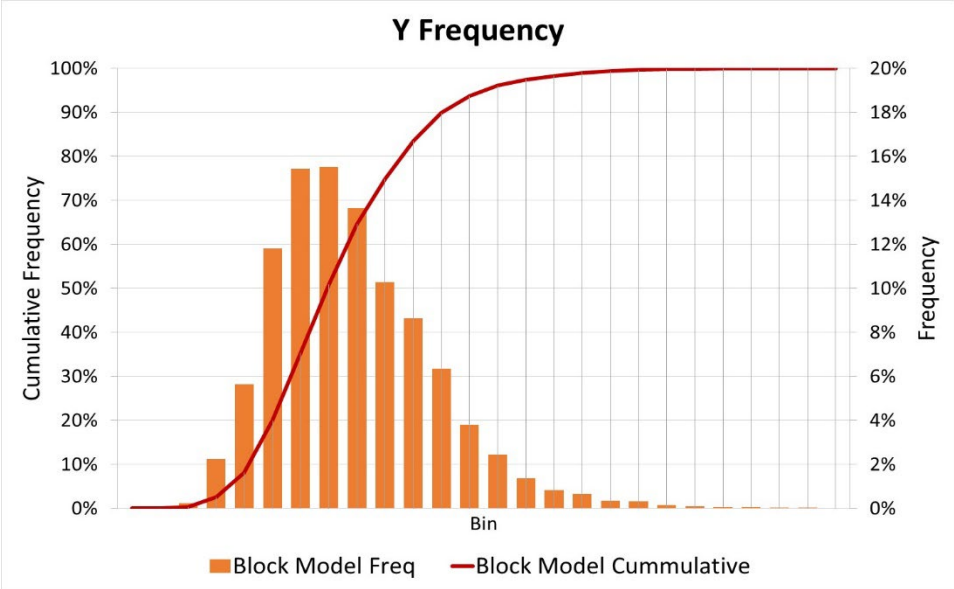

FIG 2 – Distribution of element Y within the block model.

Both elements X and Y provide the economic basis of the operation, they are processed together, recovered together and consequently sold together. The use of the separate distributions (Figures 1 and 2) to select samples for metallurgical testing can make sample selection a time-consuming process as drill hole intervals are individually assessed and reassessed in an attempt to match the metallurgical sample set distribution with that of the block model. Where this approach has been applied to large ore zones a spatial bias is often observed.

A different approach has been developed by the author[1] in which samples within large ore zones (>200 Mt) are taken at regular spatial intervals to ensure there is no bias from one area of the orebody to another. This method is not applicable to small or narrow deposits where other considerations must be taken into account. The spacing of the samples (in a grid format) is determined by the expected number of samples required and the analysis of key elemental data in combination (as opposed to individual elemental histograms). This approach has been successfully applied to a number of discrete ore zones in mass mining applications. Reverse analysis of input data has shown that the approach provides excellent statistical matching of elemental distributions while ensuring appropriate spatial coverage and weighting of all samples. This further ensures the consequent metallurgical models are not spatially biased towards one area of the ore zone.

Application of this method involves placing a 3D grid over the ore zone and selecting a single sample from a hole within each 3D space. In very large deposits, the grid layers could be 100–200 m apart in vertical height (Z direction) and 50–100 m apart in width and depth directions (X and Y directions within mining systems). The scaling will depend on the geometry of the deposit under consideration. Holes should be as close to vertical as possible so height (Z) within the ore zone can be isolated for modelling purposes.

Sample weight is a critical requirement to determine the length of core to be used. In programs managed by the author of this paper (Newcombe), a run of 30 m of half HQ core generally provides sufficient material for a full set of metallurgical analyses (approximately 100 kg). This requirement must be achieved by all samples to ensure they are all equally spatially weighted for modelling purposes. For this approach to be successful, each sample must be metallurgically tested individually. Any compositing of samples will not allow for spatial models to be developed.

Each block of ore contains both element X and Y together. Analysis of elemental data from the block model shows the range of grades of X and Y within each individual block. Figure 3 presents this data graphically, where each data point is semitransparent (darker colour = more data points). The average grade of all blocks is highlighted in blue.

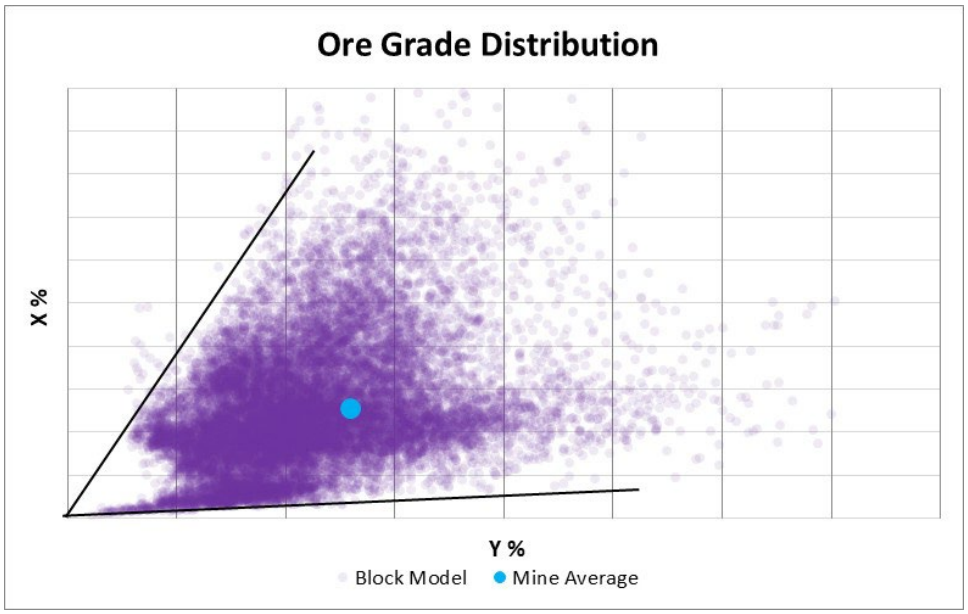

FIG 3 – Block model output for elements X and Y.

Each block will be mined at a given time based on the mine plan. Mine planning can estimate when each block will present to the mill. Mining simulation and scheduling programs such as PCBC,

Deswick, XPack, DataMine or Whittle can estimate the average grade of material to be presented to the mill. Mixing occurs within the mining process itself and as ore is moved from the pit or underground. Don't forget stockpile mixing! An output of expected daily head grades and source material type (lithology or ore zone classification) should be produced by mine planning to allow an estimate of material likely to be presented to the processing facility.

Figure 4 shows the expected daily average mine output for LOM of the material in Figure 3. Mill feed material is generally within the 'triangle'.

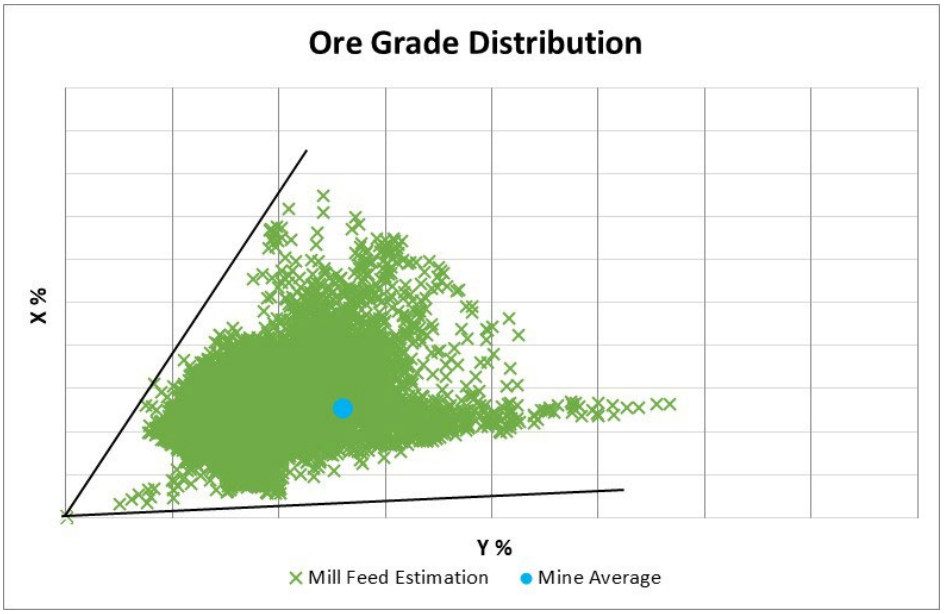

FIG 4 – Mine plan output mill feed grade estimate of element X and Y.

Similarities are observed between the two data sets; however, the extremities of the block model data have now been effectively blended out by the mining process. This ore zone has been sampled using the grid approach, with samples selected indicated on Figure 5 in red. Figure 5 also includes the backdrop of data from Figures 3 and 4 for comparative purposes. The average grade of the sample set is indicated in yellow and is observed to be very close to the orebody average grade (blue).

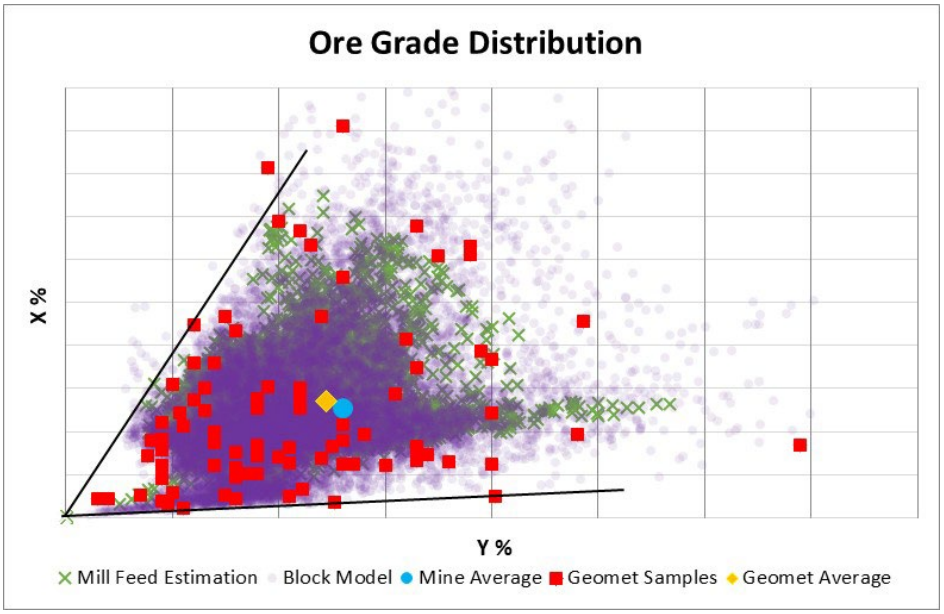

FIG 5 – Combined sample analysis.

When the distribution of the head grades of the samples used are directly compared with both the block model and mine plan output (Figures 6 and 7), the similarities in the grade distributions are clearly observed. This indicates that the sampling method (spatially weighted grid-based approach) has covered the combination of X and Y grades satisfactorily and has also incorporated the extremities of behaviour (very high or very low-grades). Further analysis shows that in addition to good spatial coverage, all relevant lithology and mineralogical types have been analysed. The implementation of this approach to sampling has allowed the successful development of recovery algorithms that have been in use for forecasting plant performance for many years at the operation under consideration. These forecasting models track within ±2 per cent of actual plant performance.

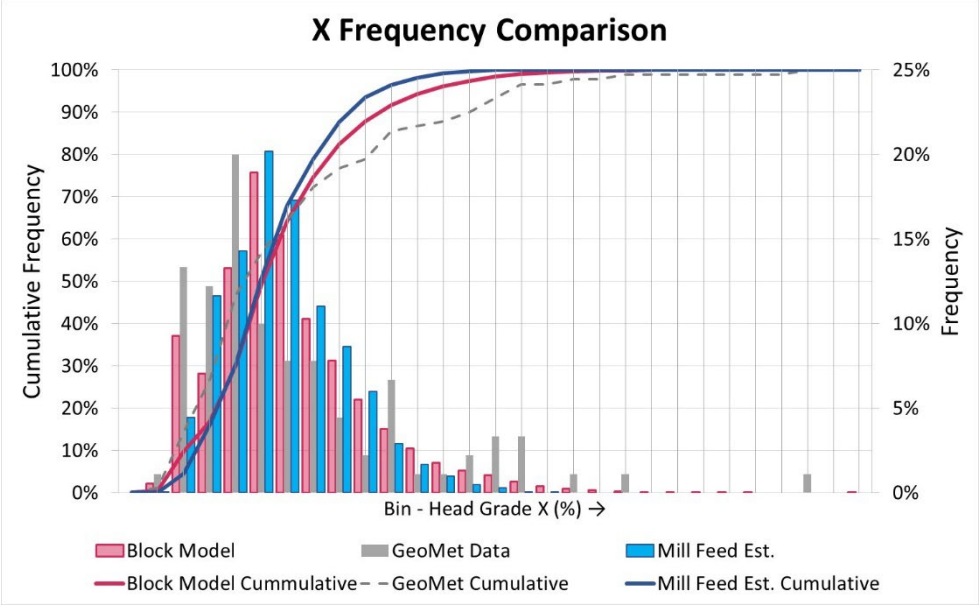

FIG 6 – Comparative distributions of element X.

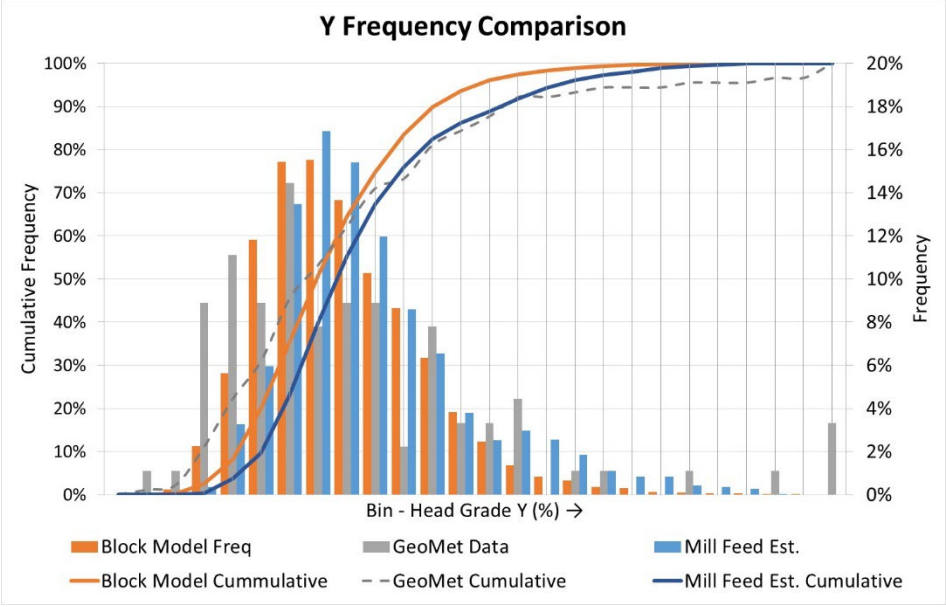

FIG 7 – Comparative distributions of element Y.

STANDARDISED TEST WORK PROGRAMS

Once sample selection has been completed, the individual composites require metallurgical testing. In existing operations the site standard test that represents plant recovery should be used. In new deposits where no current standard is in place, a test work regime should be established that best represents the likely unit operations and processing route for the anticipated plant. A standard test work regime would typically incorporate the following elements:

- Sample geo-chemistry (full multi-element analysis).
- Modal mineralogy assessment for ore texture.
- XRD for clays or targeted Au deportment work for Au deposits.
- Hardness testing with a view to mill simulation. Must include as a minimum:
  - SMC (SAG Mill Comminution) Test.
  - BBWi (Bond-Ball Work Index).
- Further hardness testing should consider:
  - CWi (Crusher Work Index).
  - BRWi (Bond-Rod Work Index).
  - Ai (Abrasion Index).
- Standard set of tests for each major unit operation of the plant including (as appropriate):
  - Flotation testing.
  - Leaching methods.
  - Gravity (GRG) and Au, Ag, Cu diagnostics.
- Targeted testing including (flow sheet dependent):
  - slurry rheology.
  - flotation cleaner circuit configuration.
  - grind sensitivity (both primary grind and regrind).
  - reagent consumption.
  - recycle stream impact.
  - site water impact.
  - environmental impacts (acid mine drainage, tailings properties).

There may be other tests required dependent on the nature of the deposit under consideration. An example of a test work flow sheet is presented in Figure 8.

If possible, a point load test (PLT) should be included on a full core sample taken prior to and after the end of the 30 m of geomet core and a segment in the middle (15 m). PLT is used by structural geologists and mining engineers in their structural evaluation of deposits. It is recommended that wherever possible PTL is incorporated into the geomet program to allow comparison between the geotechnical and geometallurgical data sets. It is important to note that PLT must be done on a piece of whole core and that the test is considered destructive, ie the material used for the PTL cannot be used again for any other type of hardness evaluation. The PLT needs to be incorporated into the core processing procedure to ensure that samples are managed correctly. Once the core has been cut lengthways, the PLT is no longer possible.

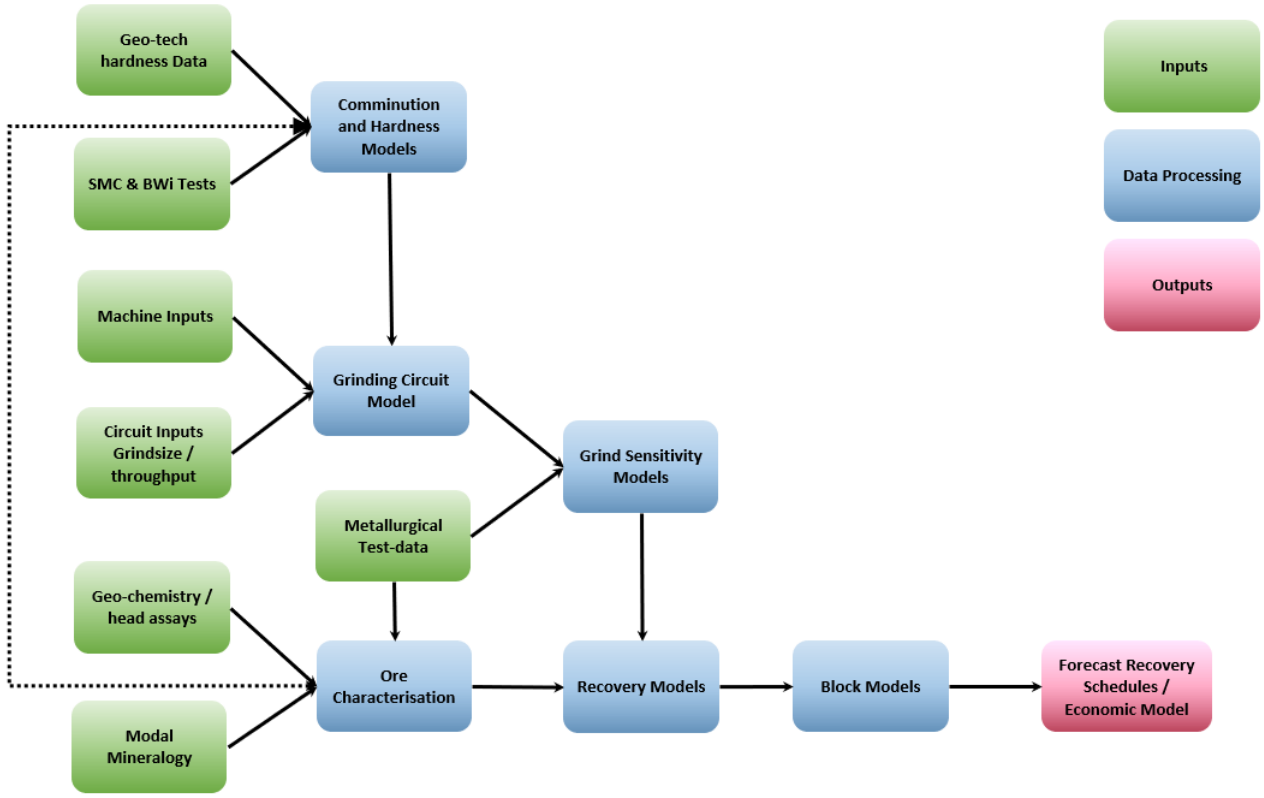

FIG 8 – Example geomet testing flow chart to produce data ready for scheduling and recovery forecasting.

The final destination of the geomet work is the recovery models used for the economic evaluation of a deposit. This output must be compatible with the data existing in both the block model and the mine planning system. This usually dictates that any recovery algorithm should be based on universally measured elemental head assays. The metallurgical algorithms developed should also reflect the different metallurgical domains, with each domain having its own algorithm as required. Ore characterisation work then becomes a primary consideration to the segregation of ores within the block model. Figure 9 shows how the recovery models are used in conjunction with mineralogical evaluation and primary ore hardness characteristics to culminate in the final set of recovery algorithms for an ore zone. Note that there is interaction between hardness models (for circuit simulation), ore characterisation (various mineralogical inputs and lithology considerations) and the recovery models themselves. The process of finalising the recovery models is iterative between these three major inputs as they each affect the other and the consequent final result that is used by mine planning. In the authors' experience, ores are regrouped several times before metallurgical domains can be finalised.

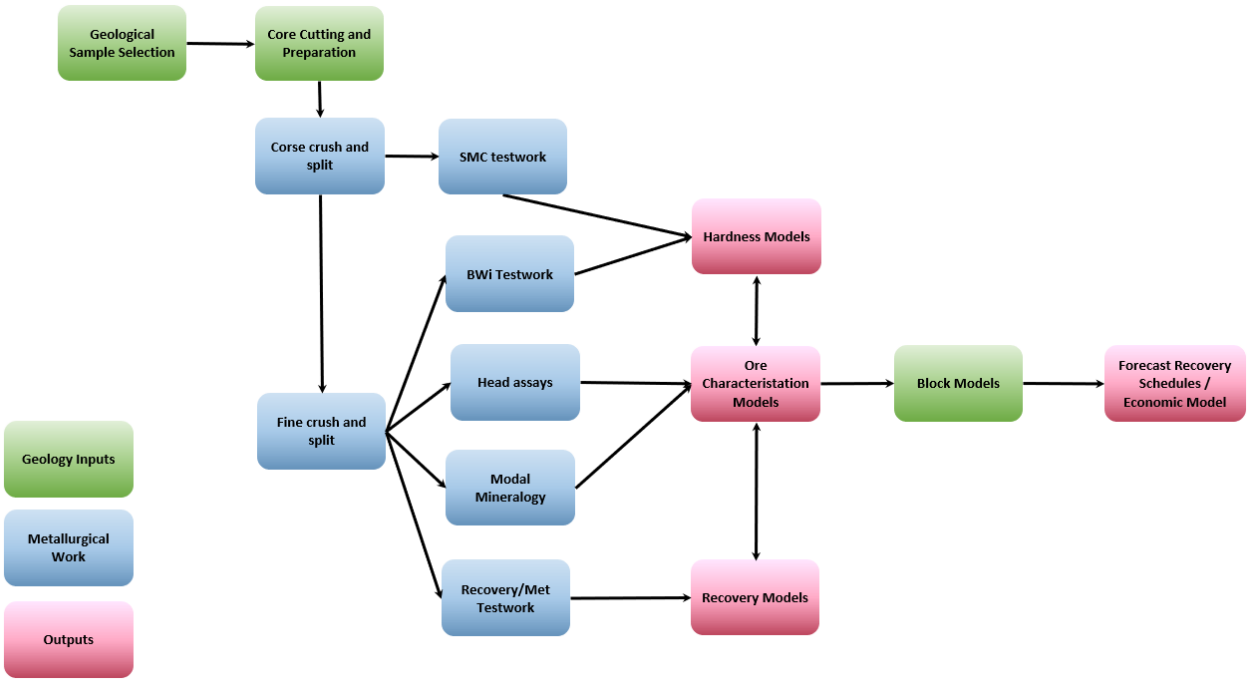

FIG 9 – Geometallurgical modelling process flow chart.

DATA EVALUATION

Large amounts of data are generated by complex metallurgical evaluation. Mineralogy data is used in combination with metallurgical response data in an iterative process to determine whether grouping of samples is achievable and appropriate.

Comminution data

An example of hardness data modelling using mineralogical inputs is presented in Figure 10. The original data set in this case is for Ore A, which was modelled using key minerals for their impact on ore hardness properties. A subsequent data set from a neighbouring ore zone (Ore B) was generated and tested against the Ore A data set to determine if any measurable change in comminution properties could be observed which may change the mill output P80 to hydrometallurgical processing. The mineralogy data indicates that these two ores should process in a similar way through the plant.

The hardness parameters must be relatable to a universally measured variable in the mine planning system to allow an output of data over time. In this case spatial location and elemental head assays were available to be used. In this case the Ore A BWi is mineralogically related to quartz, sphene and chlorite. Regression analysis of elemental data and spatial tags allowed a model to be developed that uses Fe assays for BWi and Dwi, with DWi found to be spatially related to height within the ore zone. Note that these models will be bounded based on their source data set.

$$\text{Ore A BWi (kWh/t)} = 18.2 + 0.797 \times \text{Fe\%} \quad (1)$$

$$\text{Ore A DWi (kWh/m}^3\text{)} = 25.2 + 0.438 \times \text{Fe (\%)} - 0.0037 \times \text{Z (m)} \quad (2)$$

The BWi model was validated with Ore B, which also showed strong correlation to quartz and sphene.

$$\text{Ore B BWi} = 18.593 + 0.564 \times \text{Fe (\%)} \quad (3)$$

The similarities between the relationships for BWi and statistical equivalence testing indicated that these two adjacent ore zones will have similar properties in processing through the mill. At the time of writing, DWi data for Ore B was not available.

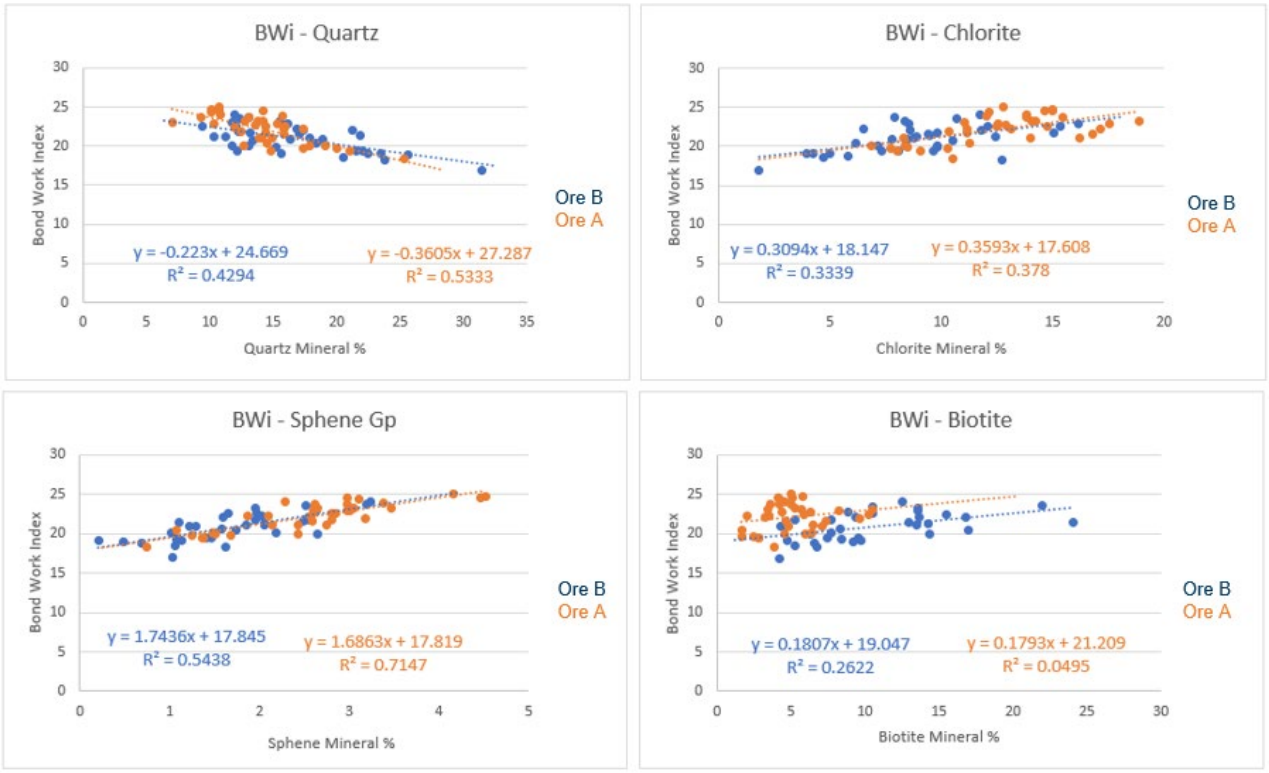

FIG 10 – Hardness parameter and mineralogical relationship development.

The data generated by modelling of hardness parameters allows an annualised estimate of key variables that can subsequently be used in mill throughput simulations. An example of this output data is presented in Figure 11. Any stockpiled material that is going to be part of the mill feed plan should be included in this type of work.

How this data may be utilised in comminution simulations is presented in Figure 12. This provides estimates of mill throughput based on the ore input data from all known sources as per the mine plan. Using the comminution data generated for each ore type in combination can provide estimates of wet plant feed P80 (milling circuit product) and power requirements. Simulations can be performed to evaluate the impact of running the comminution circuit with various ore feed blends and circuit operating conditions (maximum power draw versus target throughput etc).

A key output for metallurgical circuit financial modelling is the P80 grind-size produced by the primary milling circuit (flotation or leach feed P80 μm). Grind sensitivity test work allows the recovery impact of target elements to be determined. An example of grind sensitivity data is present in Figure 13. The slope of the P80-recovery curve provides an estimate of the per cent recovery loss per micron increase in grind-size, this is often referred to as the *Delta* recovery loss. Delta recovery loss with P80 can then be applied to the P80 prediction from comminution simulation data to provide an adjustment to the overall recovery calculations for financial modelling work.

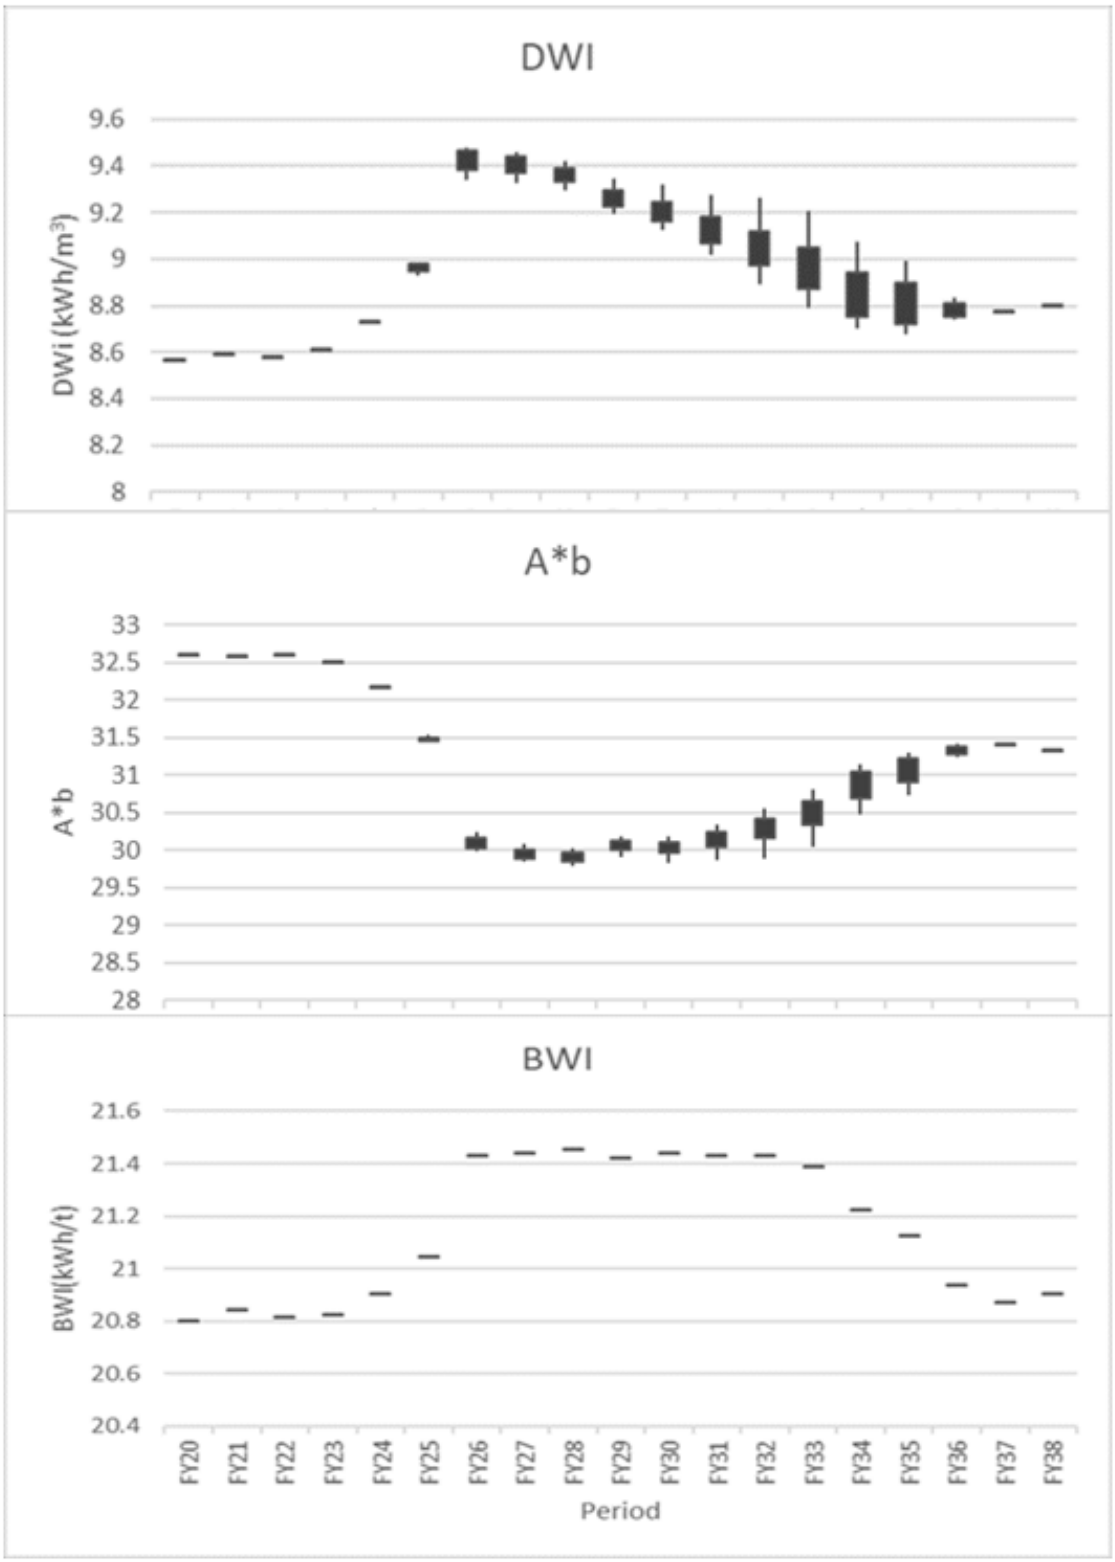

FIG 11 – Example of annualised hardness parameters DWi, A*b and BWi.

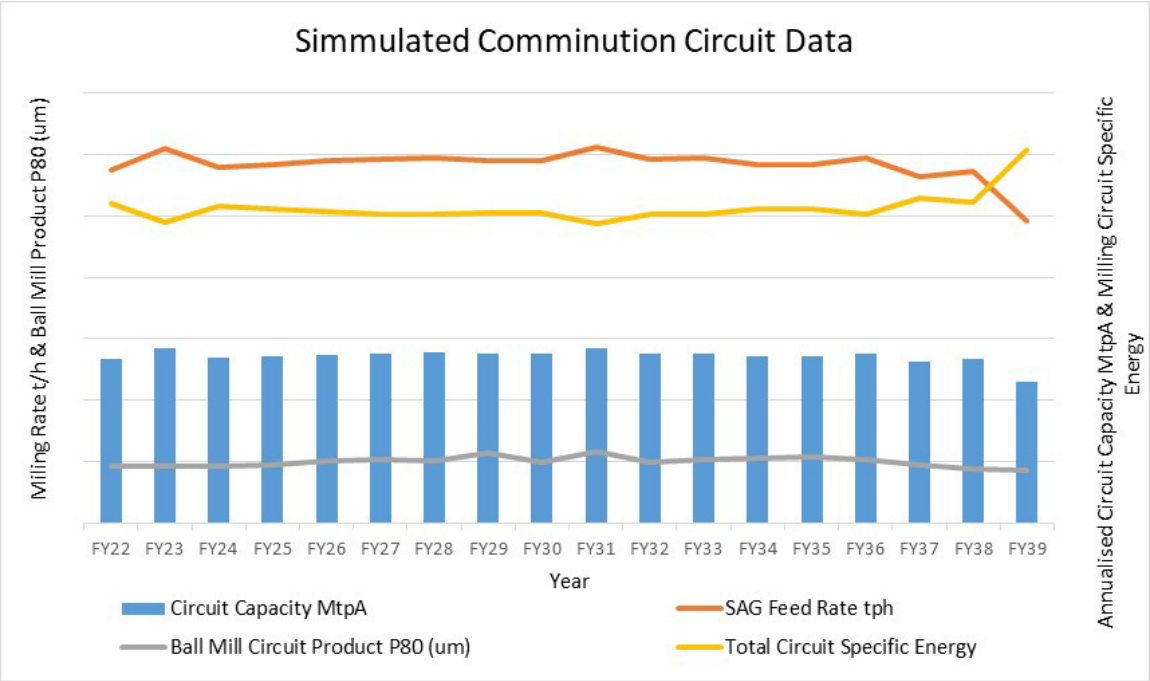

FIG 12 – Example of annualised comminution circuit simulation data.

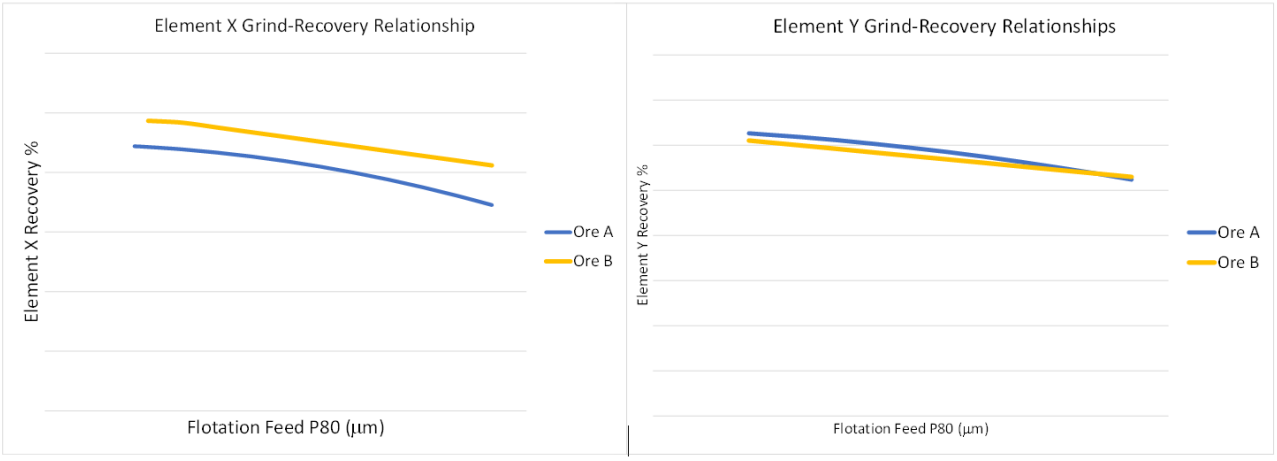

FIG 13 – Example of grind sensitivity estimation for elements X and Y.

Recovery modelling

Effective financial evaluation of an ore relies on the recovery models to be a good representation of all types within a deposit. Key questions which must be considered are:

- How many target value elements for recovery modelling are within the ore? (What do we get paid for?) Au, Ag, Zn, Pb, Cu, Ag, Ni or Mo? Or any combination of these or others.
- What will impact recovery? In the case of Au leaching, preg-robbing contaminants must be considered. What is the mineral liberation size and grind sensitivity.
- What else is being recovered? Penalty elements that will cause financial impacts need to be considered.

Metallurgical data is evaluated in conjunction with sample mineralogy using an iterative approach to establish groups of samples based on both metallurgical response and feed mineralogy. Host rock modal mineralogy, grain size data, and mineral association data is utilised. Spatial location is modelled to determine if there is regional variability and if ore zones can be established and bounded with their own recovery models. The modelling method used is multivariable regression analysis (generally non-linear). The process of modelling is in itself a complex process and will be discussed in detail in a subsequent paper.

The culmination of modelling work results in recoveries for each ore type or domain to be calculated (Figure 14). The algorithms for each ore type are used within the mine planning system in conjunction with grind sensitivity adjustments to estimate output metal units and average recovery for the processing facility on an annualised basis (Figure 15).

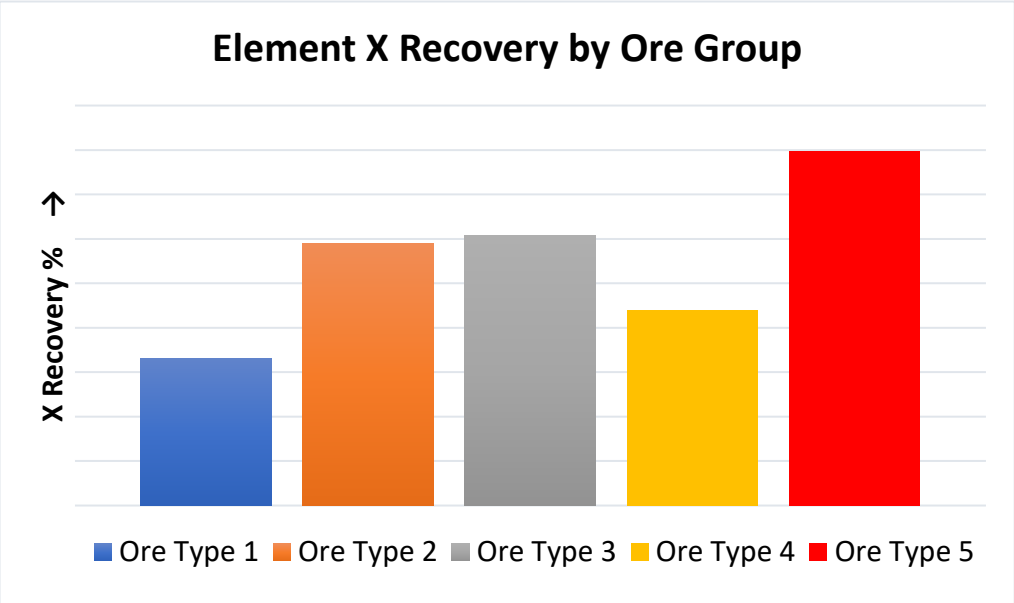

FIG 14 – Example of ore type recovery average variability.

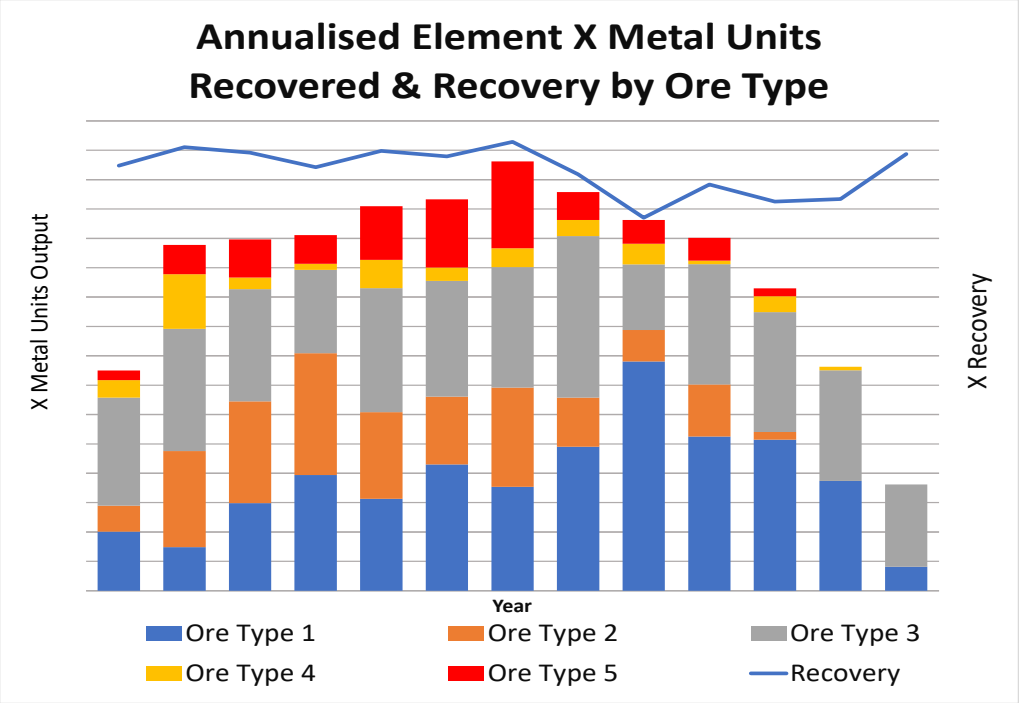

FIG 15 – Example of application of ore type recovery data to estimate average metal production and recovery.

INTEGRATION ACROSS LIFE-OF-MINE PLANNING

As described in previous sections, geometallurgical test work can unlock significantly more for a mining project than just recovery functions. The key to successful integration of the full suite of orebody knowledge (OBK) requires two key elements:

1. Knowing your orebody with well understood spatially captured data; and
2. A system that allows people to integrate knowledge and develop this into practical plans.

The first step for an organisation to know its orebody is to have a well-defined drilling program with good QAQC and data capture within a database. A carefully constructed program can add significant value. Understandably, the first focus of exploration teams is the identification of valuable elements and minerals. However, it is the authors' experience that significant business value (and time) is lost when other parts of the planning process are not considered in follow up drilling once a target has been identified as prospective.

Once a target is identified the definition of needs for a drilling program expands to:

- Further definition of the geological setting and valuable elements;
- The geotechnical setting as it relates to the mining method (rock mass characteristics, stress regime, and factors important to excavation stability) and hydrogeology information.
- The geometallurgical factors such as head grades, mineralogy, hardness and key mineralogical properties such as grain size and mineral association.

These form the basis of the data required for full orebody knowledge and the ability to define the best Mine to Mill plan. The requirements for each operation will be unique and influenced by the orebody itself as well as the organisation conducting the work. The ability to create meaningful test work programs that have quality outputs for planning integration comes from a well-defined drilling and data collection program.

Once test work programs and modelling is complete, the process of bringing the data generated together into a mine production model is the role of the mine planning team. Although traditionally this is an area of speciality for mining engineers, larger operations and those operations with complex orebodies are increasingly using teams comprising of geologists and metallurgists to extract the best from the planning process.

The key elements of a good mine production model for mass mining are:

- A valuation field parameter within the spatial block model to enable economic planning.
- The ability to calculate and output parameters that matter to the ore treatment planning process, including parameters that impact on rate, grind size and 'red flag' elements that can result in significant impacts to processing.
- The ability to provide feedback loops to enable team members to collaborate on key drivers of the success of the project.

In determining the value of each block, the team will need to consider:

- Head grade of economic elements
- Geometallurgical domains for accurate recovery estimates and interaction planning where domain interaction issues exist.
- Orebody parameters that affect the saleable value of the operations product (deleterious elements and expected concentrate quality)
- Geotechnical factors that affect input costs, including poor ground conditions, drill and blast performance characteristics, caving performance and water ingress.
- Mill performance characteristics that increase or decrease costs and throughput rates and adjusting the value of a block to account for these.

Bringing the elements of the plan together in one 3D space with the impact of each OBK field transparently shown allows an understanding of the entire value chain for each member of the planning team. With an increasing focus on the use of AI tools in the mine planning industry, the correct assignment of this value field is of even greater importance.

Other important elements of the mine production plan are also brought together into the model at the same time as the creation of the valuation field. This process can be as simple as aggregating other models, whilst at other times it can require software to interpret or calculate results. Once created, the full OBK model can then be used to create the mine and processing plans. Figure 16 presents an example of an OBK flow sheet for Mine to Mill planning purposes.

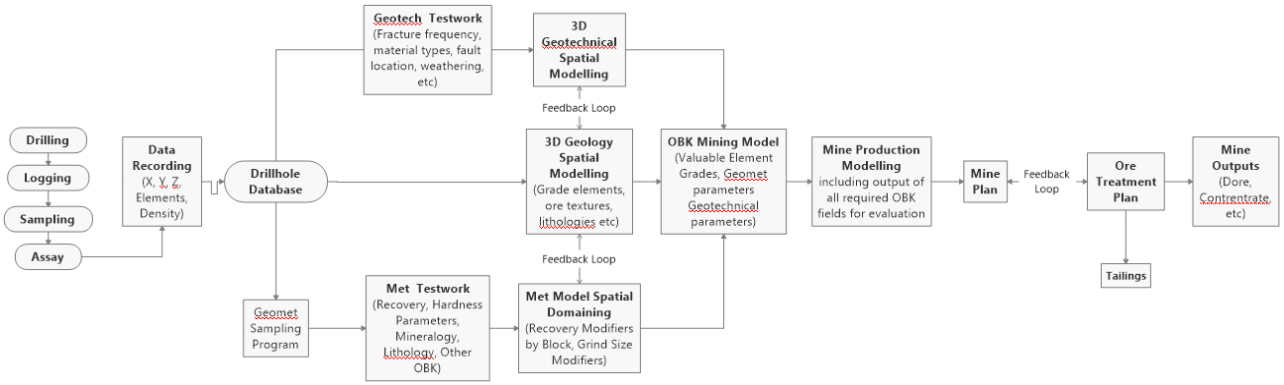

FIG 16 – Typical OBK Mine to Mill planning flow sheet.

Quite often at this point, the question is asked by management 'Why is this the answer?'. The answer is almost invariably in a drill hole interpretation or a model created by a technical expert. By bringing the orebody knowledge together in one central mine planning model, the answer to this question can be more clearly articulated, investigated and tested. This allows better decision-making and operational responses to upcoming issues before they become today's problems.

CONCLUSION

In large scale mining operations, a grid-based sample selection process is proposed for feasibility study level deposit evaluation. This method has been successfully applied to a number of ore zones and deposits.

Appropriate spatial coverage is essential. Samples must have equal spatial weighting within the overall ore zone to allow integration of spatial models with mining systems – this means no mixtures. Ore interaction test work can be undertaken as part of an additional program to check for any issues that may be caused by mixing of different ore types.

Feed material evaluation should include multi-element assay and mineralogical analysis. The metallurgical test work requirements are dictated by the expected processing route of the ore.

Modal mineralogy is required to determine measurable links to both geology and key metallurgical performance parameters.

Defining a 'geometallurgical' domain is only possible when the observed metallurgical response is supported (or explained) by both the mineralogy and the geology of a system.

LIBS, XRF and Raman sensors for optimal bauxite sorting

ABSTRACT

Bauxite, bauxite residues (BR) and Bayer Liquor are important resources for Al, Sc, V and Ga. Bauxite is currently the solely source for primary aluminium. At global scale about 80 plants produce alumina. From these resources, about 1–1.4 t of bauxite residues are generated per tonne of alumina (Ujaczki *et al,* 2018). Bauxites present heterogeneous grades at lateral and vertical scale, variable mineralogy, and chemistry. Therefore, it is important to localise most precisely minerals hosting valuable metals for Al, Sc, V and Ga, but also hazardous minerals/metals for processing such as reactive silica (aluminosilicates), TiO_2 (rutile, anatase), and minerals generating moisture (phyllosilicates). This must be done at the beginning of the value chain on mine sites to reduce transport and processing costs, and BR volumes. In this study, different types of sensors were applied to major lithologies of the karst bauxite deposits of SODICAPEI (Villeveyrac, Southern France), for optimal bauxite sorting. Therefore, the applicability of Laser-Induced Breakdown Spectroscopy (LIBS) was investigated with an industrial LIBS system and a LIBS core scanning system. Furthermore, first time-gated Raman and XRF spectroscopic analyses were performed with the multi-sensor ANCORELOG system. Our results, obtained in the frame of the EIT ANCORELOG and T-REX projects, show that LIBS is powerful to precisely define the bottom and top layer of bauxite ores and define the bauxite types by measurement of major and trace elements (Al, Mg, K, Na, Ca, C, Si, Ti, Fe, S). Furthermore, LIBS can access the critical parameters crucial for bauxite processing. XRF gives semiquantitative data for Mn, Fe, Cr, Ti, V, Ca, K while time-gated Raman spectroscopy allows deciphering clay minerals, Ti-minerals, boehmite and carbonates, all allowing defining bauxite on and offset.

INTRODUCTION

Bauxite production and bauxite residues

Bauxite is the most important raw and feed material for alumina (Al_2O_3) production worldwide with the major producers Australia, China, Brazil, Guinea, and India, and further reserves in Vietnam, Jamaica, and Indonesia (USGS, 2021). Bauxite is a tropical soil formed on Al-rich rocks with variable morphologies and topographies, and therefore ore grades are heterogenous at vertical and horizontal scale. About 85 per cent of the bauxite is converted into alumina through the Bayer process, then into aluminium metal through the Hall-Heroult process, while 10 per cent of Al is used for non-metal products, and 5 per cent in refractory and abrasive materials.

In 2021, primary aluminium production globally amounts to 5747 kt at a daily rate of 185.4 kt. Western and Central Europe produced 279 kt, while Russia and Eastern Europe produced 350 kt. A yearly increase of about 5.2 per cent of Al production was noted based on July 2021-data (https://international-aluminium.org/july-2021-global-primary-aluminium-production/). Until 2030, a 4 per cent-increasing Al demand is expected. Bauxite residues are the world-largest industrial by-products estimated at around >4 Bt with an annual growth of 120 Mt (bauxite.world-aluminium.org). This reflects approximately 1–1.4 t of bauxite residues (BR) generated per tonne of alumina produced (Ujaczki *et al,* 2018). Bauxite residues represent an excellent resource for scandium, vanadium, gallium, and titanium (Vind *et al,* 2018).

Why do we need analytical sensors to optimise separation of bauxite ore from waste?

We must reduce the annual growth of about 120 million t of BR and the associated environmental impact of bauxite processing. Bauxite processing including mining, refining, anode production, electrolysis, and casting, emits 16.1 t of CO_2 per tonne of Al. Considering global CO_2 emissions, primary Al production accounts for 92 526 kt of CO_2/a (https://international-aluminium.org/july-2021-global-primary-aluminium-production/).

Europe produces only 10 per cent of the total bauxite which is needed for Al production. For that reason, bauxite ores are imported from eg Australia and Guinea, and transported at high cost to feed the EU processing plants.

A first step to leave low-grade and most waste material in the ground, requires efficient mining, based on detailed geomodels. Moreover, a second step of sorting should occur at different processing steps, starting with sorting rare metal bearing BRs hosting eg Sc, V, Ga from ‘barren’ materials. The latter are suitable for eg cement additives.

Bauxite from different regions have variable chemical and mineralogical compositions (eg Guinean deposits: Schulte and Foley, 2013; Barry *et al,* 2021). The feed materials are crushed, grinded and homogenised at the plant. For Bayer processing, a constant chemical composition must be ensured (https://www.removal-project.com/wp-content/uploads/2021/09/removal-policy-report-20210923.pdf). Therefore, the monitoring of the feed with analytical sensors will contribute to anticipating dysfunction in processing and further process optimisation.

Solutions for sensor-based material sorting

Laser induced breakdown spectroscopy (LIBS) is more and more used in the mining and processing industries (Pedarnig *et al*, 2021; Noll *et al*, 2018). It performs multi-element chemical analyses with minimal destruction, using a highly energetic pulsed laser for *in situ* excitation of the atomic species at the sample surface (Cremers and Radziemski, 2006; Hahn and Omenetto, 2012). This multi-elemental technology can be applied as well-aimed point measurements, as line scan, or as imaging tool (Pedarnig *et al*, 2021; Rifai *et al*, 2020; Jolivet *et al*, 2019). LIBS measurements are fast (eg Rifai *et al*, 2020), can operate under harsh conditions (Pedarnig *et al*, 2021; Noll *et al*, 2018), and can also access the light elements (Harmon and Senesi, 2021).

However, quantitative use of LIBS on rocks, soils, and processing materials (muds and slurries) is challenging, as the plasma strongly responds to physical and chemical variations on the sample surface (eg Harmon and Senesi, 2021). Moreover, when analysing slurries, the detected LIBS signal

is weakened because part of the light energy is absorbed by water (Khajehzadeh *et al,* 2016). In general, calibrated LIBS data can be considered as semi-quantitative when compared to conventional laboratory analyses. Thereto, several different calibration and classification methods for LIBS applications have been developed (eg Harmon and Senesi, 2021; Galbács, 2015).

A wide variation in LIBS instruments exists, of which many are customised for particularly applications. The optimal specification of the different components (laser, spectrometer, optical components) of a LIBS system depends on the application. Commercial LIBS instruments include portable handheld instruments (Rakovský *et al*, 2014), industrial instruments for various sorting, quality control, or routine analysis applications (Pedarnig *et al*, 2021), drill core scanner, as well as imaging LIBS instruments:

- Raman Spectroscopy, a well-known non-destructive method to analyse and identify minerals, has been further developed for use in portable equipment or for being installed on Mars Rovers for Martian surface exploration (Veneranda *et al*, 2021). Time-gated (TG) or time-resolved (TR) Raman spectrometers have been developed to obtain fluorescence-free Raman spectra with only a single laser as source of excitation (Kögler and Heilala, 2020; Beyssac, 2020). Furthermore, the hardware is miniaturised so that the instruments can be used in-field on Earth and planetary applications (Veneranda *et al,* 2021 and papers therein). Time-gated Raman spectroscopy suppresses the fluorescence and disturbing signals. Time-gated Raman is essentially used in sensing industrial processing, followed by mineralogical applications (Kögler and Heilala, 2020). The Timegate Instruments (copyright) developed a Raman instrument specifically dedicated to the entire value chain from exploration, processing to recycling of materials (www.timegate.com). For Raman-based mineral identification, open access mineral libraries are available (eg RUFF Lafuente *et al*, 2015); USGS spectral library (Kokaly *et al*, 2017) or the Raman Open database ROD (El Mendili *et al*, 2020), which can be adapted and extended to the target materials.
- Portable XRF (pXRF) is a non-destructive and well-established method, which is widely used in the mining and processing industries for obtaining reliable Quality Assurances/Quality Control (QA/QC) validated by laboratory analysis (Lemière, 2018; Duée *et al*, 2019). Such analyses can be performed as line and or point analyses. Several XRF scanners are in operation such as the Minalyzer (https://minalyze.com/), combining XRF, high resolution photography and topography, designed for the mining and processing industries, while others, such as Avaatech (www.avaatech.com), are designed for sedimentary and marine applications. JC Bachmann (www.jcbachmann.com) developed an XRF device within the ANCORELOG project for a combined analytical expert system for chemical logging and monitoring drill cores and production processes.

In the frame of the EIT projects ANCORELOG and T-REX (https://www.dmt-group.com/ancorelog-1.html) a modular combined analytical sensor system with X-Ray Fluorescence (XRF), time-gated Raman spectroscopy, and short wave-infrared spectroscopy (SWIR) was developed.

This paper demonstrates the performance of in-field sensors on an artificially composed bauxite drill core profile which is typical for Karst environments, as present in Southern France, or South-eastern Europe. A typical drill core profile from the Southern France bauxite presents the top sedimentary rocks, various bauxite ore and grades, and the bottom dolomitised limestone. Results from In-field instruments (XRF, LIBS, pIR, Raman) is compared to those from laboratory XRF, LIBS and X-Ray Diffraction (XRD). Recommendation for industrial use of sensor combination based on this study are presented.

SAMPLE MATERIALS

The samples used in this study come from the karst-type bauxite deposit, SODICAPEI, close to Villeveyrac in Southern France. The lithologies of the samples comprise from right to left (Figure 1): bottom dolomitised limestone (karst), pisolitic bauxite, red bauxite, pisolitic bauxite, pisolitic bauxite conglomerate, red clay with bauxite, the marker horizon composed of black shale, marl, and sandy shale. The black shale marker horizon indicates the proximity of the onset of the bauxite. This layer is oxidised in some parts of the ore deposit to red shale.

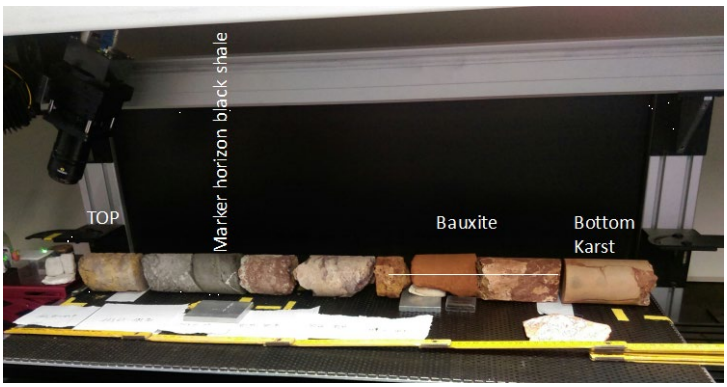

FIG 1 – LIBS measurement configuration of the composite bauxite profile for a line scan with the LTB core scanner from 2011 (from Meima *et al*, 2021).

ANALYTICAL METHODS

Portable infrared spectroscopy

For accessing mineralogy, was applied with an ASD Fieldspec 3® (Panalytical) at the BRGM (Orléans, France). Prior to measurements, the signal was calibrated on the white reference material, Spectralon®. Each spectrum is composed of averaged 250 consecutive acquisitions to decrease the background noise. The measurement window is 1.7 cm in diameter. The device can acquire a total of 2150 spectral bands and has its own halogen light source. For each sample, we selected the pIR measurement points considering colour and texture parameters. Spectra are Hull-corrected (Phang *et al,* 2006).

X-Ray Diffraction analyses

For determining mineralogical compositions, were performed at ERAMET IDEAS, Trappes, France. An X'Pert Pro Panalytical diffractometer with CuKα radiation at 450 kV and 40 mA was used on (<80 microns)-agate-milled samples. The analytical conditions of the diffractometer were 3–80 °2 Theta with counting times 188 s every 0.0167° in an Al-rotating sample holder. The COD (http://www.crystallography.net/cod/) database and high SCORE software was used for diffractogram interpretation.

X-Ray Fluorescence analyses

For accessing major and minor elements**,** were performed with a Panalytical Axiosm AX-WD XRF (X-ray tube SST-m AX Rh, 4 kW) at ERAMET IDEAS, TRAPPES, France. The samples were milled (<100 microns, dried at 105°C for 24H prior to fusion with LiBr flux at 1050°C for 30 min.

Laser Induced Breakdown Spectroscopy

for fast screening of spatial distributions of major and minor elements was performed with three different LIBS instruments (Table 1). The instruments are very different from each other, which mainly manifests in the intensity and resolution of the LIBS spectra, the speed of measurement, and tolerance with respect to sample morphology. The instruments will be referred to as LIBS core scanner and LIBS industrial. Their specifications can be found in Table 1. For a more detailed description of the core scanner instruments, the reader is referred to Kuhn *et al* (2016) and Bauer *et al* (2022).

TABLE 1

Specifications of LIBS instruments applied in this study.

Specification	LIBS core scanner	GeoLIBScanner	Industrial LIBS system
Manufacturer	LTB, 2011	LTB, 2021	Spectral Industries, 2021
Application (this paper)	Line scan	Imaging LIBS	Line scan
Laser	Nd:YAG Q-switched 1064 nm, 35 mJ, 20 Hz	Nd:YAG Q-switched 1064 nm, 25 mJ, 100 Hz	Nd:YAG Q-switched 1064 nm, 1 mJ, 10 kHz
Spot size	~ 200 µm	~ 50 µm	~200 µm
Detector system	Echelle spectrograph and CCD	Echelle spectrograph and CCD	Czerny-Turner and CCD
Spectral range	285–960 nm	210–1000 nm	180–450 nm
Spectral resolution	0.021–0.070 nm	0.047–0.222 nm	0.09–0.11 nm
Working distance	25 cm	2 cm (autofocus using morphology scan)	19 cm
Measurement speed	2 spectra / second	Up to 50 spectra / second	Up to 300 spectra / second
Other	XY stage (2.5 × 100 cm), air suction	XY stage (60 × 110 cm), air suction	

A prototype LIBS core scanner (LTB, Berlin) was used for a line scan across the composite bauxite profile as shown in Figure 1. For a detailed description of these measurements, the reader is referred to Meima *et al* (2021). In summary, a step size of 200 µm was applied, and each single LIBS measurement consisted of one cleaning shot and three accumulated measurement shots. Additionally, another prototype LIBS core scanner (geoLIBScanner, LTB) was used for detailed imaging LIBS on the core section ‘pisolitic bauxite’ and ‘red bauxite’ to visualise the spatial variation in mineral chemistry. Thereto, single-pulse measurements, and a step size of 50 µm were applied. All spectra were processed by calculating the intensity of multiple emission lines for each of the target elements. Measurements that were out of focus were removed from the data set. Further processing included normalisation to reduce normal shot-to-shot variation. The data were plotted as a function of core length or as 2D images to visualise compositional variations within and between samples. For classification purposes, the supervised classification algorithm Spectral Angle Mapper was applied. A calibration of the LIBS data was not attempted in this study, because it was the objective of this study to investigate whether similarities and/or differences between samples can be recognised in the raw LIBS data.

Measurements with a commercial industrial LIBS system (Spectral Industries) where undertaken in the SPECTRAL Industries laser lab facility in Delft, Netherlands. The specifications of the instrument are shown in Table 1. Samples were placed within focus of the laser on a linear translation stage. The position of the sample was fine-tuned using a manual translation stage until optimal LIBS signal was achieved. The translation stage moves the core at a speed of 5 mm/s. During this continuous translation, the non-gated LIBS measurements are performed. With the applied integration time of 2 ms, each recorded spectrum is an accumulation of 20 individual plasmas generated over a length of roughly 2.5 µm of core. The main benefit of integration over multiple plasmas is that the fraction a scan that is actively ablated (and therefore sampled) is much higher as compared to single-shot spectra. On the other hand, the summation of multiple plasmas also introduces some form of averaging which makes it more difficult to detect minor trace elements or very small scale heterogeneity. The spot size of the laser at focal was not considered in this study. However, it is

expected that this spot size is significantly larger (100 to 200 µm), than the resolution mentioned above. After basic pre-processing steps, the intensities of emission lines from common elements such as K, Si, Al, Ti, C, Ca, S, and Fe were extracted.

ANCORELOG (Analytical Core Logger) is a multi-sensor drill core scanner that can be modularly equipped with several analytical sensors (Raman spectroscopy, X-Ray Fluorescence, hyperspectral cameras, LIBS). The sensors are mounted on a high-precision linear moving stage that is steered by a programmable logic controller (PLC) and allows data acquisition through spatial sensor co-registration. Data from different sensors are stored into a dedicated database where machine-learning algorithms can be applied to classify drill core samples into site-specific geological domains, waste, and valuable material. ANCORELOG's semi-automated scan process is designed to scan drill core samples with a high scan rate of up to 14 mm/s depending on the chosen sensor combination and the required accuracy and resolution. This allows its use in industrial scale drilling campaigns. For this study a combination of an XRF and a time-gated Raman sensor was used. ANCORELOG's XRF sensor, a special adaptation of J&C Bachmann's TEXAS device, was used in a continuous profile scan mode measuring a profile of 5 mm width along the complete sample length at a speed of 1 mm/s. Emission signals were integrated over the complete profile length resulting in one single measurement for each sample. The results were obtained as counts per second (cps) normalised to 120 s integration time after background signal subtraction and thus indicating a qualitative estimation of elemental concentrations. A conversion into quantitative elemental concentrations would require a site-specific sensor calibration against representative samples. ANCORELOG's Raman sensor, T-REX (Time-gated Raman for Exploration) is a special adaptation of Timegate Instruments' PicoRaman device. A precise synchronisation in the range of picoseconds between the pulsed laser excitation source and the sensitive and fast detector allows the rejection of sample-induced fluorescence emission, which has a longer delay. The time-gated Raman measurements were conducted in a combination of profile and single point scan mode. The profile scans were measured at a speed of 5 mm/s resulting in a 160 µm-wide profile line over each sample while integrating the measurement over the complete sample length. Randomly selected single spots were measured on each sample additionally. An automated matching of the obtained mixed Raman spectra with reference spectra of given target minerals from the RRUFF™ database (Lafuente *et al*, 2015) was conducted using a software module developed within the ANCORELOG project. The technical specifications of both sensors are summarised in Table 2.

TABLE 2

Technical specifications of the XRF and time-gated Raman sensors used in this study.

XRF Sensor Specification		**Time gated Raman Sensor Specifications**	
X-ray source	RTW MCB 65C-0,2 Mo	Laser Excitation Wavelength	532 nm
X-ray detector	Amptek DP5-X 25 mm^2 SDD	Laser Repetition Rate	250 kHz
		Laser Power	**230 mW max**
		Gating Adjustment Resolution	10 ps

RESULTS

An overview of the results obtained with the different sensors used in this study is presented in Tables 3 (mineralogy) and 4 (chemistry).

All samples were studied by laboratory XRF and XRD (ERAMET IDEAS, Trappes, France Prudhomme, 2018) and portable infrared (BRGM, Orléans, France) as part of the H2020 SOLSA project. The mineralogy of the analysed samples has previously been described in Meima *et al* (2021). Sandy shales and marls are composed of calcite ($CaCO_3$), kaolinite ($Al_2Si_2O_5(OH)_4$), illite ($(K,H_3O)(Al,Mg,Fe)_2(Si,Al)_4O_{10}$), vermiculite ($(Mg,Ca)_{0.7}(Mg,Fe,Al)_6(Al,Si)_8O_{22}(OH)_{4.8}H_2O$) and/or smectite ($A_{0.3}D_{2-3}[T_4O_{10}]Z_2 \cdot nH_2O$), quartz ($SiO_2$), and gypsum ($CaSO_4{\cdot}2H_2O$). In addition, the sandy shale contains goethite (FeO(OH)). In carbonated black shales, the marker horizon, similar in composition as sandy shale and marls, vermiculite, smectite and goethite are absent, but pyrite (FeS_2) and organic carbon are present. The bauxite layers start with marls and pisolitic bauxite with similar composition as the previous lithologies. Bauxite layers are rich in boehmite (AlO(OH)), hematite (Fe_2O_3), rutile (stable TiO_2), and anatase (metastable TiO_2) and may host zircon ($ZrSiO_4$). The bottom layer carbonate is mainly composed of calcite ($CaCO_3$), dolomite ($(Ca,Mg)(CO_3)_2$), hematite, goethite, and kaolinite (Table 3).

LIBS

Figure 2 shows the results of the line scan across the composite bauxite profile measured with the LIBS core scanner. These results previously published in Meima *et al* (2021), show that the different facies can be well distinguished with LIBS. The black shale horizon is easily characterised by the increased S emission. The bauxite/karst boundary is recognised by a sudden increase in Ca and decrease in Al emission. The brecciated bauxite shows already Ca. Other target elements (eg Si, Fe, Ti, Mg, Na, K, Li, C) support these observations and/or provide additional data.

Indeed, the LIBS spectra from the four key horizons (black shale, marl, red bauxite, bottom limestone) are very different from each other. The LIBS spectra of the black shale horizon are dominated by the many Fe emission lines, but also show relatively strong emission of Al, Ca, S, and occasionally C. The marl horizon is dominated by Ca emission lines, and additionally shows emission lines for eg Al, Fe, and Ti. Emission lines of Al, Ti, and Fe dominate the red bauxite horizon, and emission lines of Ca dominate the bottom carbonate horizon.

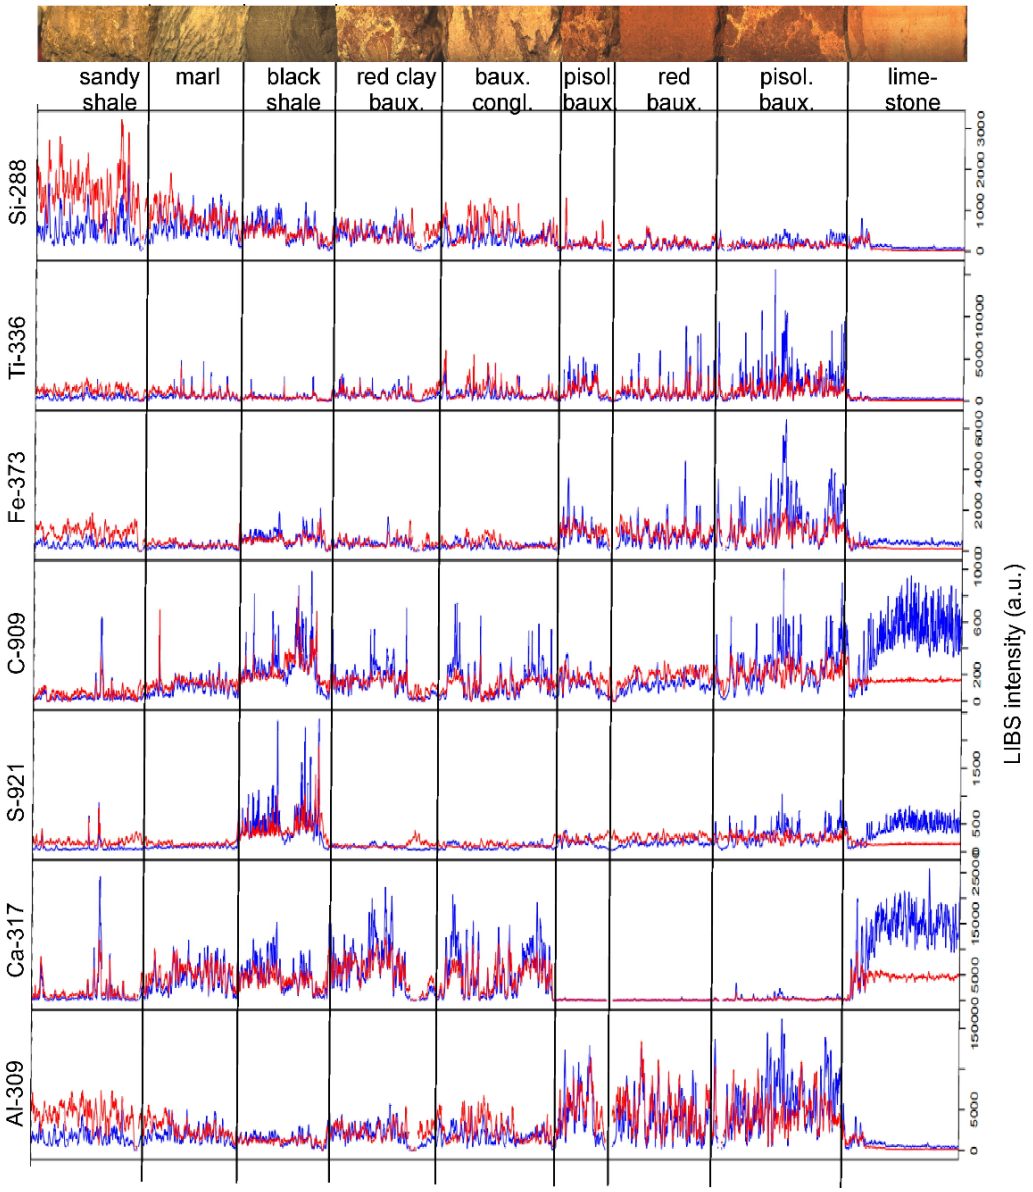

FIG 2 – Uncalibrated LIBS intensities for the composite bauxite profile as measured with the LIBS core scanner. Red lines represent normalised data, blue lines not-normalised data. A running average filter of five was applied to reduce noise and small-scale variations in the data. Unfiltered data are shown for S-921, C-909, and Ti-336 above intensity-thresholds of 500, 500, and 2500, respectively (from Meima *et al*, 2021). Please note that the relationship between LIBS intensity and element concentration is often not linear because of matrix effects.

Figure 2 also shows Ti enrichments in the brecciated bauxite, possibly representing rutile/anatase. Anatase is a heavy mineral, and it may be due to gravity that it is enriched in the brecciated part. Titanium and Ti-minerals are valuable materials to recover for its use in titanium industries. Titanium is generally easily detected with LIBS due to its many moderate and strong emission lines. A LIBS-based image of pisolitic bauxite (ER-SD00–0101) showing both distinct and diffuse Ti and Fe enrichments is shown in Figure 3.

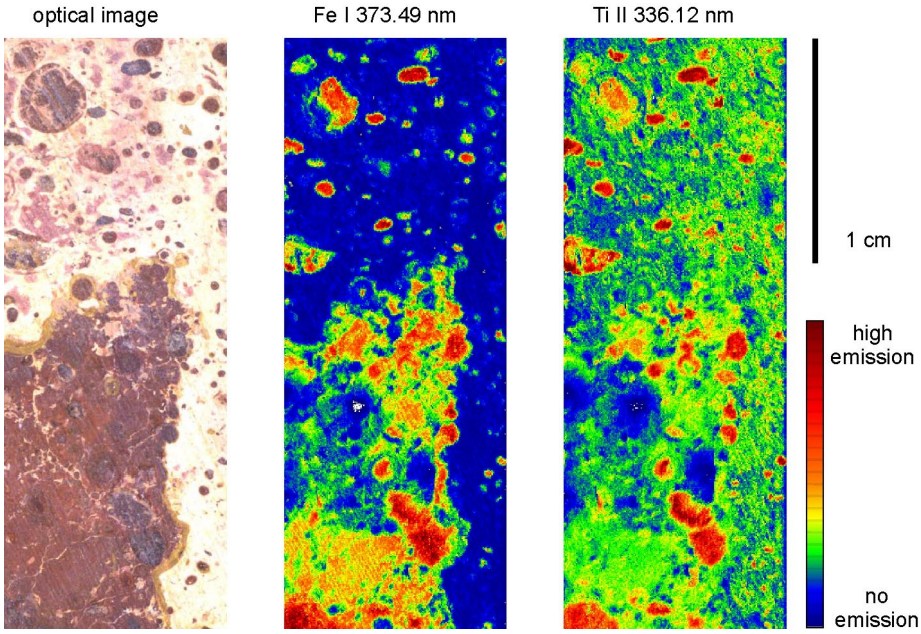

FIG 3 – LIBS-based Fe and Ti intensity distribution images (heat maps) for sample ER-SD00–0101 (pisol. baux.). The colour bar at the bottom right was scaled for each emission line individually according to the maximum observed intensity. Please note that the relationship between LIBS intensity and element concentration is often not linear because of matrix effects.

The results of the line scans obtained with the industrial LIBS system are shown in Figure 4. Due to the more limited spectral range, it was not possible to measure the C-909 line and the S-921 line. The C-193 emission in the UV was selected as a replacement for this. Unfortunately, S does not have a non-interfering emission line in the available spectral range and was therefore not included in these results.

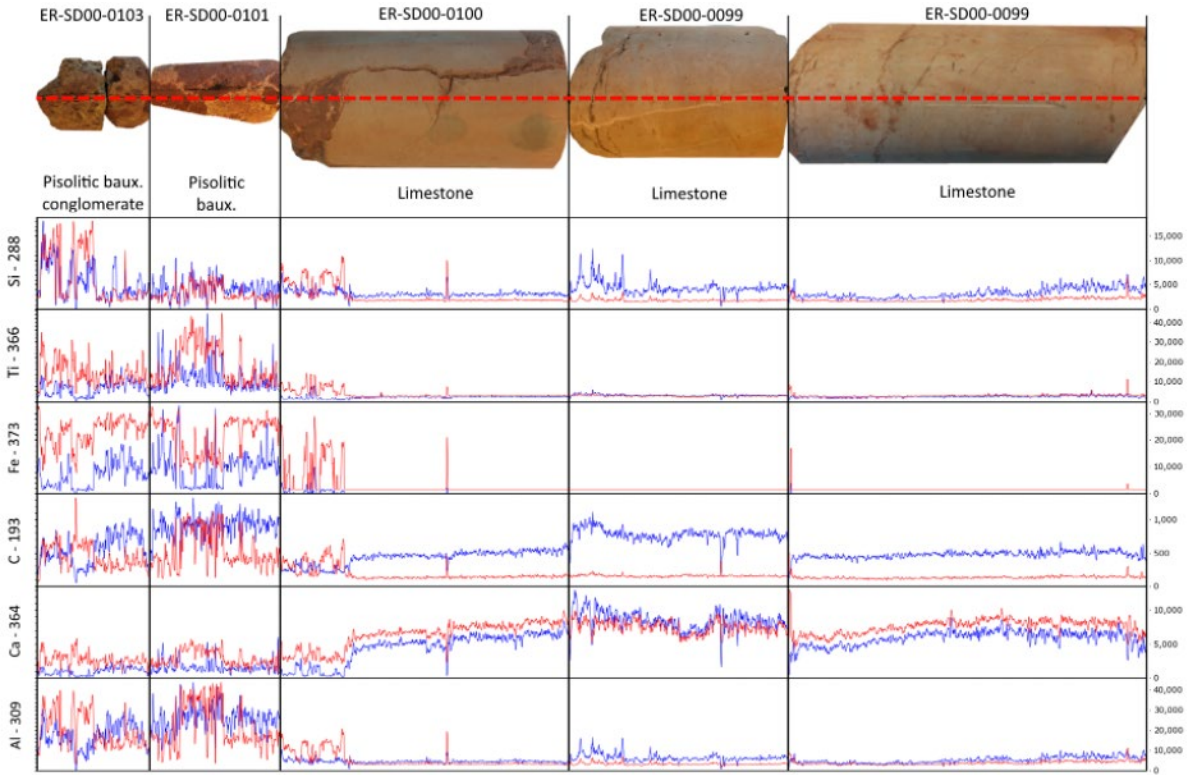

FIG 4 – LIBS line-scan results from the measurement using the industrial LIBS system (SPECTRAL) for the bottom part of the composite bauxite profile. The blue line corresponds to the intensity value of extracted peaks before normalisation, and the red line corresponds to normalised intensity.

It is important to note the following points regarding the results in Figure 4:

- The prominent spike/gap detected in the middle of the third limestone piece is caused by the crack that crosses the lines-can and defocuses the laser. This prominent feature therefore has no meaning regarding any of the measured elements.
- There might be slight differences in absolute intensity between the different samples. These changes are mostly related to differences in the laser focus position when placing the samples within the motorised stages. This difference is most prominent for example when comparing the first limestone with the second.
- The Ca I 364.xx nm emission line of Ca was selected instead of the Ca II 317.93 nm emission line used in Figure 2. This was related to the frequent saturation of the Ca II 317.93 nm line (and many of the other intense Ca lines) in the measurements with the industrial LIBS system. To prevent interference by saturation, a less intense line of Ca had to be selected.

Furthermore, most emissions used, do not show any significant overlap or interference with neighbouring peaks. Only the carbon line at 193.09 nm is occasionally partially overlapped by an Al line at 193.58 (Figure 5). This overlap is particularly present in the pisolitic bauxite samples, because these samples host both significant quantities of Al and C. The actual intensity of the C emission of those two samples is lower than the intensity presented in Figure 5.

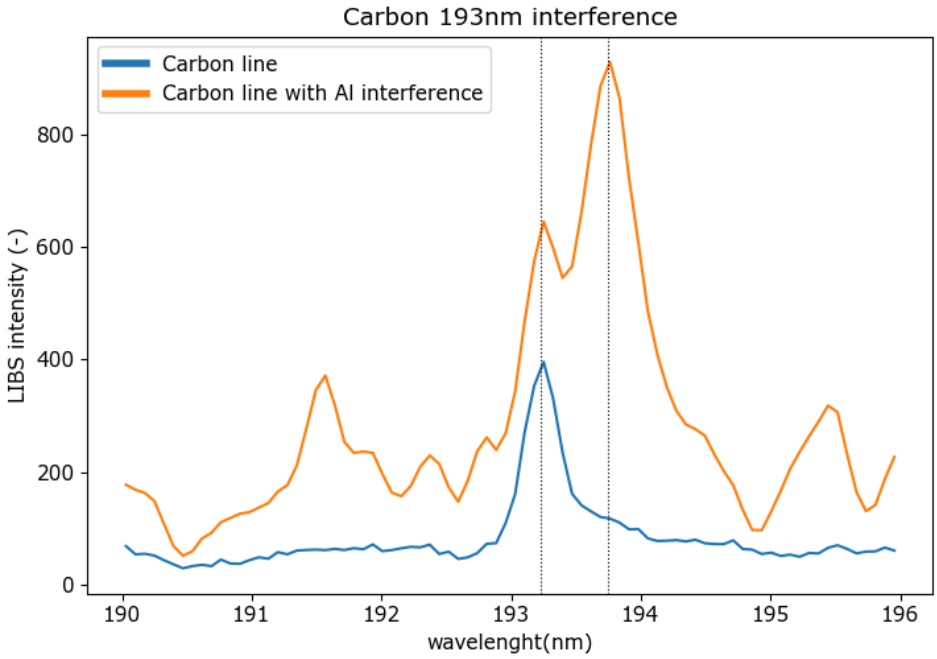

FIG 5 – Comparison of the C I 193.09 nm emission line for two samples measured with the industrial LIBS system, one without low Al contents (limestone) and one with increased Al contents (pisolitic bauxite). Shown spectra are an average of each sample. Note that there can be a slight dislocation of the measured peak due to calibration inaccuracies of the spectrometer.

LIBS-based classification of bauxite

In order to study how LIBS scan can be used to discriminate automatically against the two rock types within this sample set, a Principle Component Analysis (PCA) was performed on the data shown in Figure 4. From each sample, ten random spectra were selected and using algorithms from the python package 'Scikit-Learn' (Pedregosa *et al,* 2011). Additional pre-processing steps were performed such as normalisation, baseline correction, and removing frequently saturated wavelengths. After that, the full spectra were used as input to the algorithms.

The results from this PCA are presented in Figure 6, displaying the scores, and explaining variance and loadings of the PCA results. First of all, the elbow plot in Figure 6b displays how many Principle Components (PC's) are required to capture the variance within the data set. It shows that after only

two PC's, the explained variance does not increase strongly. These two PCs are sufficient to explain nearly 90 per cent of all variances.

The loadings presented in Figure 6c explain which variables, in this case wavelength positions, are used by the PCA to capture the variance in the data set. When using LIBS spectra, the most 'loaded' variables often correspond to emission lines of specific elements. The data show that the first two PCs are mostly based on Ca, Mg, Ti, and Al. PC1 has strong positive loadings for Ca and Mg lines and negative loadings for Al and Ti. While PC2 has strong positive loadings for Al and Ti but slightly negative loadings for Ca and Mg.

Figure 6a shows the calculated scores of each randomly selected spectrum on the first two PCs. Two clusters correspond well to the host rocks of the bauxite horizon. The limestones below the horizon score strongly on the first PC while the bauxite score is very low on this PC. This is clearly related to the high Ca and Mg content of the dolomitised limestones. There is one small cluster of datapoints from limestone (ER-SD00–100) right in between the two previously described clusters. This cluster corresponds perfectly to the top part of the sample that is the transition between limestones and bauxites.

The bauxite cluster scores universally low on PC1, but as a widespread within the second PC. This means that within the bauxites there is a strong heterogeneity regarding the Al and Ti contents.

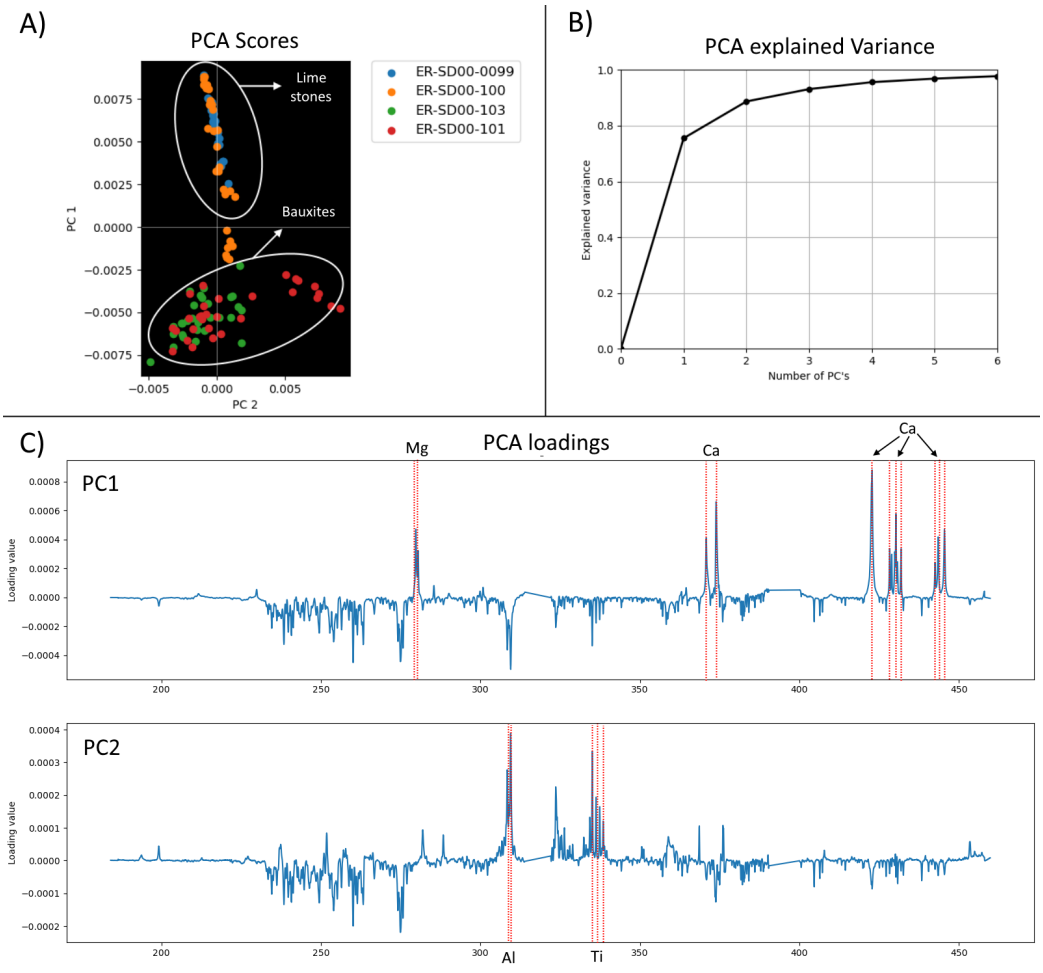

FIG 6 – Results of the PCA analysis based on the LIBS data collected with the Industrial LIBS sensor. (a) A scatterplot of the calculated Principle Component (PC) scores based on ten randomly selected spectra per sample. The y-axis indicates the score for PC1 and the x-axis indicates PC2. (b) Elbow plot of the PCA explained variance. (c) Plot of the loadings for the first two principal components.

Table 5 shows a confusion matrix with classification results for the identification of all nine lithologies based on the LIBS core scanner measurements shown in Figure 2. Thereto, a spectral database was built using the average LIBS spectra of each core piece as a reference spectrum. Best results

were obtained with several characteristic emission lines for the target elements, rather than with the full LIBS spectrum. The supervised classification algorithm Spectral Angle Mapper was then used to calculate the spectral similarity between the reference spectra in the database and all subsequent averaged spectra (n=10) from the line scan. Table 5 shows that each of the lithologies is statistically correctly classified. However, due to the heterogeneity of the sample material, correct classification will require a few measurements, preferably on different parts of the sample. In case of the limestone, for example, three spectra were classified as pisolitic bauxite, which corresponds to spectra representing the transition between limestone and bauxite (see also Figure 5). Sample heterogeneity can also be seen in the fluctuation of the LIBS intensities on the line scans (Figures 2 and 4) and in the mapping (Figure 3) as well as in the optical appearance of the sample. However, because LIBS is very fast (Table 1 industrial LIBS system with 300 spectra per second), it should be no problem to perform the required number of measurements. In conclusion, classification of LIBS data may be used to identify key horizons to separate bauxite from waste rock.

TABLE 5

Confusion matrix with classification results for the nine lithologies based on the measurements with the LIBS core scanner. Explanations in the text below.

X-Ray fluorescence

Roof rocks, bauxites, and bottom limestone can be clearly classified by chemistry (Table 3). According to the laboratory XRF results, roof rocks contain 56–69 wt. per cent SiO_2, whereas bauxites have significantly lower SiO_2 (<20 wt. per cent), except for one pisolitic bauxite which shows about 35 wt. per cent SiO_2. Bottom limestone contains <7 wt. per cent SiO_2. Al_2O_3 successively increases towards the bauxite horizon with a maximum value of 50 wt. per cent Al_2O_3, then, in the bottom limestone, it decreases below 5 wt. per cent. Similar trends are observed for Fe_2O_3, reaching up to 32 wt. per cent in the bauxite horizon. TiO_2 reflects the rutile/anatase content and is also highest in the bauxites reaching 2.6 wt. per cent. Phosphorus shows highest values in the bauxites (0.36 wt. per cent) and correlates with highest Fe_2O_3 contents. Sulfur characterises the black shales marker horizon with 3.7 wt. per cent.

Results of ANCORELOG's continuous XRF measurement profiles are plotted together with the laboratory XRF results in Figure 7. The results in cps of element specific emission lines are divided by 1000 (Fe, Mn), 200 (K, Ti) and 100 (Ca) for a better comparative presentation with laboratory results in wt. per cent. The qualitative results from ANCORELOG's profile scans reproduce the elemental concentration values derived from laboratory measurements and thus fulfill the requirements for a calibration against reference analytics on a larger sample and data set.

The increasing content of Fe and Ti towards the bauxite horizon is clearly reflected in the measurements (samples ER-SD00–0100 to ER-SD00–0103).

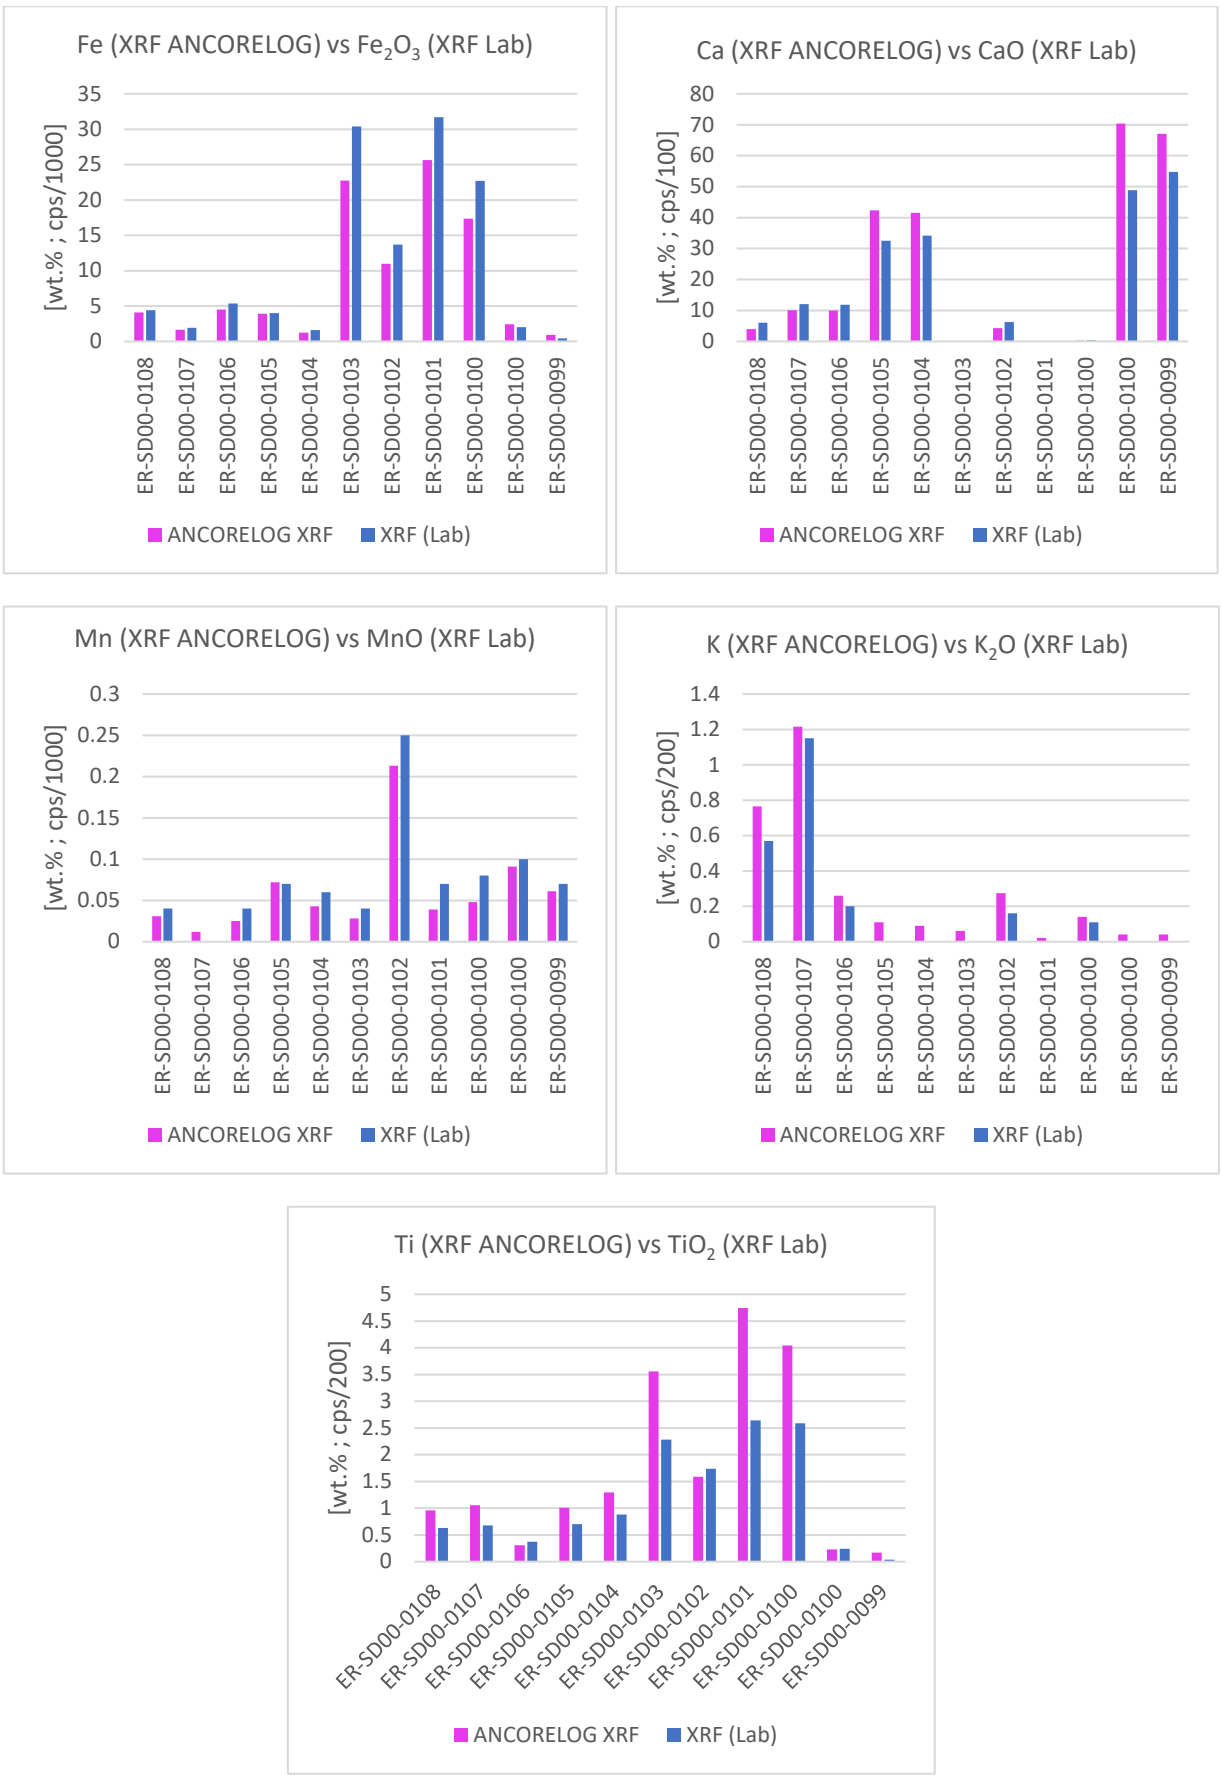

FIG 7 – ANCORELOG qualitative XRF results versus quantitative laboratory XRF results. ANCORELOG XRF values in cps are divided by 1000 (Fe, Mn), 200 (K, Ti) and 100 (Ca) for a better comparative presentation with laboratory results.

Time-gated RAMAN spectroscopy

Profile and single point measurement spectra were analysed to extract major characteristic peaks of target minerals detected by XRD and pIR reference measurements (Figure 8).

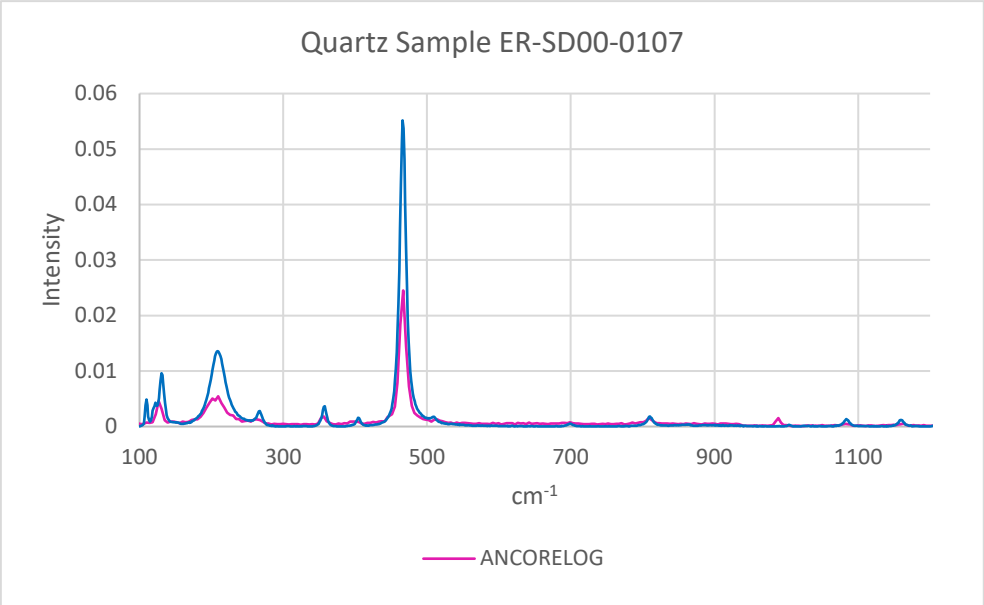
FIG 8 – Feature extraction from mixed Raman spectra: The blue line shows the mixed spectrum from a profile measurement. The green line shows a reference spectrum of a mineral found in the mixed spectrum. The red line shows a reference spectrum of a mineral that is not identifiable in the mixed spectrum. Y-axis: intensities (counts); X-axis wavelength shift (cm^{-1}).

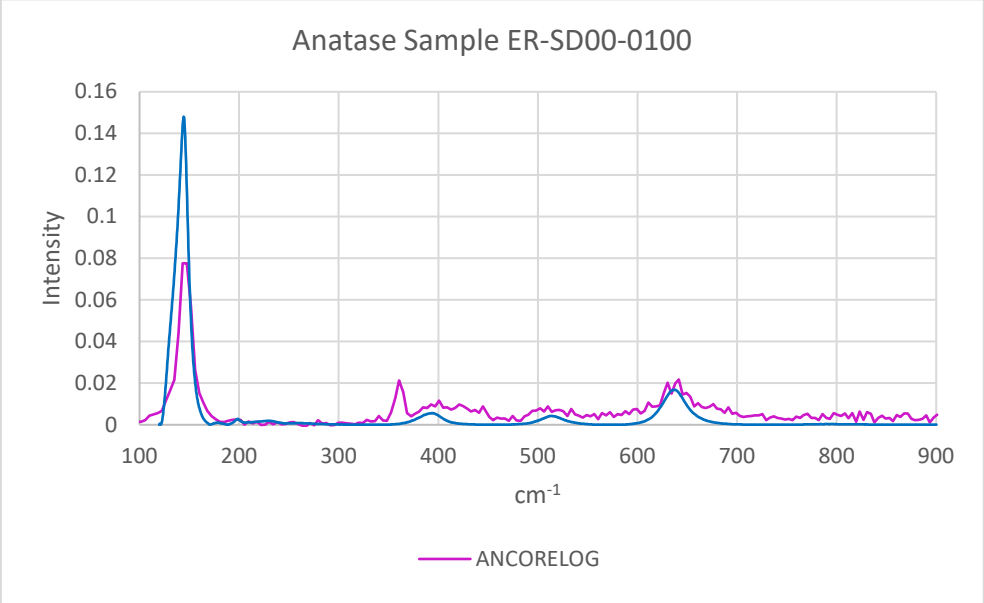
The minerals identified by the time-gated Raman sensor in the different sample sections are listed Table 3 and characteristic Raman peaks identified in the measured spectra are listed in Table 6. Example Raman spectra from the measurements representing different minerals are shown in Figure 9. Quartz shows clear Raman peaks at ~466 cm^{-1}, ~355 cm^{-1}, ~207 cm^{-1} and ~128 cm^{-1} in samples ER-SD00–0104, ER-SD00–0107 and ER-SD00–0108. Anatase presents clear Raman peaks at ~143 cm^{-1} and ~638 cm^{-1} in samples ER-SD00–0100, ER-SD00–0101, ER-SD00–0102, ER-SD00–0104 and ER-SD00–0105. Boehmite peaks located at ~498 cm^{-1} ~362 cm^{-1} are present in the spectra of samples ER-SD00–0100, ER-SD00–0101 and ER-SD00–0103. Rutile shows Raman peaks at ~610 cm^{-1}, and ~445 cm^{-1} in samples ER-SD00–0100 and ER-SD00–0104. Calcite peaks at ~1089 cm^{-1}, ~710 cm^{-1}, ~279 cm^{-1}, and ~155 cm^{-1} occur in samples ER-SD00–0099, ER-SD00–0104, ER-SD00–0105, ER-SD00–0106 and ER-SD00–0107.

TABLE 6

Raman peaks of characteristic minerals i.

Mineral	Raman Peaks [cm^{-1}]	Sample
Quartz	~466 cm^{-1}, ~355 cm^{-1}, ~207 cm^{-1}, ~128 cm^{-1}	ER-SD00–0104, ER-SD00–0107, ER-SD00–0108
Anatase	~143 cm^{-1}, ~638 cm^{-1}	ER-SD00–0100, ER-SD00–0101, ER-SD00–0102, ER-SD00–0104, ER-SD00–0105
Boehmite	~498 cm^{-1}, ~362 cm^{-1}	ER-SD00–0100, ER-SD00–0101, ER-SD00–0103
Rutile	~610 cm^{-1}, ~445 cm^{-1}	ER-SD00–0100, ER-SD00–0104
Calcite	~1089 cm^{-1}, ~710 cm^{-1}, ~279 cm^{-1}, ~155 cm^{-1}	ER-SD00–0099, ER-SD00–0104, ER-SD00–0105, ER-SD00–0106, ER-SD00–0107





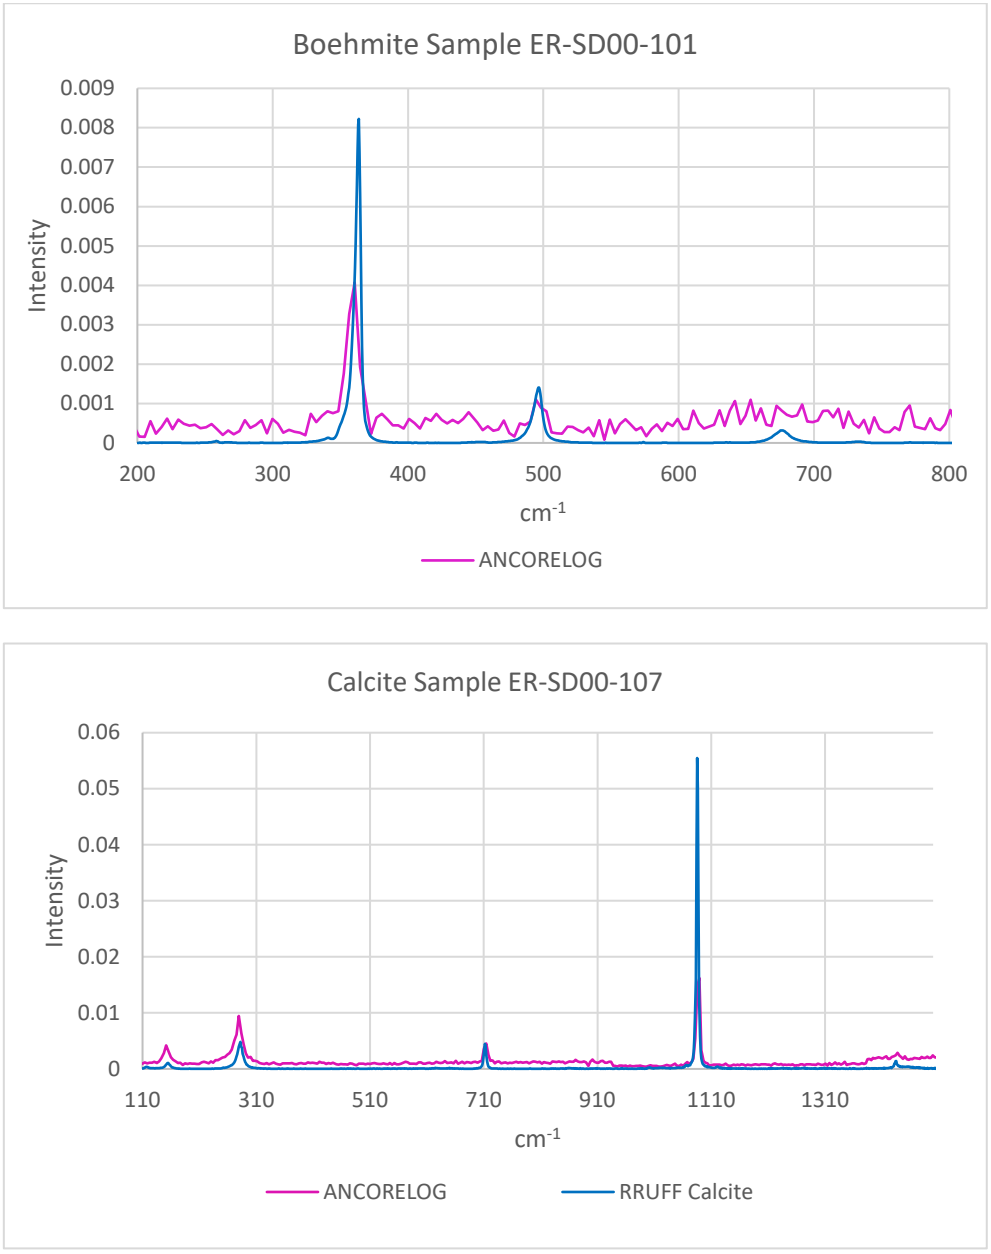


FIG 9 – Raman spectra from selected minerals. Blue line: reference spectra from the RRUFF™ database. Red line: extracted spectra from ANCORELOG measurements. X-axis: wavelength shift.

Portable Infrared spectroscopy (pIR)

Analyses were performed on each sample on characteristic features. The analytical window is 1.76 mm in diameter. Therefore, the pIR analyses/spectra represent a mixture of phases. With this field spectrometer, phyllosilicates, and iron oxyhydroxides (goethite, hematite) can be identified. Carbonates, normally present in the thermal infra-red region, were detected with the spectral line at 2333–1990 nm. Kaolinite is represented by the double peak at 2157 and 2203 nm, and the peak at 1910 (water molecule). The characteristic form of a 'shoulder' between 600 nm and 900 nm, with a peak at 876 nm in the VNIR region, indicates the presence of hematite and goethite. The measurements on all samples are summarised (Table 3).

In the bottom limestone, pIR detects mainly calcite, kaolinite, hematite, and goethite. Kaolinite, hematite, and goethite is mainly found in veins. The bauxite samples host kaolinite, hematite, and goethite. Two samples show peaks corresponding to dolomite. In the upper part of the bauxite, illite is detected. Ilite also appears to be present in lighter areas of the samples. It is important to note that Al-oxyhydroxides, such as boehmite (γ-AlO(OH), could not be detected by pIR. Rutile was detected in one single bauxite sample by pIR, but no anatase.

In the roof rocks, calcite was detected in all samples, but also illite, kaolinite, hematite and goethite are present. The 'black shale' maker horizon shows low reflectance, and hosts kaolinite, calcite, illite, hematite and goethite.

Classification by pIR of the bauxite horizon is ambiguous. The only mineral which may allow to classify bauxite from host rocks in this study, is hematite. Hematite is however also present in the lower part of the barren roof rocks (Table 3).

X-Ray Diffraction (XRD) results

The XRD results are presented in Table 3. The bottom-limestones contain mostly calcite. The bauxite samples host hematite, goethite, rutile and anatase. Calcite is detected in all samples in which boehmite is not detected. Kaolinite is detected in all bauxites and roof rocks. The roof rocks consist of quartz, clay minerals (illite, or inter-stratified illite-smectite).

DISCUSSION

Sorting of bauxite-waste by LIBS and XRF

LIBS

The results of the PCA performed on the LIBS data from the industrial LIBS sensor show that it is very feasible to distinguish the limestone-bauxite horizon using LIBS measurements alone. The horizon between bottom karst limestones and bauxites is very pronounced. Moving from the bottom limestone into the bauxites, Fe, Al, and Ti intensity rises drastically while the Ca intensity drops. In this small data set used, it is possible to make a perfect separation by setting a hard boundary only on Principle Component 1. The fact that such a classification can be made using a relatively lightweight analysis method displays the high potential of LIBS for fast classification applications. Furthermore, the confusion matrix with classification results for all nine lithologies (Table 5) shows that LIBS data can be used to identify all key horizons to separate bauxite from waste rock. Correct classification, however, will require a few LIBS measurements, preferably on different parts of the sample. This is because of sample heterogeneity. Because LIBS is very fast (Table 1 industrial LIBS system with 300 spectra per second), it should be no problem to meet this requirement.

Different LIBS systems have been tested in this study and the results can be used for the recommendation of appropriate LIBS components for industrial use on bauxite characterisation applications. Most notable fundamental differences between the tested LIBS instruments are the type of laser and type of spectrometer. The core scanner system utilises a relatively high power laser of 25 mJ that operates at 100 Hz compared to the laser used in the industrial system that operates at 1 mJ and 10 kHz. The ablation and sampling characteristics of both systems will therefore be intrinsically different. Due to the high laser power of the core scanner laser, ablation will be better for that set-up. However, the sampling properties of the industrial system are much better due to the very high repetition rate of the laser. This allows for faster scanning of core, which is often required for feasibility in industrial applications. However, when evaluating minor/trace elements or small-scale heterogeneity, a core scanner system will be of advantage. Furthermore, a high-resolution spectrometer is also of advantage when analysing minor or trace elements. This is especially relevant for bauxite, because valuable elements such as V and Sc are oft associated with iron or titanium minerals, and both iron and titanium show a very large number of emission lines in the same spectral window as eg vanadium. The spectral resolution of the core scanner system has been shown to be high enough to separate characteristic V emission lines from the titanium and iron emission lines.

ANCORELOG XRF

Portable XRF, eg provided by Olympus were tested on bauxites. Although light elements reveal low detection limits, Al_2O_3, reactive SiO_2, TiO_2 and Fe_2O_3 can be reliable analysed (https://www.olympus-ims.com/fr/portable-xrd-for-bauxite-exploration-mining-and-extraction/).

ANCORELOG's fast XRF profile scan allows for mapping of elemental concentrations and thus detecting lithological boundaries. Due to the limited number of samples in this study, a calibration of

ANCORELOG's XRF results against laboratory reference measurements has not been conducted. With a larger number of samples and a data calibration on reference samples against laboratory results would enable a quantitative estimation of elemental concentrations. Light elements with an atomic number Z<18 are difficult to measure by XRF due to, among other reasons, the Auger effect that constitutes a non-radiative transition or internal conversion of K series photons or the fact that the energy of the emission lines is low. So, the photons are easily absorbed and generate a weak signal (Laperche and Lemière, 2021). Choosing a different set-up of components and measurement geometry enables a more precise measurement of Si, Al, and S, but also impedes the usage in an industrial environment with high production rates as required in exploration drill core logging campaigns.

Mineralogical information of bauxite-waste by Raman-pIR

Laboratory micro-Raman spectroscopy was carried out on drill core parts from laterite profiles. Although perfect results were obtained, micro-Raman it is too time consuming for online-real time analyses. However, it can be used on selected samples in the mine workshop (eg Duée *et al,* 2019; El Mendili *et al,* 2019; Secchi *et al*, 2018). Bauxite mineralogy from Northern Brazil mines was investigated by micro-Raman spectroscopy (Leite Faulstich *et al,* 2011). Results show that gibbsite, clay minerals, Ti-oxides, ironoxhydroxides, and quartz were detected. Greek bauxites were investigated by micro-Raman showing the performance for analysing polymorphe diaspore and boehmite (Gamaletsos *et al,* 2007).

The ANCORELOG time-gated Raman spectroscope is the first which will operate as an online mineral analyser on a drill core logger (Havisto *et al,* 2021). The time-gated Raman sensor used in the ANCORELOG system allows fast and automated profile core scanning with scan rates of up to 20 mm/s. In this study we clearly demonstrated that the target minerals boehmite, anatase and rutile, typical for the bauxite horizon, can be identified. Iron oxyhydroxides could not be detected. The mineralogy determined by the Timegate Raman spectrometer is coherent with the mineralogy determined by laboratory XRD and pIR. Therefore, we exclude phase transformation related to instrumental configuration such as laser power (El Mendili *et al,* 2010), or matrix effects to the fine-grained soil material.

Algorithms dedicated to unmixing the measurement spectra and thus identifying characteristic mineral signatures must be adapted to specific site requirements and become more precise with a growing number of samples and data.

Infrared spectroscopy as portable instruments or hyperspectral core scanner (SWIR, VNIR) is used since some years on drill cores (eg malvernpanalytical.com; corescan.com). Some tests on bauxite with VNIR-SWIR were performed in field on drill cores from the Villeveyrac bauxite deposit (Orberger *et al,* 2019). However, mineral databases which are adapted to the material to be analysed and smart software to rapidly interpret the data are crucial (eg Bui *et al,* 2018 and papers therein). In this study, pIR covering the VNIR and SWIR spectra, was used. This method is powerful to detect the clay minerals kaolinite and illite, goethite, and hematite. The presence of hematite mainly in the bauxite samples can be used to classify the ore samples. However, a cross-method approach using time-gated Raman in addition to detect Ti-minerals and Al-hydroxides (here boehmite) is necessary to complete pIR results.

Recommendation for mining and processing industries

Table 7 summarises the performance of each sensor on bauxite material. For brownfield exploration, beneficiation, and further processing (hydro and pyrometallurgy), a concept study must be performed in tight collaboration with the industrial partner. This study would be composed of laboratory mineralogy and chemistry, followed by test analyses using the in-field instruments on the target material(s). Then, the sensor combination, sensor configuration, and sensor calibration for the specific materials will be defined. A suitable mineral database will be established. For the case study here, Table 7 shows the performances and final recommendations.

TABLE 7

Sensor performances for bauxite and waste material sorting.

For the here studied karst bauxite profile, during drilling, the bauxite on and offset can be defined by chemistry using Al, Si, Mg, Fe, Ti, Ca, C and S. All elements are detectable by LIBS; XRF will allow to do semiquantitative analyses for the metals Ti, Fe, Mn, Ca, K in Karst bauxites. Cr is present (eg Greek bauxites, Vind *et al,* 2018). For process design, mineralogy is important. Time-gated Raman spectroscopy will detect the Ti-bearing minerals, Al-hydroxides (eg boehmite) calcite, quartz and clay minerals, while pIR will enhance the knowledge on iron-oxyhydroxides. As iron-oxyhydroxides are the main phosphorus carrier, they can be used as proxy for targeting lab analyses. This classification method can be used for primary sorting of bauxite from waste. On selected samples, LIBS mapping more focused on trace elements accumulation, and/or XRT and CT analyses can be performed (Bauer *et al,* 2022).

CONCLUSIONS

1. Rapid and efficient bauxite characterisation is possible through industrial LIBS. ANCORELOG Profile scans with the XRF and time-gated Raman spectrometer can clearly distinguish between bauxite horizons, and the top and bottom Al-barren sedimentary rocks. Target minerals for the bauxite horizon are boehmite, anatase, rutile, goethite, and hematite. Calcite and dolomite indicate the bottom Karst.
2. Chemical tracing by XRF is possible using increasing Fe contents from the top sedimentary rocks, from low to high Al bearing bauxites and decreasing Fe contents in the dolomitised limestones. Titanium is another key element which can easily determine the Al-rich horizons, as Ti and Al are positively correlated in this study.
3. Our study shows that time-gated Raman is an important tool also for defining titanium minerals, in exploration, mining and processing. Anatase, rutile and ilmenite can be distinguished (see also Bauer *et al,* 2022).
4. The use of analytical sensors on raw materials for early quality evaluation can help significantly to reduce the environmental impact of mining and processing. Most waste can be left in place, and an efficient parameter definition for ore sorting during crushing and beneficiation on mine sites will contribute to reducing transport costs. Thus, CO_2 emissions will be reduced, less waste is entering the aluminium production, also saving energy, water, and gas emissions.

OUTLOOK

- Sensor-calibration must be performed on bauxite materials to obtain semi-quantitative data. Raman spectroscopy, XRF and LIBS must be performed on bauxite of different origins to establish a solid database for efficient and reliable data interpretation.
- Scandium, V and Ga will be extracted in the future at the end of the KIC EIT projects Scaleup (www.scale-technology.eu and VALORE. Several processing steps are involved needing a QA/QC as do the final commercial products Sc-hydroxides, oxides and fluorides, or V-pentoxides, salts, nitrates, or Ga. A sensor-based approach could be successful here as well.

For example, LIBS and XRF can detect Sc in Sc-extraction products, although it could not be detected in bauxite (Meima *et al,* 2021). Furthermore, V und Sc can be detected with LIBS and XRF.

As outlined by Abe Mitchell (2022; EXXON Mobil, USA), Industry 4.0 brought and is still bringing analytical sensors to the mining and processing industries. Industry 5.0 must shift from the technological data assess level to a holistic data-understanding and goal setting, human-centered approach. The core must be people from the mining and processing industries (geologists, technicians, mine and plant managers, operators), to better understand all these data, and convert them into actionable insights.

ACKNOWLEDGEMENTS

We thank the EIT RawMaterials projects: ANCORELOG (N°17028), the EIT T-Rex project (N°19122), the ScaVanger (N°20093), Scaleup projects (N°21013), VALORE (N°21018) and the H2020 project SOLSA (N°689868) for financial support of this project.

ABSTRACT

Geometallurgy is a very valuable and insightful practice that links geology characteristics to mineral processing performance. The aim being to predict the behaviour of the ore during processing using only geological properties such as geochemistry, rock type and mineralogy. These predictions of downstream performance are populated into the geological block model for more informed mine planning and can assist in optimised mineral processing design. It requires thousands of samples of drill core from across the orebody to undergo various metallurgical characterisation tests. The results of which are used to build prediction models showing the ore's response to mineral processing unit operations such as grinding, flotation and leaching. The final stage is this the distribution of these responses throughout the geological block model using suitable geostatistical techniques.

A complement to the proven and well documented geometallurgy practice is a digital approach using only the information in the geological block model and historical operating data. It involves integration of masses of historical data and information from all stages of the mining value chain from geology to mineral processing, through (1) a data fusion technique where the ore is tracked from the mine through all stages of the operation using mathematical validation methods and (2) application of machine learning for generation of superior prediction models. The process is called orebody learning.

Orebody learning converts spatial geological data into a time series geological data (fused geological data) suitable for machine learning modelling of downstream processes such as dig rate, load and haul, crushing, milling, and separation. Orebody knowledge acquired through data fusion ore tracking and machine learning is based on tens to hundreds of millions of tonnes of ore data and its actual response to processing.

Two case studies demonstrate how orebody knowledge is translated into operational insights by adding new 'operational experience' variables to the block model. This provides accurate inputs to mine planning and scheduling and employs predictions that are based on actual plant operating data rather than empirical models.

The first case study relates to Ban Houayxai, a gold operation located in northern Laos.

During its operation, the Ban Houayxai CIL (carbon-in-leach) gold plant experienced extended periods of very low gold recovery, less than 50 per cent gold recovery. The losses, high gold content in tails, were thought to be a result of gold locked in silicates and sulfides and to limited to fresh, unweathered rocks (Carpenter *et al,* 2018). Internal petrographic and geochemical studies failed to clearly identify problematic zones in the orebody and the reason for high gold losses.

Orebody learning and data fused ore tracking was implemented using two years of operating data. This is equivalent to the tracking of ten million tonnes of ore from the pit to waste dumps and to the plant. The data was merged and collated to produce a digital representation of the operation from pit to plant. This digital representation included periods of low gold recovery pertaining to the processing of fresh unweathered ore.

The application of machine learning techniques to CIL predict gold tail grade (Au g/t) using only variables in the geological block model enabled gold tail grade to be spatially linked to information in the geological block model, referred to as orebody learning. Block-by-block predictions of gold tail grade were added to the geological block models as new block model variables.

Orebody learning using data fusion for ore tracking and machine learning prediction models identified potentially problematic high tails blocks in the LOM (Life-of-mine) block model and allowed planning and scheduling engineers to proactively either stockpile or blend this material to avoid previous high tail grade excursions (Figure 1).

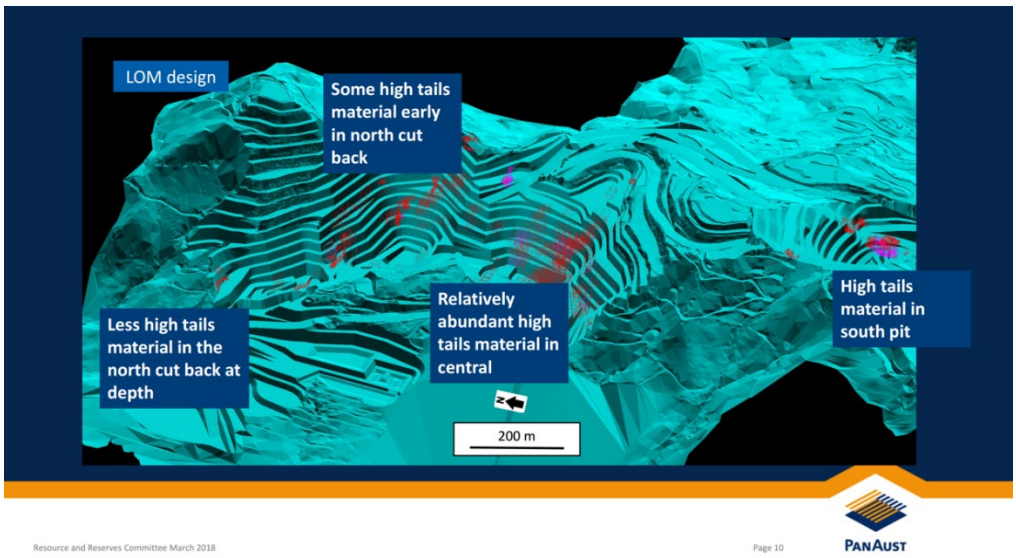

FIG 1 – Identification of problematic (high tail grade) blocks in the Life-of-mine block model using orebody learning (a combination of data fused ore tracking and machine learning).

The second case study relates to a very large magnetite plant consisting of multiple process trains, at the head of which are AG mills. The throughput of these mills dictates the capacity and production of the operation.

The aim was to develop a prediction model for AG mill throughput using only variables from within the geological block model. This facilitated a collaboration between mining and process engineers for proactive planning for variations in ore type and properties.

Mining, loading, primary crusher as well as coarse ore stockpile (COS) data was fused to create digital representation of the whole value chain. In this instance, the COS proved the most challenging part of the system to model and track material through. This was overcome by the use of virtual stockpiles and an iterative modelling methodology to verify the movement of ore through the stockpile. This amounted to tracking 17.2 Mt of ore from the pit, through the primary crushers, the COS and the AG mills.

Machine learning was used to generate an AG mill throughput prediction model. In total 25 variables were used in the algorithm used to predict AG mill throughput. In house validation of the AG mill throughput prediction indicated less than 5 per cent deviation on a month-on-month basis to actual throughput rates.

The overall performance of machine learning prediction model using unseen test data, data not used in the model building, is shown below in Figure 2.

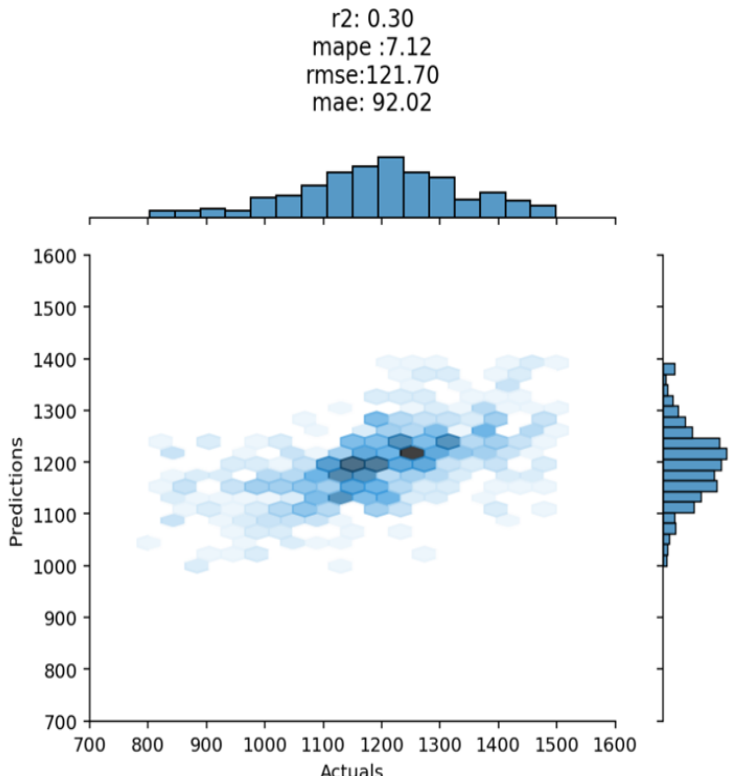

FIG 2 – Machine learning model accuracy (unseen data) for AG mill throughput.

Machine learning predictions for AG mill throughput were populated into the geological block model on a block-by-block basis. A visualisation of the AG mill throughput prediction for each block using Vulcan software is shown in Figure 3.

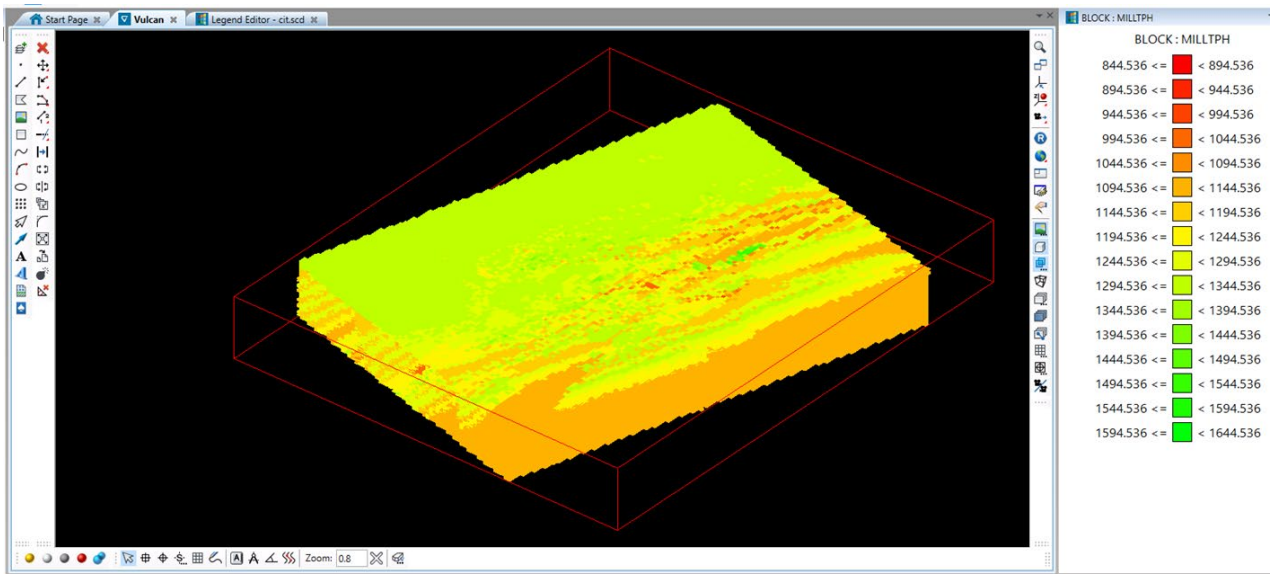

FIG 3 – Machine learning model AG mill throughput populated in geological block model.

In conclusion, geometallurgy is holistic approach to understanding processing characteristics as a function of ore type and ore variability. Orebody learning through the use of data fused ore tracking and machine learning prediction models is a complementary yet alternative approach to conventional geometallurgy. It avoids the extensive and repeated sampling, characterisation test work and statistical and empirical modelling. Rather involves integration of masses of data from all stages of the mining value chain from geology to mineral processing and builds machine learning prediction models based on tens to hundreds of millions of tonnes of ore data and its actual response to processing.

Orebody learning facilitates strengthening of the ties between the connected mining disciplines by sharing and merging data, no matter the source of the data. The case studies presented provide examples of accurate inputs for plant design decisions, mine planning and life-of-mine optimisation.

ABSTRACT

Comminution is the most energy-intensive stage in mining and the design of an effective and efficient comminution circuit requires knowledge of the machine-specific ore hardness from the early stages of the development of an ore deposit. Geometallurgy seeks to quantify the impact of variability in ore characteristics such as comminution response on the net present value of the deposit. A typical geometallurgical program aims to maximise operational potential by integrating measures of mining and processing attributes into 3D orebody models that reflect the economic value and allow mining companies to manage technical and operational risk and uncertainty (Keeney, 2010; Dominy and O'Connor, 2016). To understand the processing behaviour and its variability at a deposit scale, and aid the prediction of metallurgical performance, measures of intrinsic ore properties are integrated with processing parameters quantified using small-scale physical testing, and the resulting data is combined with geological and mining information which place it in a spatial context (Keeney, 2010; Dobby *et al*, 2004).

High-Pressure Grinding Rolls (HPGR) technology has been introduced to metal mining as a tertiary, quaternary, and pebble crusher, after many years of application in the cement and diamonds industry (Davaanyam, 2015). With its application in base and precious metal mining, many questions arise on the performance of this device in the context of the heterogeneity of ore deposits.

The industry-standard laboratory tests for comminution characterisation include the SMC test (Morrell, 2004) and the Bond Ball Mill Work Index (BBMWi) test (Bond, 1961). While the indices A*b and BBMWi resulting from these tests are accepted to characterise the size reduction of materials in SAG mills and ball mills, there is no equivalent widely-accepted laboratory-scale test for the HPGR. Despite suggestions in the literature about its greater energy efficiency, this device has not been widely adopted in metal mining. The absence of studies analysing the effect of ore variability in the context of compression breakage, the mechanism of rock breakage in the HPGR, could be one of the reasons for this. Some approaches have been developed to use the piston and die test (PDT) as a small-scale laboratory test, but most of these have focused on the development of a method for sizing HPGR units (eg Davaanyam, 2015; McClintock, 2018).

This study compares the results of widely-accepted small-scale comminution tests on ore samples from a porphyry Cu-Au deposit in Chile with results from the Packed Bed Test (PBT) used to characterise HPGR breakage response and explores the relationships between them. Specifically, the metallurgical data for comminution characterisation consisted of the results of the HRC™Packed Bed Test (Herbst *et al*, 2011), the SMC test, and the Bond Ball Mill Work Index test performed on 115 samples from 21 drill holes.

The Packed Bed Test uses a piston-and-die press configuration to compress a relatively small mass of sample under tightly-controlled test conditions, capturing the force applied and the resulting displacement of the piston. In order to identify an index of compressibility at the scale of geometallurgical modelling, several parameters were estimated from the test results. These included the reduction ratios R_{50} and R_{80}, Bed Height Reduction, Bed Compaction ratio and Bed Porosity Reduction.

The parameter R_{80} derived from the PBT, which represents the ratio between the 80 per cent passing sizes in the feed and the product (F_{80}/P_{80}), shows a very strong correlation with the A*b index obtained from SMC Tests, displaying higher values for the softer ores. The relationships of this

variable with the energy variables DWi (Drop Weight index), Standard circuit specific energy (SCSE) and Mih (HPGR ore work index) resulting from the SMC Test are strong, negative and nonlinear. However, there are no significant correlations between the PBT and SMC results and the BBMWi results.

Some of the differences between the results of the tests are explained by the different breakage mechanisms employed in each of the tests since the PBT uses compression, the SMC test uses impact and the BBMWi test uses impact and abrasion. Another potential reason is that the size fractions examined in each test differ: the PBT and SMC test are performed on a feed size range between 10 and 30 mm, and the BBMWi feed must be 100 per cent finer than 3.35 mm and for these samples has an average F_{80} of 2.16 mm.

Analysis of the mineralogical characteristics of the ores identified the main ore characteristics controlling the breakage response, which are similar for the SMC and PBT. The comminution test results of the PBT and the SMC tests show several moderate to strong correlations with the mineralogical characteristics of the ore measured using quantitative X-ray diffraction and QEMSCAN. The comminution variables also show moderate to strong relationships with geochemistry. The variability of the PBT and SMC test results agree in the spatial and geological context. The relationships identified were used as inputs for the development of predictive models of hardness across the deposit.

The similarities between the PBT and SMC test results support its use in geometallurgy to assess ore hardness in compression breakage. Additionally, the mineralogical controls identified for the ore tested can be used as proxies for ore hardness at a deposit scale where the results of physical tests are not available. For many early-stage projects, where only limited amounts of drill core samples exist, the possibility to use small-scale compression tests will, in turn, facilitate the early consideration of HPGR technology in the flow sheet design and will allow the use of geometallurgical information to characterise the operational risk due to ore heterogeneity.

ACKNOWLEDGEMENTS

This work is part of a research project funded by NuevaUnión SpA and the Sustainable Minerals Institute International Centre of Excellence Chile. The University of Queensland is acknowledged for its funding through the UQ Research Training Scholarship and the Complex Orebodies Program. Thanks are extended to staff from NuevaUnión SpA, Teck Resources Limited and Newmont Corporation for their continued support and comments throughout the project, and the approval to publish this work. SMI BRC and JKMRC staff are also acknowledged for their valuable comments during this research.

ABSTRACT

Mineral processing of various ores is largely driven by mineralogical factors, making mineralogical characterisation a significant part of a mineral processing project at any stage in the mine value chain. As more low-grade and complex ores are being discovered and developed, mineral processing engineers require more comprehensive and accurate information on the ores and metallurgical products being processed in order to understand the ore better during process development and plant operation. There is a variety of conventional and advanced techniques used in research and commercial mineralogy laboratories. Based on their features and capabilities, mineralogy techniques used in a process mineralogy laboratory can be classified into five categories: qualitative, semi-quantitative, quantitative mineral analysis, quantitative elemental analysis and mineral surface analysis. Each of the techniques has its advantages and limitations and has to be selected and applied primarily based on its merit when considering a mineralogy program to ensure the information obtained is reliable and accurate.

INTRODUCTION

It is well known that geological and mineralogical characteristics and parameters of an orebody such as grade, bulk mineralogy, metal deportment, ore texture and hardness often vary vertically and laterally within an orebody, and such variability has a direct impact on mineral processing and extractive metallurgy. It is important for mineral processors to understand the characteristics and variability of the ore to be processed during flow sheet development and mill operation. As an important part, mineralogy plays a critical role in ore characterisation of a mineral program. To ensure the information acquired in a mineralogy program is reliable and accurate, selecting the right tool(s) is extremely important and a standard operating procedure must be followed in any mineralogy program related to mineral processing. Without using the right tool, mineralogy data can be discounted or even misleading.

There is a variety of mineralogy techniques employed in mineral research and commercial labs (Table 1). These techniques are mainly based on the availability of existing instrument platforms and on the need for information required for mineral processing. Each of the mineralogy techniques has its advantages and limitations, and has to be selected and applied primarily based on its features/capabilities when considering a mineralogical program. Conventional analytical techniques such as optical microscopy, SEM and XRD are still being used in many mineralogical laboratories for their easy-operating and/or low-cost features, while automated mineralogy techniques have been widely used in recent years for their robust and rapid analytical capabilities to provide information on model mineralogy including grain size distribution, liberation and association of target minerals. D-SIMS and LA-ICP-MS have been used in quantifying trace metals (such as Au, Ag and PGE) carried in sulfide minerals of refractory ores. TOF-SIMS and XPS are mainly used for mineral surface analysis to detect and quantify surface adsorbent such as the chemicals used in sulfide flotation and the gold adsorbed on the surface of carbonaceous matter by preg-robbing. More often, a combination of conventional and advanced techniques are required for characterising the complex ores.

TABLE 1

Main techniques used in process mineralogy.

Category	Technique	Abbreviation	Application	Feature
Qualitative Mineral Analysis	Stereoscopy	SS	Mineral identification and sample preparation	10 μm LR
	Microscopy	MS	Mineral identification and semi-quantitative analysis of bulk material	0.5–1 μm LR
Semi-Quant Mineral Analysis	Automated Digital Image System	ADIS	Mineral identification and semi-quantitative analysis of bulk material	1 μm LR
	X-ray Diffraction	XRD	Mineral identification and semi-quantitative analysis of bulk material	0.5 wt% MDL
	Scanning Electron Microscopy	SEM	Mineral identification and semi-quantitative analysis of bulk material	0.5% MDL, 0.5 μm LR
Quantitative Mineral Analysis	Mineral Liberation Analyser	MLA	Mineral identification, quantitative analysis and imaging of bulk material	0.5% MDL, 0.5 μm LR
	Quantitative Evaluation of Materials by Scanning Electron Microscopy	QEMSCAN		
	Advanced Mineral Identification and Characterisation System	AMICS		
	TESCAN Integrated Mineralogical Analyser	TIMA		
Quantitative Elemental Analysis	Electron Probe Microanalysis	EPMA	Quantitative elemental analysis and imaging of individual particles	200 ppm MDL, 1 μm LR, 1–2 μm DR
	Proton-induced X-ray Emission	PIXE		10–100 ppm MDL 25–100 μm LR 15–50 μm DR
	Dynamic Secondary Ion Mass Spectrometry	D-SIMS		100–500 ppb MDL, ≥1 μm LR
	Laser Ablation Inductively Coupled Plasma Mass Spectrometry	LA-ICP-MS		ppm-ppb
	Time of Flight Laser Ion Mass Spectrometry	TOF-LIMS		1–100 ppm MDL, 2 μm LR, 100–300 Å DR
Mineral Surface Analysis	Time of Flight Resonance Ionisation Mass Spectrometry	TOF-RIMS	Surface analysis and imaging of bulk and individual particles (TOF-LIMS inorganic, TOF-SIMS inorganic and organic)	10 ppb MDL
	Time of Flight Secondary Ion Mass Spectrometry	TOF-SIMS		500 Å LR, 10 Å DR
	X-ray Photon Spectrometry	XPS		0.01–1 wt% MDL

Modified from Zhou *et al* (2004) and AMTEL (2022). Note: LR: Lateral Resolution; DR: Depth Resolution; MDL: Minimum Detection Limit.

This paper reviews the advantages and limitations of the five categories of techniques and discusses how to select and apply these techniques to acquire the reliable and accurate information required for a mineral processing program. Considering the importance of sampling and sample preparation in mineralogical study, a brief introduction to the techniques commonly used in mineralogy labs is also provided. Examples will be presented where applicable.

SAMPLE PREPARATION AND PRECONCENTRATION

The importance of sampling and sample preparation can never be overemphasized. Typically, the focus of laboratory results is on the analytical method, and sampling is pretty much taken for granted.

However, sampling is the major source of error in the analytical process, potentially, is an overwhelming source of error for any metallurgical project. The selection of the actual sample preparation procedures depends on the type and size of the sample, the mineralogy, and the analytical and budgetary constraints (LeVier, 2019). Actually, the quality of all analyses is dependent on the quality of sampling and sample preparation no matter how advanced the analytical technique is. It is not possible to obtain quality mineralogical information without quality samples. Therefore, standard sample preparation procedures must be followed in any analytical and mineralogical study program to ensure sample representativity and to avoid cross-contamination. In any case, it is highly recommended: (1) to get the sample preparation done in a dedicated area; (2) to split each sample using a riffler; (3) to start from low-grade samples towards high-grade samples; and (4) to clean the working area and used tools thoroughly after each use (Zhou *et al*, 2004).

Sample preparation

As with any analytical technique, sample preparation is crucial to obtaining reliable information. Samples used for a process-related mineralogical study may include large hand specimens, drill cores, rock chips, run-of-mine ores, flotation concentrate and tailings, leach residue and other metallurgical products. Usually, these samples need to be prepared before analysed using selected sample preparation techniques. More information on sample preparation and some standard procedures can be found in the references (Stanley and Laflamme, 1998; Zhou *et al*, 2004; Aylmore, 2019).

Mineralogy sample preparation usually starts from crushing and then going through grinding, screening (dry and wet), splitting for various test work and chemical analysis, pre-concentration, preparation of granular samples for surface analysis, preparation of polished thin sections and blocks for microscopic examination, and preparation of polished grain mounts for microscopic examination and instrumental analysis. Size distribution is critical for mineral processing. To avoid over-grinding, stage-crushing is highly recommended for all mineralogy samples. Trial grinding should be conducted prior to grinding of real samples to get an estimation of the time required for the test samples. Ground material needs to be screened after each run with coarse fraction going back to further grinding. Same as sample crushing and grinding, extra caution should be taken during polishing of grain mounts and over-polishing should always be avoided. This is particularly important for samples containing gold and silver minerals due to their softness. Samples for surface analysis (Figure 1a and 1b) should be kept at low temperature after it is taken in the lab or plant and analysed soon after preparation to avoid any surface oxidation or contamination. When conducting quantification of trace elements using EPMA, D-SIMS, LA-ICP-MS or other microbeam techniques, it is recommended to have mineral particles pre-selected to ensure data representativity and instrument efficiency. It is well known that gold-bearing sulfide (typically pyrite and arsenopyrite) often occur in three or four morphological types and gold in each variety may vary greatly. It is highly recommended to pre-select the sulfide particles under a microscope based on the morphological types and abundance of each type (Figure 1c). Random selection of target mineral particles should be avoided due to poor representativity.

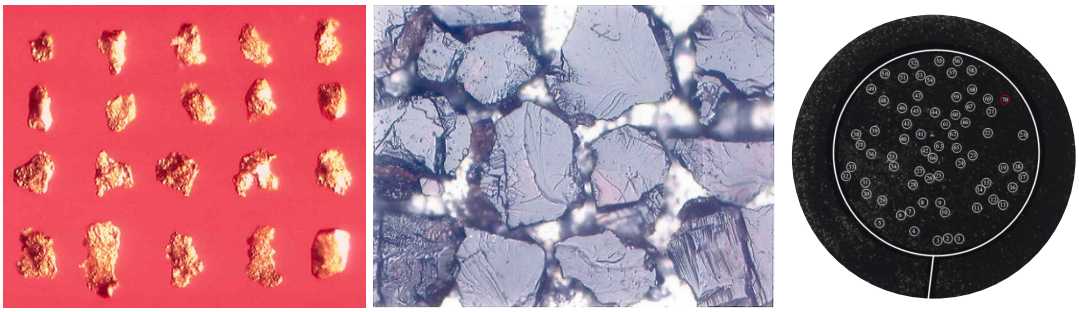

FIG 1 – Mineralogy samples prepared under stereoscope and optical microscope. (a) Individual -20 μm gold particles picked out from tailings for surface analysis; (b) sphalerite grains cluster prepared for surface analysis; (c) sulfide mineral particles selected in a polished section for quantification of submicroscopic gold using D-SIMS.

Pre-concentration

Most of the elements with economic value occur in low to extremely low abundance in the earth's crust and require pre-concentration prior to mineralogical characterisation to make the data acquired more representative and meaningful. This is particularly important for any mineralogy program of precious metals, critical metals and some other trace elements. For bulk mineralogy analysis using optical microscopy and/or automated instruments, common practice is to prepare one or more polished sections of unconcentrated material for direct analysis (screened size fractions may be required for certain samples to acquire better data quality). However, it is difficult (if not impossible) to get quality data on unrepresentative samples in metal deportment study programs because most mineralogy programs only use a few grams material if preconcentration is not involved. Thus, for any metal deportment study program, particularly for low-grade ores or tailings, large subsamples (one kilogram or more per sample depending on the grade) split from well-mixed as-received material using standard rifflers are highly recommended.

The pre-concentration techniques and equipment commonly-used in process mineralogy laboratories may include Knelson concentrator, shaking table, heavy liquid separation (HLS) and superpanner. These techniques use gravity to separate and concentrate minerals based on specific gravity difference of various minerals without changing the shape, grain size and surface properties except HLS (some labs use chemical-based heavy liquid products such as Sodium polytungstate or Methylene iodine as heavy media which may alter the mineral surface chemistry).

Superpanner is a unique and highly recommended preconcentration device for mineralogy labs. It is usually used to further concentrate the Sink fraction generated from heavy liquid separation, but can also be used to concentrate any other samples containing heavy minerals. After working for 20–30 minutes, heavy minerals and silicates are separated in decreasing S.G. of major minerals in the sample and a small amount of highly concentrated 'tip' (in case of a gold sample, tip contains all liberated gold particles and other heavy minerals), a 'clean' sulfide fraction and silicate fraction will be obtained for instrumental analysis and assayed for elements of interest (Figure 2). For gold deportment study, one or more polished sections are made from each product for gold scanning using microscope or automated mineral analyser, to determine the gold mineral species, size distribution, association, and for quantitative analysis by the electron microprobe to determine the mineral chemistry. Work completed by the senior author showed that the recovery of heavy minerals using this technique is ~99 per cent and the total amount of liberated gold and attached gold (both directly cyanide leachable) determined by this method is much closer to the gold recovery by cyanide leaching (Zhou *et al*, 2004).

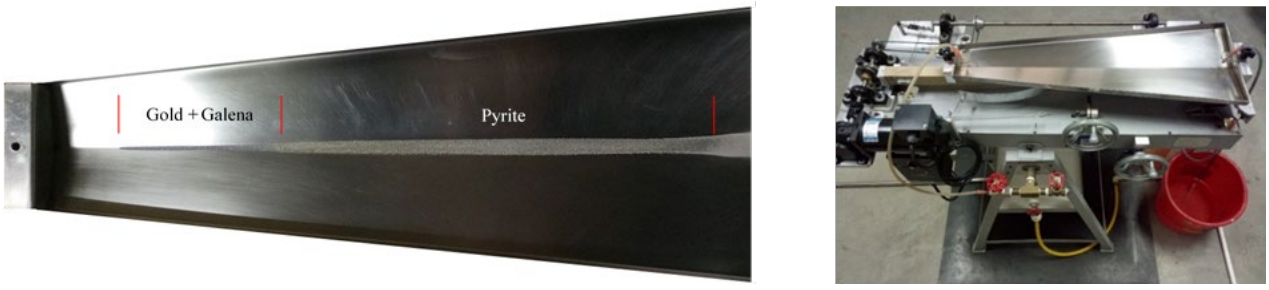

FIG 2 – Photographs showing the separation of a sulfide gold ore (left) by superpanner (right) Gold, galena, pyrite and silicate fraction were well separated.

TECHNIQUES FOR QUALITATIVE ANALYSIS

Qualitative techniques in this paper refer to those conventional mineralogy techniques such as stereoscopy and optical microscopy. Both microscopic techniques are commonly used for mineral identification, grain size measurement, liberation assessment and sample preparation for advanced instrumental analysis (Craig and Vaughan, 1994; Petruk, 2000; Zhou *et al*, 2004). The minimum detection limit (MDL) for both techniques are 1 μm and 10 μm lateral resolution (LR), respectively. In addition to mineral identification and morphological study, stereoscopy is often used for grain sample preparation for microbeam analysis such as TOF-LIMS and TOF-SIMS analysis which requires individual mineral particles (Figure 1a and 1b) and for quality check of final products generated by preconcentration techniques such as heavy liquid separation and superpanning. It is

also used for diamond selection in mineralogy labs and for quality check of the gravity or flotation concentrate in mineral processing labs. Optical microscope is also used for particle selection in some mineralogy labs which conduct instrumental analysis of individual mineral particles using EPMA, SIMS and LA-ICP-MS (Figure 1c), although it is mainly used for examination of polished thin section under transmitted light and polished section under reflected light for mineral identification, texture description, alteration classification, particle size measurement, and liberation and association determination of target minerals (Figure 3). Sample preparation for instrumental analysis is critical for any mineralogical program and will be discussed in detail in the next sections. Without quality samples, it would not be possible to produce quality results.

The advantages of stereoscopy and optical microscopy are that these techniques are fast and cost-effective, easy to operate and require low capital investment. They also offer excellent visual images (Figures 1 and 3). The limitations are that stereoscopy and microscopy only offer qualitative or semi-quantitative results. They are operator-dependent and it can be difficult to get the reliable data when the ore is complex and/or the sample is fine (<20 μm). However, stereoscopy and microscopy remain critical in many mineralogical studies and will not be replaced by advanced techniques in the foreseeable future. They are good for use in lab and at mine site.

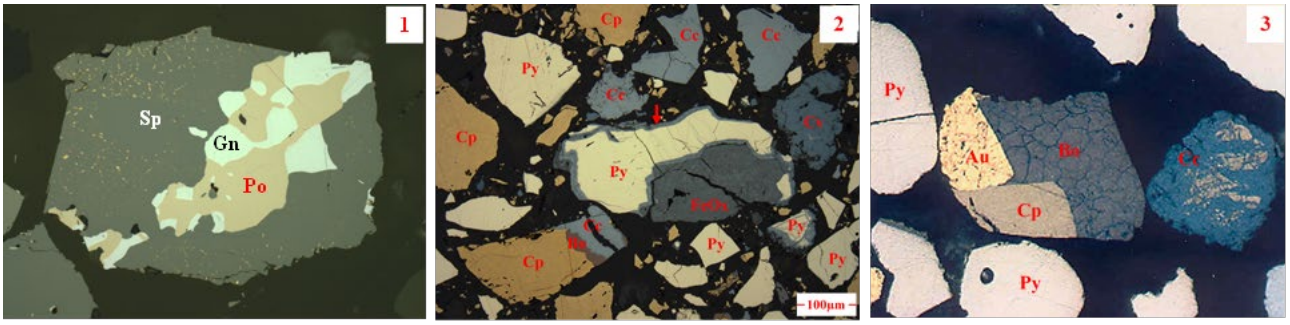

FIG 3 – Reflected light photomicrographs showing mineralogical composition, grain size, liberation and association of target minerals in tails and concentrate samples. (1) A composite particle of sphalerite (Sp) with locked galena (Gn), pyrrhotite (Po) and chalcopyrite (tiny green dots) from an Ag-Pb-Zn flotation tail; (2) Chalcopyrite (Cp), bornite (Bo), chalcocite (Cc), covellite (Cv), pyrite (Py) and iron oxide (FeOx) in a copper concentrate; (3) gold (Au), chalcopyrite (Cp), bornite (Bo), covellite (blue vein in Bo), pyrite (Py) and chalcocite (Cc) with Cp (greenish microinclusions) in a copper-gold concentrate.

TECHNIQUES FOR SEMI-QUANTITATIVE ANALYSIS

Information on mineral speciation, quantity and texture of mineral of interest is required for each ore being developed and processed. At the early stage of a development project or during processing of non-refractory ore, semi-quantitative analysis may provide the essential mineralogical information required for project evaluation or plant operation. Automated Digital Image System (ADIS), X-ray Diffraction (XRD) and Scanning Electron Microscopy (SEM) are the three major semi-quantitative techniques commonly used in mineralogy labs for identification and quantification of minerals in common ore samples.

Automated Digital Image System (ADIS)

ADIS is an optical microscopy system with imaging capability. Image analysis techniques have been described in detail by Petruk (1988, 2000), Lastra *et al* (1994, 2016) and Berry *et al* (2008). These techniques, if applied properly, can be more productive and provide better quality results than optical methods. Sized ore samples can be examined optically using an ore microscope equipped with an automated digital imaging system (ADIS). ADIS assigns imaging thresholds based upon colour and intensity to individual mineral species. Minerals with distinctive colour under reflected light such as chalcopyrite, bornite, chalcocite, covellite, galena, sphalerite, magnetite, hematite, pyrrhotite and pyrite are easily measured. Silicate minerals are grouped as non-opaque gangue minerals and are differentiated from the epoxy background using a coating technique. Same as optical microscopy, ADIS is fast and cost-effective, easy to operate and require low capital investment. In addition to excellent statistics, ADIS also offers quality visual images and information on mineral grain size and

liberation characteristics, making the system a great tool for lab and mine use. Available information and the senior author's experience showed that it is difficult for the system to differentiate minerals with the same or similar reflected colours. It is also ineffective and inaccurate for analysing complex ores.

X-ray Diffraction (XRD)

XRD is a powerful tool in minerals and materials studies and offers both qualitative and semi-quantitative results. Rietveld method is the most commonly used methodology to achieve quantitative phase analysis of crystalline materials. XRD uses X-ray (0.05–0.25 nm) to identify minerals through analysing their crystal structures and is considered to be most accurate technique in mineral identification because each mineral is unique in its crystal lattice. 10–40 μm powder material of ore sample is commonly used in XRD analysis and results are presented in two forms, a pattern showing the mineral species and qualitative/semi-quantitative data showing bulk mineralogy and mineral content in the sample analysed (MDL is about 0.5 wt per cent for semi-quantitative analysis depending on crystallinity of minerals present in the samples).

XRD is commonly used in mineralogy labs to determine the mineralogical composition of feed and metallurgical products on a daily basis. It is a preferred tool for speciation and quantification of clays, pyrrhotite and some other minerals. Actually, it is the only technique that can accurately distinguish the two types of pyrrhotites and has been used in characterising a number of pyrrhotite ores (Becker *et al*, 2008, 2010; Multani *et al*, 2018).

Structurally, there are two types of pyrrhotite, hexagonal pyrrhotite (Fe_9S_{10}, 47.37 per cent Fe) is weakly magnetic or nonmagnetic, while monoclinic pyrrhotite (Fe_7S_8, 46.7 per cent Fe) is highly magnetic. Different crystalline forms of pyrrhotite behave differently in beneficiation circuits, and carefully constructed and controlled processes, eg flotation units, are thus required to achieve good separation of pentlandite and hexagonal pyrrhotite. Monoclinic pyrrhotite is readily removed by drum magnets, but hexagonal pyrrhotite is almost unaffected. Under many conditions, hexagonal pyrrhotite has similar flotation kinetics to pentlandite.

In addition to minerals analysis, XRD is also used in analysis of metals, polymers, catalysts, pharmaceuticals, plastics, thin-film coatings, ceramics and semiconductors. In terms of unit cost and turnaround time, XRD is relatively cost-effective and fast if ore is simple. It is generally operator-independent due to sophisticated software. Application of XRD is limited in mineral quantification due to its higher detection limit. It is not accurate for low abundance minerals (1–3 per cent DT) and not suitable for detection and quantification of trace minerals such as gold, silver and PGMs. Some X-ray spectra may overlap and hard to evaluate. No textural information (grain size/liberation) available from XRD analysis is another disadvantage of the XRD analysis. When textural information is required, optical microscopy, SEM or automated mineralogy techniques are recommended.

SEM has been used in many mineralogy labs for different purposes. The advantages and limitations are discussed in the next section in conjunction with automated mineralogy techniques.

TECHNIQUES FOR QUANTITATIVE MINERAL ANALYSIS

Among the mineralogical factors affecting mineral processing, liberation, grain size distribution and association of target minerals are the three most important ones impacting various processes. In most ores, target minerals must be liberated or exposed prior to processing to achieve acceptable recovery and concentrate grade, although target minerals in some ores may not need complete liberation for concentration. For example, gold in a sulfide ore is often recovered by gravity, flotation, cyanidation or a combination of these techniques after milling, while gold in a copper-gold ore is usually recovered into a copper concentrate by flotation as liberated or binary particles. In the UG2 PGE ore, fine-grained PGMs (~10 μm) associated with sulfide minerals are recovered by flotation as composite particles to avoid loss of liberated fine PGMs. Therefore, it is important to have the information on liberation, grain size and association of target minerals during process development and plant operation.

In the past three decades, SEM-based automated mineralogy gained significant progress due to rapid development of analytical technologies and instrument hardware. Several advanced mineral analysis systems have been developed and widely used in the mining industry for their robust and

rapid analytical capabilities to provide information required for mineral processing (Gregory *et al*, 2013; Gu, 2003; Gu *et al*, 2014; Zhou and Gu, 2016; Multani *et al*, 2018; Aylmore *et al*, 2018a, 2018b; Aylmore, 2019). These techniques include Mineral Liberation Analyser (MLA), Quantitative Evaluation of Materials by Scanning Electron Microscopy (QEMSCAN), Advanced Mineral Identification and Characterisation System (AMICS), Tescan Integrated Mineralogical Analyser (TIMA), INCAMineral and BGRIMM Process Mineralogy Analyser (BPMA). The information that can be obtained from automated SEM systems includes: (1) modal mineralogy (the percentage of each mineral in the sample); (2) grain size distribution (distribution of grain sizes of target mineral in the sample); (3) mineral liberation (the liberation degree of the mineral of interest based on exposed surface area of particles; (4) mineral locking (a measure of target mineral enclosed in other minerals based on exposed surface area of the mineral of interest; (5) mineral association (a measure of the relationship of target mineral with the host mineral(s) in the sample.

Automated mineralogy techniques offer excellent statistics for major, moderate and minor minerals with quantitative analysis down to 0.1 per cent level. It also provides textural information (grain size, liberation, locking and association). The systems are generally operator-independent for simple ores. Figure 4 presents the information on modal mineralogy and sulfide liberation characteristics of five head samples from a sulfide gold ore. Modal mineralogy shows that the head samples are mainly composed of pyrite, siderite with moderate amounts of quartz, silicate, iron oxides and minor amounts of arsenopyrite and jarosite. Pyrite is the primary sulfide mineral in the head samples, accounting for 18.3 per cent in #3 Head to 36.3 per cent in #5 Head. Pyrite liberation data indicate that liberated pyrite and middling particles accounted for over 90 per cent in all five head samples. In addition to modal mineralogy and liberation data of target minerals, automated mineralogy techniques can also create cumulative grain size distribution curves to guide grinding and mineralogically limiting grade-recovery curves to predict correlation between concentrate grade and recovery (Aghamirian *et al*, 2012). Automated mineralogy techniques have the following limitations: (1) cannot detect and quantify elements in solid solution and do not provide real image for automated analysis; (2) fine particles can be missed at lower magnification (the minimum particle size for gold minerals can be detected and measured at 400X is ~0.6 μm); (3) statistics for trace minerals can be poor if preconcentration was not conducted; (4) cost-wise, they are moderately expensive to expensive for multi-size fractions; (5) operator-dependent when mineralogy is complex; and (6) not suitable for ores containing minerals with similar chemistry such as magnetite and hematite, pyrite and marcasite, and enargite and tennantite (classification or speciation can be wrong due to similar mineral chemistry). Like SEM, when used for bright phase (such as gold, silver and PGM) search, automated mineralogy techniques will take a considerably longer time if the sample contains a large amount of minerals with high backscatter signals such as galena, native silver and native tellurium. If this is the case, it is recommended that an optical microscope be used for bright phase search under the guidance of an experienced mineralogist. It is also recommended that a brief observation of polished sections under optical microscope is taken prior to instrument analysis to gain some knowledge of the samples for better setting up the instrument operating conditions. When analysis of iron oxide (such as magnetite, hematite and goethite) is required, it is suggested that quantification of the total Fe-oxide content be done by automated instrument and determination of the proportion of the different Fe-oxides by optical microscope.

	#1 Head	#2 Head	#3 Head	#4 Head	#5 Head
Barren Pyrite/Marcasite	0.00	0.00	0.00	0.00	0.00
Locked Pyrite/Marcasite	2.97	1.98	3.19	4.22	2.30

TECHNIQUES FOR QUANTITATIVE ELEMENTAL ANALYSIS

Mineral chemistry and concentration of trace element in host minerals are important to mineral processing because they often controls the target metal recovery and concentrate grade and often impact process selection and plant operation, and need to be quantitatively determined in a mineralogy program. The quantification of major constituents of a mineral is commonly done by electron probe microanalysis (EPMA), while the quantification of trace elements (such as Au, Ag, PGE and some critical metals) in host minerals is commonly done by Dynamic Secondary Ion Mass Spectrometry (D-SIMS), Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS), Proton-induced X-ray Emission (PIXE) or other microbeam techniques.

Electron Probe Microanalysis (EPMA)

EPMA offers quantitative analysis of major and minor elements and also distribution of elements of interest in many metallic and non-metallic minerals. The minimum detection limit (MDL) is generally considered to be 0.02 per cent or 200 ppm for most elements. It is suitable for quantification of Au and Ag in native gold and electrum, Ag in dyscrasite, freibergite and other silver minerals, Fe in sphalerite and spodumene, Ni in pentlandite and pyrrhotite, As in pyrite and marcasite, and Ag in galena among other elements. EPMA is cost-effective comparing to other microbeam techniques. However, EPMA is standard dependent and not suitable for trace element analysis.

Sphalerite (ZnS) is the world's primary source of Zn. It is commonly formed with impurities such as Fe, Cu, Cd, Ga, In, Ge and Mn among others (Lepetit *et al*, 2003; Cook *et al*, 2009). It is well known that iron in sphalerite varies between deposits in different locations and in some cases between single samples from a given deposit, and has an impact on sphalerite floatability. Boulton *et al* (2005) investigated the effect of iron in sphalerite on the froth flotation of sphalerite at alkaline pH. It was found that a critical copper sulfate concentration exists where sphalerite recovery is maximised, above which the recovery of sphalerite then decreases. The presence of iron in sphalerite is detrimental to the rate of sphalerite flotation and hence its recovery, with the coarser particles being more affected than the fines. The presence of iron reduces the activation of sphalerite by copper, which in turn results in a reduction in collector adsorption. Yu *et al* (2019) found that the floatability of sphalerite from the Huize lead-zinc mine in China varied greatly with the iron impurity content. The flotation experiments conducted on the three types of sphalerites with iron content of 2.30 wt. per cent, 3.20 wt. per cent and 4.66 wt. per cent showed that the flotation recovery increased with the increase in iron impurity content. Therefore, the iron content in sphalerite needs to be quantified using a mineralogy tool for each deposit or each of the ore types in a given deposit. This type of analysis is commonly done in a mineralogy lab using EPMA.

The Dumont deposit is a large (1066 Mt probable reserve) low-grade (0.27 per cent Ni) nickel sulfide deposit in Canada. During the pre-feasibility study from 2010 to 2012, a detailed mineralogical program including 1980 QEMSCAN samples and 7260 electron microprobe points were undertaken to increase the understanding of the nickel deportment in the various recoverable and non-recoverable phases in a spatial context across the deposit (Muinonen *et al*, 2013). Disseminated

ultramafic-hosted nickel mineralisation is characterised by disseminated blebs of pentlandite ((Ni, Fe)$_9$S$_8$), heazlewoodite (Ni$_3$S$_2$), and the ferro-nickel alloy, awaruite (Ni$_{2.5}$Fe), occurring in various proportions throughout the sill. Nickel can also occur in the crystal structure of several silicate minerals including olivine and serpentine. Quantifying the difference in the nickel deportment between metallic and silicate phases is critical in understanding metallurgical response in different areas of the deposit. Electron microprobe analyses were performed to quantify the variability of nickel content (tenor) in key minerals of interest for samples from locations throughout the Dumont deposit. All minerals analysed showed low variability in nickel tenor throughout the sill except for pentlandite and serpentine. Pentlandite shows the most variability of the metallic minerals and exhibits a bimodal population. For samples where nickel tenor in pentlandite is lower, the lower nickel values are mostly associated with an increase in iron. The lower tenor pentlandite, averaging 27 per cent Ni, is highly correlated with the areas of higher Fe Serpentine. The pentlandite outside these areas has an average Ni tenor of 34 per cent. Fe-serpentine is correlated to higher nickel in silicates. This understanding of the differences in the high Fe-serpentine area was a key breakthrough used to define the Pn-rich domains. Obviously, nickel deportment will impact nickel recovery and concentrate grade.

Lac des Iles platinum-group elements deposit located in north-west Ontario, Canada is the only known palladium ore in the world. In an early study conducted by Zhou using EPMA on the deportment of PGE in a flotation concentrate from Lac des Iles plant indicated that Pd-bearing minerals account for 91 per cent in the concentrate, including vysotskite ((Pd, Pt, Ni)S), stillwaterite (Pd$_8$As$_3$), kotulskite (Pd(Te,Bi)), isomertieite (Pd$_{11}$Sb$_2$As$_2$), merenskite ((Pd, Pt)(Te,Bi)$_2$, sperrylite (PtAs$_2$) and a minor amounts of other PGE-carriers in the order of decreasing abundance (Zhou, 2007).

Dynamic Secondary Ion Mass Spectrometry (D-SIMS)

D-SIMS and LA-ICP-MS are the two most common techniques that have been used in quantifying trace elements contained in other minerals such as submicroscopic gold carried by sulfide minerals in refractory ores and trace critical elements present in solid solution in Zn-bearing ores. Zhou *et al* (2004) and Chryssoulis and McMullen (2016) used a comprehensive approach including D-SIMS in gold deportment studies.

D-SIMS is one of a few most important microbeam techniques applied in minerals studies because of its unique quantification and mapping capabilities. It has been used in quantifying Au and other trace elements for more than three decades (Chryssoulis and Cabri, 1990; Chryssoulis and McMullen, 2016; Zhou *et al*, 2004; Zhou and Fleming, 2007). Theoretically, it can detect and measure all the elements in the periodic table in concentration from ~1 per cent to 10 ppb and has the ability to discriminate between the isotopes of many elements. The element and isotope contents can be measured with a sensitivity that is as high as the sensitivity of bulk analysis methods, such as atomic absorption (McMahon and Cabri, 1998). Its exceptional operational capabilities include: (1) small beam size: 15–20 μm; (2) quantitative analysis with low detection limit (0.3–0.5 ppm for Au); (3) shallow beam sampling depth (0.5–1 μm); (4) individual particle analysis; (5) depth concentration profiling; and (6) element mapping.

High sensitivity makes SIMS an excellent analytical tool for the quantification of trace elements in a variety of materials. It is considered to be the best technique for quantification of submicroscopic gold in sulfides. The SIMS in-depth concentration profiling is used to discriminate colloidal gold and solid solution gold. Colloidal gold (0.02–0.1 μm) can be identified from the ‘spikes’ and ‘bumps’ in the in-depth concentration profiles of gold, whereas solid solution gold is characterised by ‘flat’ in-depth profiles (Figure 5a and 5b). SIMS mapping is used to show the location and distribution of submicroscopic gold in host minerals (Figure 5c).

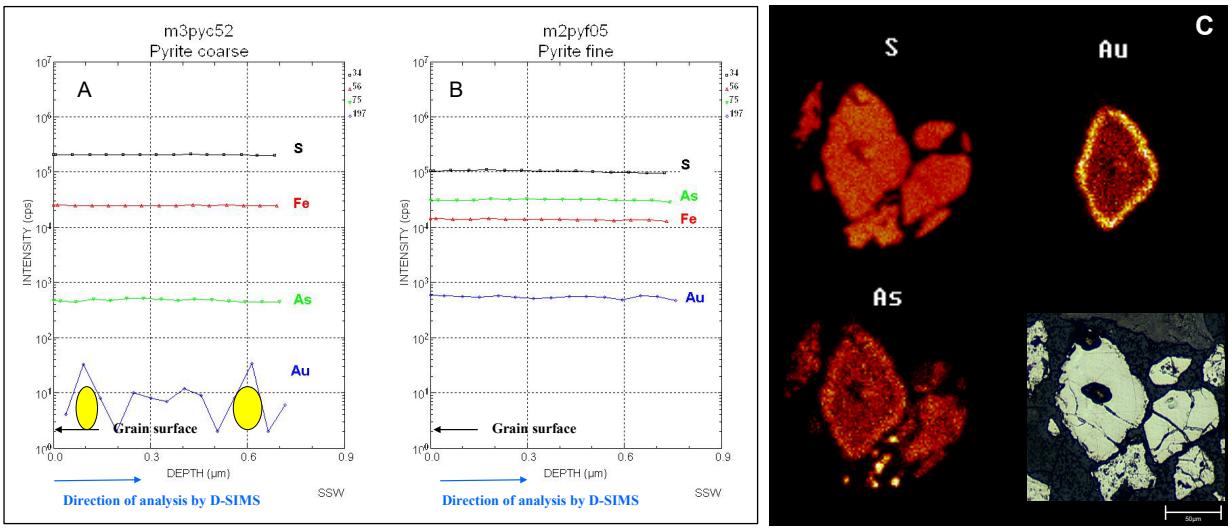

FIG 5 – SIMS in-depth concentration profiles (a and b) and elemental maps (c). (a) Colloidal gold (3.10 ppm, ~0.1 μm in size) in coarse pyrite; (b) solid solution gold (220.7 ppm) in fine pyrite; (c) SIMS elemental maps showing the distribution of Au, As and S in an Au-bearing zoned pyrite. Au concentration in the outer accretion zone (323 ppm, shown in golden yellow) is much higher than that in the core (143 ppm). The lower right optical picture shows the grain size of pyrite particle (Figure 5c was adapted from Zhou and Fleming, 2007).

As discussed earlier, sample preparation and particle selection are very important steps in a SIMS study. During the study, the mineralogist should work closely with the SIMS operator to ensure that the standard study procedure is followed.

It is worth pointing out that D-SIMS is not suitable for major elements analysis and non-sulfide minerals. It is standard dependent and moderately expensive comparing to EPMA and LA-ICP-MS.

Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS)

LA-ICP-MS was first used in 2003 to determine whether Au is distributed homogeneously in sulfides, particularly arsenopyrite, or is contained as micronuggets in the Lodestar prospect in eastern Newfoundland (Hinchey *et al*, 2003). Since then, the technique has been widely used in mineralogical and geochemical studies, mostly in quantification and distribution of trace elements such as Au, Ag, As, Bi, Cd, Co, Cu, Fe, Ga, Ge, In, Mn, Mo, Ni, Pb, Sb, Se, Sn and Tl in geological samples and metallurgical products (Cabri *et al*, 2008, 2010, 2017; Cook *et al*, 2011; Gregory *et al*, 2013; Liu *et al*, 2013; Raimondo *et al*, 2017; Gao *et al*, 2019; Xu *et al*, 2021). Available information has shown that LA-ICP-MS offers excellent potential in trace element analysis through significantly improved detection limits for *in situ* analysis, and the ability to generate profiles through minerals by progressive ablation. The system is capable of determining, with good accuracy, a large suite of trace elements in various mineral hosts including silicates, carbonates, phosphates, oxides, and sulfides. Limits of detection vary from a few ppm to a few ppb depending upon a number of operating variables, such as pit size and number of elements determined. Sampling resolution better than 10 μm can be achieved, although ablation pits on the order of 40 μm are usually used, when grain size allows, to provide better precision and detection limits. Like D-SIMS, LA-ICP-MS has imaging capability in addition to *in situ* analysis.

Sphalerite is an important host mineral for a wide range of minor and trace elements. Cook *et al* (2009) used LA-ICP-MS to investigate the distribution of Ag, As, Bi, Cd, Co, Cu, Fe, Ga, Ge, In, Mn, Mo, Ni, Pb, Sb, Se, Sn and Tl in samples collected from 26 ore deposits, including specimens with wt. per cent levels of Mn, Cd, In, Sn and Hg. The results showed that the technique provided accurate trace element data, confirming that Cd, Co, Ga, Ge, In, Mn, Sn, As and Tl are present in solid solution. The concentrations of most elements vary over several orders of magnitude between deposits and in some cases between single samples from a given deposit. Sphalerite was characterised by a specific range of Cd (typically 0.2–1.0 wt. per cent) in each deposit.

The Kevitsa Ni–Cu–PGE deposit is a low-grade, disseminated sulfide deposit, which resides in the upper ultramafic unit of the Kevitsa intrusion. Commissioning of the Kevitsa operation began in 2012. A Cu–Ni sequential flotation circuit produces two concentrates, a Ni–PGE concentrate and a Cu–Au concentrate, with some Au, Pt and Pd. Earlier studies had reported trace concentrations of platinum-group elements in several minerals using the electron microprobe. In an effort to evaluate PGE and Au recovery performance in more detail and identify opportunities to improve recovery, a heavy mineral concentrate from a processed stream of 'run-of-mine' mill feed containing elevated levels of PGE and Au was studied using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), which has much lower limits of detection, to target potential carrier minerals (sulfide, sulfarsenide, and arsenide) as part of a process mineralogy study of the ore, with the data used to determine the deportment of the precious metals. Trace precious-metal data were obtained on pentlandite, pyrite, gersdorffite, maucherite, and nickeline for Rh, Pd, Os, Ir, Pt, and Au. A unique feature of the data was the new discovery that nickeline is a significant carrier of Au (up to 74.1 ppm), in addition to Rh, Pd, Os, Ir, and Pt. The unexpected concentration of gold in nickeline demonstrates the versatility of LA-ICP-MS analysis when using an appropriate calibration standard and established protocols (Cabri *et al*, 2017).

TECHNIQUES FOR MINERAL SURFACE ANALYSIS

Surface issues can affect flotation and leaching performance and need to be analysed and assessed for improving the plant operation. TOF-SIMS and XPS are the two main techniques among others used for surface analysis to detect and quantify surface adsorbent such as the chemicals used in sulfide flotation and the gold adsorbed on the surface of carbonaceous matter by preg-robbing.

Time of Flight Secondary Ion Mass Spectrometry (TOF-SIMS)

TOF-SIMS uses a pulsed, primary ion beam to desorbs and ionise species from a sample surface. It is a non-destructive technique offering comprehensive inorganic and organic surface analysis. The minimum detection limits are in the low ppm to ppb range. It possesses imaging capabilities with spatial resolution down to 0.3 μm and features elemental depth profiling. It is one of few techniques available for both individual mineral particle and cluster surface analysis with detection limits in the low ppm/ppb concentrations.

Applications of TOF-SIMS include identification of collectors on individual mineral particles from plant samples; measurements of collector loadings on mineral grains from flotation circuit at plant concentration levels. Practical detection limits are less than 1 g/t; identification of activators and depressants on mineral particles – comparative analysis on the degree of activation or depression of mineral phases during flotation; characterisation and mapping of surface coatings on gold grains from cyanide leach residues; and evaluation of preg-robbing capability of carbonaceous matter and quantification of adsorbed gold (Chryssoulis and McMullen, 2016; Dimov and Hart, 2017). In a gold deportment study conducted by the senior author on a carbonaceous ore containing total carbonaceous matter (TCM) and disseminated TCM, TOF-SIMS quantitative analysis showed substantial concentrations of preg-robbed surface gold (59 ppm) on the carbonaceous material. The preg-robbed surface gold was present in two different forms: metallic gold and gold compound $Au(CN)_2$, accounting for 14 per cent and 86 per cent, respectively (Zhou, 2011).

SUMMARY

Mineral processing of various ores is largely driven by mineralogical factors and requires mineralogical information at each stage of a mineral project. Mineralogists use a variety of conventional and advanced techniques to characterise the ore and metallurgical products and provide solution to mineral processers in supporting project development and plant operation. Each of the mineralogy techniques is designed or borrowed based on metallurgical needs and has its advantages and limitations. Selection of the mineralogy techniques must be based on the capability of each technique and the information being sought for mineral processing. During the exploration or at the early stage of a development project, qualitative and semi-quantitative mineralogy techniques will provide the information required for target identification and project evaluation. During project development, a large amount of mineralogical information acquired through advanced mineralogy techniques will be required to support process selection and flow sheet development. After commissioning, mineralogy information will still be required for production prediction and

trouble-shooting, and selection of mineralogy techniques will be based on the nature of the ore to be processed and the issues encountered in the plant. In many cases, a set of mineralogy techniques are required for a comprehensive geometallurgy program during project development and plant operation.

When considering a mineralogical program, it is always good to understand what kind of the information is required and which instrument is good for such analysis. Selecting a qualified laboratory and an experienced mineralogist for the mineralogical program is critical for getting the best quality. Instrument provides data, mineralogist provides solution.

ABSTRACT

Copper (Cu) is a critical metal in the transition to a low-carbon power supply. Presently, low-grade copper sulfide ores account for almost 80 per cent of the global reserves. Large amounts of water are required to process these low-grade copper ores. The mining industry utilises lixiviants from recycled water from different sources to conserve water, whilst enhancing Cu recovery. Some utilise intermediate to pregnant leach solutions, sea water, and processed water from electrowinning circuits with highly variable concentrations of ions. Previous studies have highlighted the formation of precipitates that passivate the surfaces of minerals in these low-grade copper ores and/or block flow paths for lixiviant during heap leaching. In this study, we utilised concepts of phase replacement to devise an innovative means of controlling precipitation and increasing copper recovery using industrial brine as opposed to freshwater. We propose the formation of Al-rich phases (such as $AlSO_4^+$ or alunite) to replace iron sulfate and iron hydroxysulfates (such as jarosite) during the chalcopyrite dissolution-precipitation mechanism. The rationale is to have available Fe^{3+} throughout the chalcopyrite leaching process. We tested this method by carrying out various batch experiments using $CaCl_2$, $AlCl_3$, and NaCl industrial brine types compared to freshwater and explored the capacity to leach Cu from chalcopyrite. There is higher Cu recovery during oxidative leaching of chalcopyrite in industrial brine with 91 per cent recovery using $AlCl_3$-rich brine, 84 per cent with NaCl-rich brine, and 56 per cent with $CaCl_2$-rich brine as compared to 35 per cent recovery using freshwater. In the absence of Al^{3+}, various forms of iron sulfates, and jarosite are formed, reducing the availability of Fe^{3+} for chalcopyrite dissolution. The introduction of Al^{3+} leads to the formation of $AlSO_4^+$ species, thus lowering sulfate activity and the tendency for K-jarosite formation.

INTRODUCTION

Copper (Cu) is a critical metal in the transition to low-carbon-based electrification. This shift towards a greener economy will require sustainable copper mining. Leaching of low-grade ores for copper results in high processing costs and a large volume of tailings. Also, these low-grade ores require large volumes of water to process (Dunne, 2012 and references therein). Water resources are particularly scarce in remote and arid environments (such as the Atacama Desert of Chile and the iron oxide copper-gold (IOCG) deposits of Australia) where mining often occurs. It is estimated that by 2025, as water scarcity intensifies, more countries will be severely short of water (Dunne, 2012 and references therein). The mining industry utilises lixiviants from recycled brine from different sources to conserve water whilst enhancing copper (Cu) recovery. Some of these sources are intermediate to pregnant leach solutions, sea water, and processed water from electrowinning circuits with highly variable concentrations of major and minor cations (eg K, Na, Mg, Mn, Cu, Fe etc), and anions (mostly sulfate and chloride). In the present study, we show how industrial brine can be utilised in processing low-grade porphyry copper minerals. We utilised concepts of coupled dissolution-precipitation and mineral replacement to minimise precipitation at the surface of Cu-bearing minerals (passivation) and to increase copper recovery using industrial brine as opposed to freshwater.

Past research (Hernández *et al,* 2018, 2020; Velásquez-Yévenes *et al,* 2018; Watling *et al*, 2014) including our ongoing study highlighted that there is higher copper recovery when using sea water/brine as compared to freshwater for copper leaching. However, there is hydroxysulfate,

hydroxide, silicate, and oxide precipitation during porphyry copper heap leaching with highly concentrated brines. These precipitates tend to either passivate the surface of minerals in these low-grade copper ores and/or block flow paths for lixiviant in leaching heaps. This in turn leads to reduced mineral-lixiviant contact and subsequently low copper recovery. Our study points to iron hydroxide and hydroxysulfate formation as major inhibitors for chalcopyrite dissolution, but the passivation of the chalcopyrite surface by precipitates such as iron hydroxide or iron hydroxysulfate (eg jarosite) might not be the main hindrance to efficient chalcopyrite dissolution. If the water chemistry favours the formation of hydrous precipitates such as aluminium sulfate minerals as opposed to jarosite, Cu recovery may still proceed at a high rate. In effect, we propose that the main hindrance to chalcopyrite dissolution is not necessarily passivation by jarosite but the decrease in available Fe^{3+} for oxidative leaching of chalcopyrite.

To control iron hydroxysulfate (such as jarosite) passivation during heap leaching, past research has proposed: (1) the application of highly active thermophiles (D'Hugues *et al,* 2002); (2) the use of additives such as silver (Ag) or other external electrode materials as a catalyst; (3) physical processes for the removal of jarosite; and (4) pH control to minimise the formation of jarosite (Yang *et al*, 2018 and references therein). Our proposed method differs from the above, in that, we propose the formation of Al-rich precipitates to replace jarosite during the chalcopyrite dissolution-precipitation mechanism. The rationale is to have available Fe^{3+} throughout the chalcopyrite leaching process. The results of test work undertaken using $CaCl_2$, $AlCl_3$, and NaCl industrial brine types as compared to freshwater for leaching low-grade porphyry copper sulfide ore are the subject of this paper. Watling *et al* (2014) remark NaCl as a primary source of chloride for cupric-cuprous chloride complexation during chalcopyrite leaching. The use of $CaCl_2$ (Faine *et al*, 2009) as patented in the CuproChlor® process for chalcopyrite leaching highlights the formation of gypsum for agglomeration and chloride source as merits. In this study, we report for the first time on the $AlCl_3$ leaching of chalcopyrite.

Coupled dissolution – precipitation reactions during chalcopyrite dissolution

Proton promoted dissolution of chalcopyrite occurs as (Kimball *et al*, 2010):

$$\mathrm{CuFeS_{2(s)} + 4H^{+}_{(aq)} = Cu^{2+}_{(aq)} + Fe^{2+}_{(aq)} + 2H_2S_{(aq)}} \quad (1)$$

In the presence of oxygen and ferric ions, chalcopyrite dissolves respectively as (Kimball *et al*, 2010):

$$\mathrm{CuFeS_{2(s)} + 4O_{2(aq)} = Cu^{2+}_{(aq)} + Fe^{2+}_{(aq)} + 2SO^{2-}_{4(aq)}} \quad (2)$$

$$\mathrm{CuFeS_{2(s)} + 16Fe^{3+}_{(aq)} + 8H_2O = Cu^{2+}_{(aq)} + 17Fe^{2+}_{(aq)} + 2SO^{2-}_{4(aq)} + 16H^{+}_{(aq)}} \quad (3)$$

There is jarosite precipitation during the dissolution of chalcopyrite as:

$$\mathrm{CuFeS_{2(s)} + 4O_{2(aq)} + K^{+}_{(aq)} + 6H_2O + 2Fe^{3+}_{(aq)} = Cu^{+}_{(aq)} + KFe_3(SO_4)_2(OH)_{6(s)} + 6H^{+}_{(aq)}} \quad (4)$$

Also, in this study, we propose alunite precipitation during chalcopyrite dissolution as:

$$\mathrm{CuFeS_{2(s)} + 4O_{2(aq)} + K^{+}_{(aq)} + 6H_2O + 3Al^{3+}_{(aq)} = Cu^{+}_{(aq)} + KAl_3(SO_4)_2(OH)_{6(s)} + Fe^{3+}_{(aq)} + 6H^{+}_{(aq)}} \quad (5)$$

According to Sequeira *et al* (2008), chalcopyrite can undergo a phase replacement reaction as:

$$\mathrm{CuFeS_{2\,(s)} + CuSO_{4(aq)} = 2CuS_{(s)} + FeSO_{4(aq)}} \quad (6)$$

followed by the oxidation-reduction couple as:

$$\mathrm{6CuS_{(s)} + 3CuSO_{4(aq)} + 4H_2O = 5Cu_{1.8}S_{(s)} + 4H_2SO_{4(aq)}} \quad (7)$$

MATERIALS

Ore sample

The low-grade porphyry copper sulfide sample was obtained from the ORE Research and Exploration Pty Ltd, Bayswater, Melbourne – Australia. The samples were pulverised, homogenised, and resampled for X-ray diffraction (XRD) analysis at the Land and Water division of CSIRO in Adelaide (Table 1). The BET surface area of the pulverised sample was measured using a Micromeritics surface analyser at the School of Engineering, the University of Melbourne (Table 1).

Chemical reagents

All chemicals used in this study were analytical grade.

METHODS

Brine preparation

The calculated masses of the various salts were added to known masses of 18.2 mΩ MilliQ water (DI) at 25°C. The pH was adjusted with 1 M NaOH and 2 M HCl. Subsequently, $FeCl_3$ was added to provide ferric ion (Fe^{3+}) as an oxidant in some experiments. The pH was rechecked and readjusted before measuring Eh. It is important to note that the Eh value was mainly influenced by Fe^{3+}. The solution was filtered through a membrane filter with a 0.45 µm pore size and transferred into Nalgene bottles. The Eh and pH were rechecked and pH readjusted, if needed, before the start of the experiment. pH standards of 1, 4, and 7 were used throughout. The pH and Eh were measured with the Metrohm 902 Titrando. Note that there is a possibility of a pale yellow thin-film precipitate formation on the walls of the leaching bottles, especially during the preparation and storage of solutions with $FeCl_3$. To resolve this, it is recommended that Na_2SO_4 be weighed and dissolved first before adding the other salts.

Near-equilibrium batch test

Two different series of near-equilibrium batch experiments were conducted using DI and artificially prepared industrial brine. The industrial brines were classified as $CaCl_2$-dominated brine, NaCl-dominated brine, and $AlCl_3$-dominated brine. Table 2 shows the compositions of the various reagents used in this study. In all the tests, 5 g of 0.45–1.00 mm granulated ore sample was utilised in a 100 mL of brine held in a Nalgene bottle. We were able to conduct five tests in parallel in a water bath utilising an in-house continuously stirred experimental set-up. Before the experiment, the sample was sonicated and rinsed in DI, acetone, and DI for each step lasting 15 minutes, respectively. The aim was to remove any fines and possibly oxidised phases at the surface of the ore material. The experiments were conducted over a 12-to-72-hour period.

TABLE 2

Conditions of the near-equilibrium batch test. All tests were acidified with 0.2 M HCl, except for BB2, BB15A, BB3A, and BB15B, which were acidified with 0.5 M H_2SO_4. Unit for all ions is in mol/L.

BB22	0.10	0.87	0.50	0.14	1.00	3.69	0.50	pH 1.5; 45°C

Chemical and data analysis

A 1.5 mL volume of solution was sampled from each test at times 2, 4, 6, 8, 12, 24, 48, and 72 hours. The solution samples were filtered through a membrane filter with a 0.25 µm pore size. Ions were analysed with ICP-OES (Agilent Technologies 5100) against aqueous standards in 2 per cent ultra-pure nitric acid (HNO_3). Eh and pH were measured in untreated samples after allowing the solution to stand for a while for consistent duplicate measurements. To determine mineral stability under the given experimental conditions, stability diagrams were derived using the Geochemist Workbench (GWB) software (version 15.0).

RESULTS

Changes in fluid composition are presented for the NaCl, the $CaCl_2$, the $AlCl_3$-dominated brines, and the freshwater leaching experiments.

Leaching in fresh water system

The copper recovery with 0.1 mol/L Fe^{3+} (BB1) reached 40 per cent as compared to less than 5 per cent for the case without (BB2) (Figure 1). This shows that for higher copper dissolution, copper sulfide leaching is via oxidation coupled to Fe^{3+} reduction as opposed to proton dissolution. The higher recovery is also positively related to the higher Eh observed in the ferric promoted leaching. There is a decline in the total sulfur (as sulfate, SO_4^{2-}) concentration, suggesting the likely precipitation of sulfate phases, possibly together with Fe, Cu, or other metals. The increase in copper dissolution positively correlates to a decrease in total iron (Fe) concentration for the ferric-promoted leaching mechanism. In the case of proton-promoted leaching, there is no significant variation in the total iron or sulfate concentration over the leaching period.

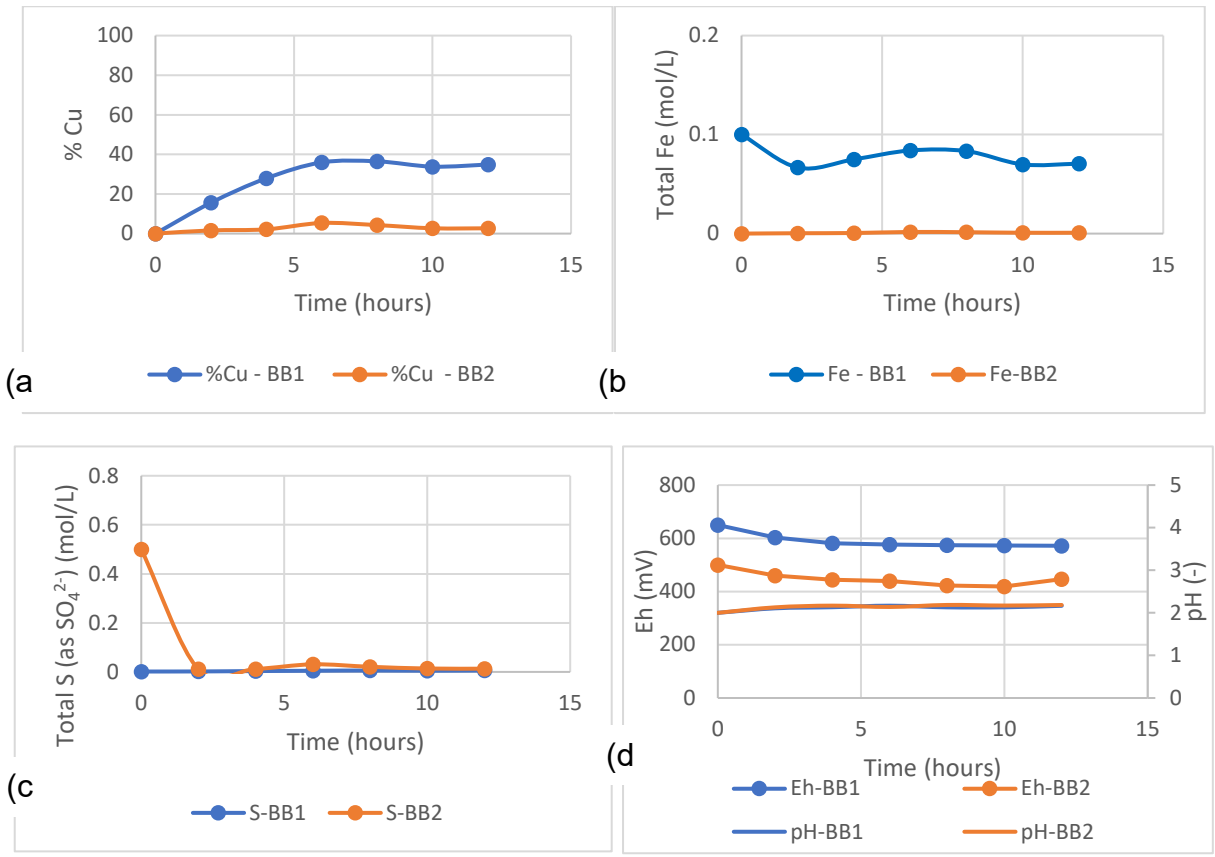

FIG 1 – Leaching in freshwater (a) % copper recovery (b) total Fe (mol/L) (c) total S (as SO_4^{2-}) (mol/L) (d) Eh – pH with oxidant (BB1) at 25°C and without oxidant at 25°C (BB2).

Leaching in $CaCl_2$ brine

We investigated $CaCl_2$ as a reagent for the dissolution of low-grade copper sulfides with (Fe-BB17) and without (Fe-BB15A) Fe^{3+} as an oxidant (Figure 2). Without Fe^{3+}, copper recovery is lower (at ~10 per cent) with possible sulfate precipitation at higher pH (~pH 4), whereas copper recovery reaches almost 60 per cent due to the reaction of ferric initially added at higher Eh (~530 mV) and lower pH (~1.5). Faine *et al* (2009) highlighted the formation of gypsum during the leaching of copper sulfides in $CaCl_2$ lixiviant. Gypsum is known to form hydration bonds that aid very fine particles to cluster together during agglomeration to form near-uniform large particles, hence, reducing local fluid flow due to segregation and possible fines migration during ion transport in a heap leach. In our study, it was observed that the instantaneous formation of a gelatinous mixture involving $CaCl_2$ would not be practicable for heap leaching, as pumping such a mixture would prove difficult.

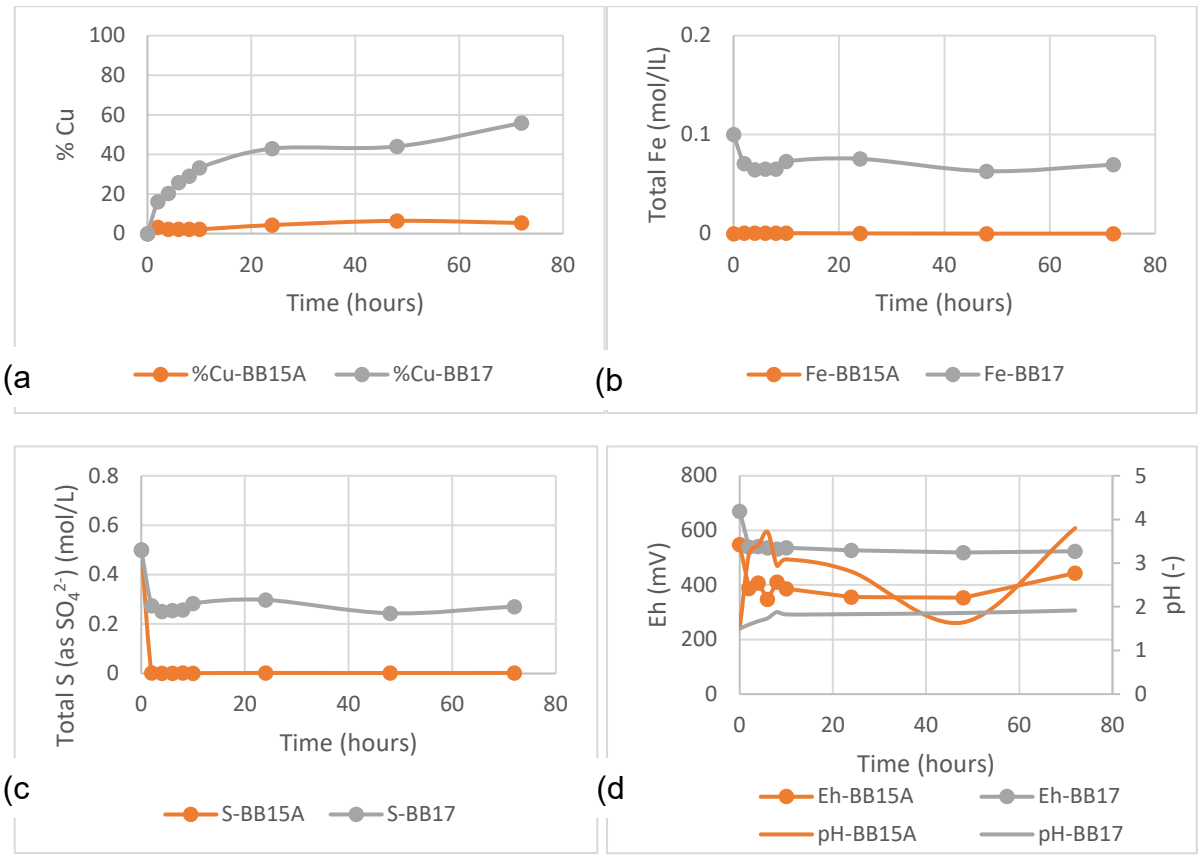

FIG 2 – Leaching in $CaCl_2$ saturated brine (a) % copper recovery (b) total Fe (mol/L) (c) total S (as SO_4^{2-}) (mol/L) (d) Eh – pH with oxidant (BB17) at 25°C and without oxidant (BB15A) at 25°C.

Leaching in NaCl brine

In this study, the goal is to optimise copper recovery utilising high chloride (~5 M) brine due to the scarcity of freshwater for mining. In almost all NaCl brine leaching tests of copper sulfide, we observe a sudden rise (initial 2 hours of leaching) and drop before a continuous increment in copper recovery (Figure 3). This will likely be correlated with pH and the precipitation-dissolution of basic copper salts. Dissolved iron (Fe) declines immediately while total sulfur (as SO_4^{2-}) requires some time to reach a new steady-state concentration. The experiment involving NaCl-rich brine, without ferric iron as an oxidant, demonstrates that the presence of chloride and low pH (~1.5) alone does not lead to high Cu recovery, even in the presence of oxygen (Exp. BB3-A, Figure 3). Leaching in the presence of ferric (Fe^{3+}) and at higher Eh accelerate the copper recovery. This is further increased and influenced by temperature: the highest copper recovery of ~84 per cent was reported at 45°C (BB11). In a low concentration NaCl medium, copper recovery reached 25 per cent, whereas the recovery increased further to 60–88 per cent in the presence of a high chloride concentration. This is expected because high chloride concentration results in high cuprous and cupric chloro complex formation (Brugger *et al*, 2001). Also, high chloride ensures the stability of the various copper ions in the solution during the period of dissolution. The formation of chloride bridges between solution complexes and the surface of the reacting sulfide minerals facilitates electron transfer (Senanayake and Muir, 2003). The availability of high Fe^{3+} concentrations drives the oxidation of cuprous to cupric copper.

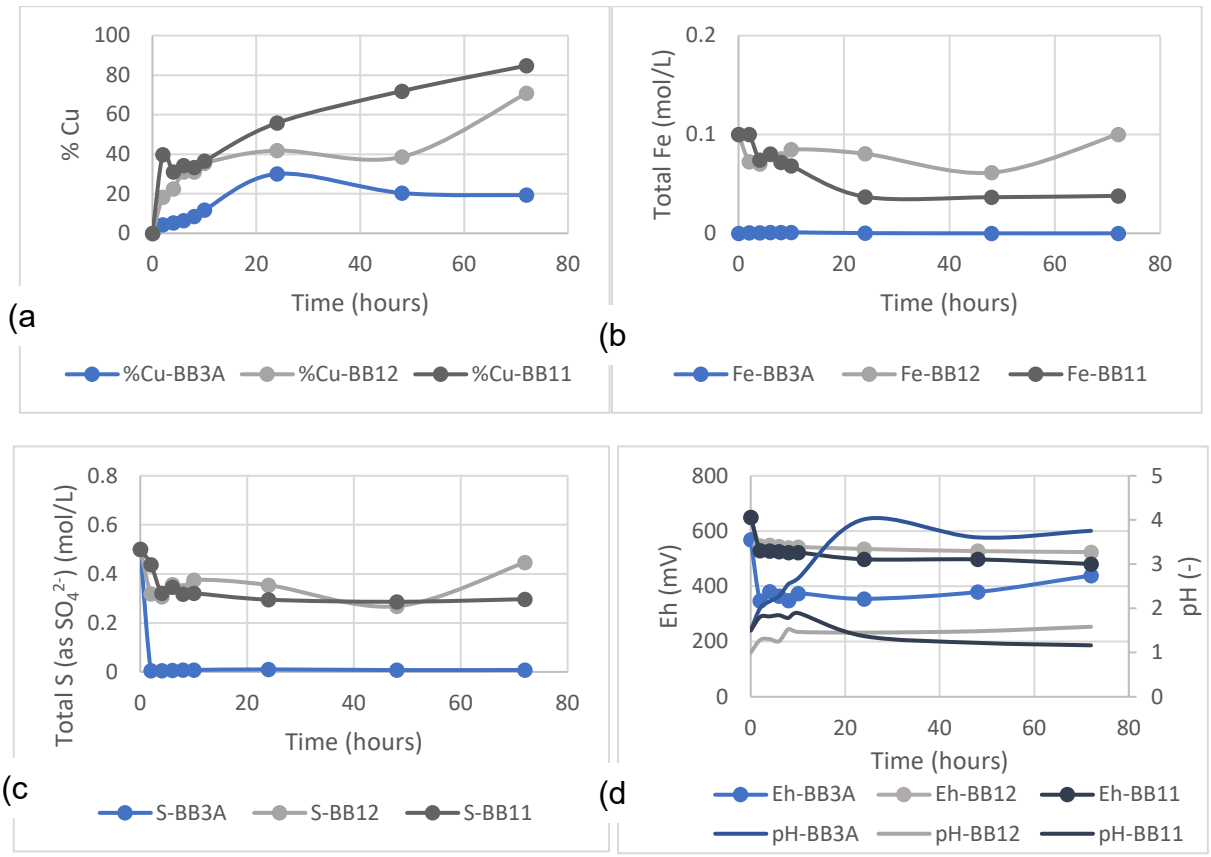

FIG 3 – Leaching in NaCl saturated brine (a) % copper recovery (b) total Fe (mol/L) (c) total S (as SO_4^{2-}) (mol/L) (d) Eh – pH with oxidant (BB12) at 25°C, with oxidant at 45°C (BB11) and without oxidant (BB3A) at 25°C.

Leaching in $AlCl_3$ brine

In this study, we propose the use of $AlCl_3$ in place of NaCl to favour (i) potential mineral replacement reactions where primary copper sulfides (chalcopyrite and bornite) may form easily leachable forms such as chalcocite; (ii) the formation of aluminium sulfates over iron hydroxysulfates (eg jarosite) to increase the availability of Fe^{3+} and a high Eh for enhanced copper recovery; (iii) the presence of $AlCl_3$ as a Lewis acid results in extremely low pH and (iv) a coagulation ability of the Al-rich precipitate to form hydration bonds and adhere to the mineral surface thereby limiting solution, fine particle, and ion transport. As found for the other brine media (NaCl and $CaCl_2$), the absence of ferric (Fe^{3+}) leads to the lowest copper recovery (20 per cent) (Figure 4). The highest copper recovery is reported for the case with the highest temperature and the presence of ferric iron. At 45°C, 35°C and 25°C, the Cu recovery was 90 per cent, 70 per cent and 60 per cent, respectively. At ambient temperature, an increase in copper recovery is maintained for a consistently high sulfate concentration. Similarly, despite the initial sharp decrease at 45°C, high copper recovery was found for consistently high total iron concentration. The sharp decrease and recovery in Fe concentration indicate a rapid reaction with regeneration that will require an oxidant, most likely oxygen. Clearly, in all experiments involving $AlCl_3$ and Fe^{3+} (added as $FeCl_3$ and from the ferrous ion generated which is re-oxidised to generate the ferric ion oxidant), there is a continuously high availability of ferric iron required for chalcopyrite dissolution as indicated by a high Eh of approximately 580 mV (Figure 4d). Also, there is iron sulfate precipitation, which may lead to surface passivation of chalcopyrite. There may also be some form of aluminium sulfates or aluminium hydroxysulfate phases, however, these phases are hydrous and less stable (Bigham and Nordstrom, 2000) as compared to iron hydroxysulfate formed in NaCl brine. The pH for the case without Fe^{3+} rises to almost pH 2.5, whereas the case with Fe^{3+} maintains a lower pH <1.3 (Figure 4d).

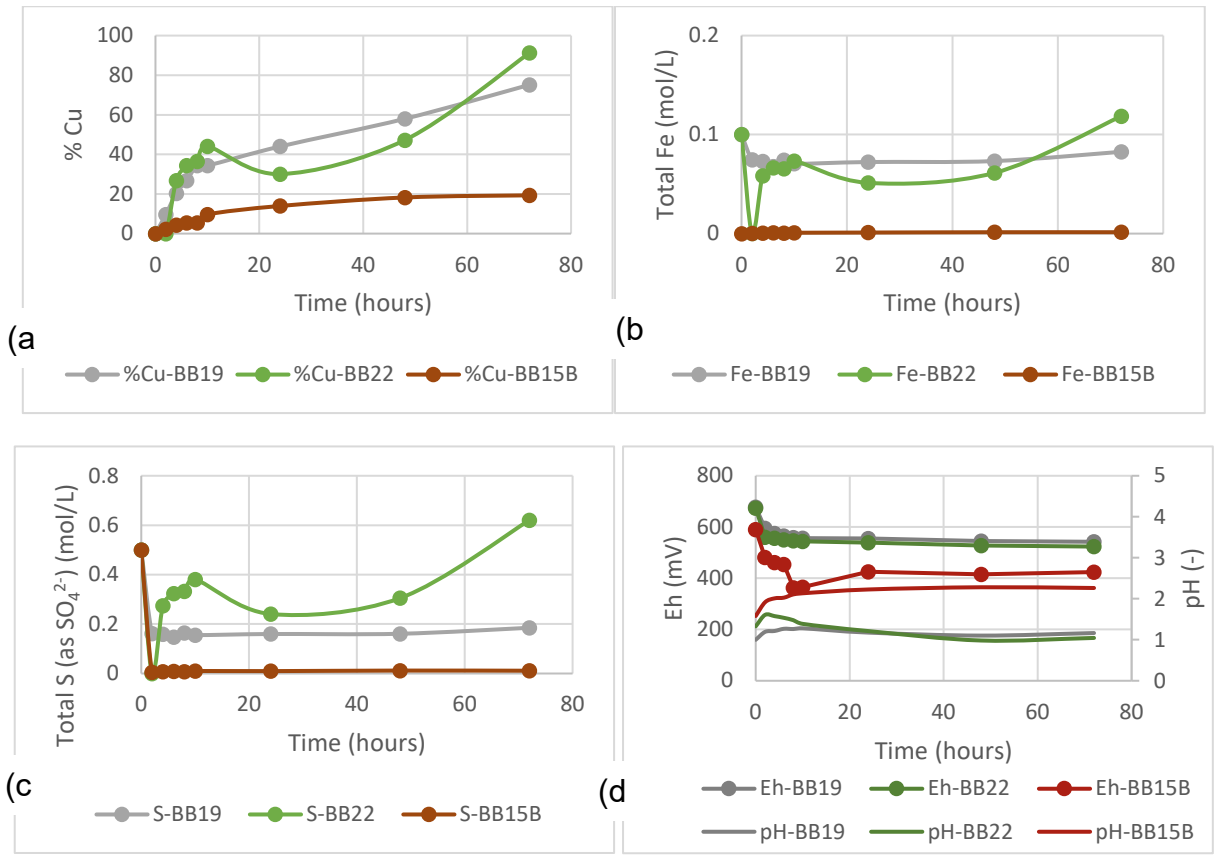

FIG 4 – Leaching in $AlCl_3$ saturated brine (a) % copper recovery (b) total Fe (mol/L) (c) total S (as SO_4^{2-}) (mol/L) (d) Eh – pH with oxidant (BB19) at 25°C, with oxidant at 45°C (BB22), and without oxidant (BB15B) at 25°C.

Discussion

Why $AlCl_3$ for low-grade porphyry copper sulfide leaching?

Almost all copper recovery experiments show that leaching in $AlCl_3$-dominated brine with an initial ferric ion concentration of 0.1 mol/L is the most effective (Figures 3 and 4). Aluminium leads to a higher Eh (above 530 mV) due to an increase in the availability of Fe^{3+} with little or no jarosite formation. At a relatively high pH of 1.5, there is 56 per cent copper recovery for NaCl, while a maximum Cu recovery of 50.5 per cent was observed for the $AlCl_3$-dominated brine. As the pH decreases to pH 1.0, the recovery of copper increases to 75 per cent for $AlCl_3$-dominated as compared to 70 per cent for NaCl-dominated brine.

Mineralogically, it can be suggested that in the absence of Al^{3+}, there is the formation of forms of iron sulfate, sodium sulfate, hydronium sulfate, and jarosite which decrease the available Fe^{3+} for chalcopyrite dissolution (Figure 5a). In contrast, the introduction of Al^{3+} leads to the formation of $AlSO_4^+$ species, thus lowering sulfate activity and the tendency for K-jarosite formation. As a result of this, the K-jarosite region of stability shrinks in the presence of Al^{3+} (Figure 5b). More research is being conducted to evaluate the mineralogical changes occurring during experiments to test some of these observations in changing thermodynamic stability. Bigham and Nordstrom (2000) noted that Al remains predominately dissolved at pH<4.5, that is, pH values below the first hydrolysis constant for Al (pK = 5.0).

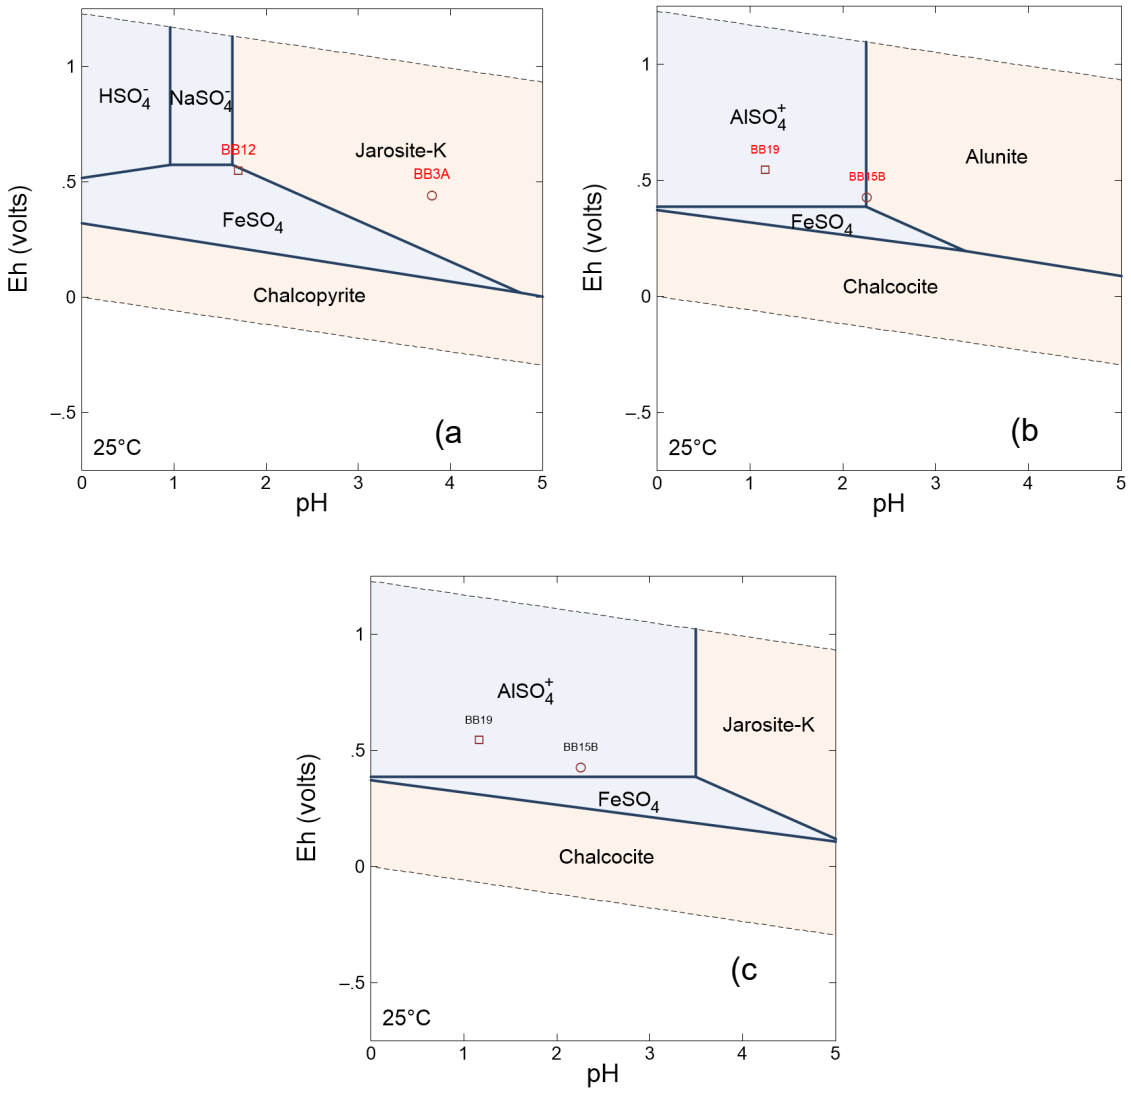

FIG 5 – These plots utilised the final effluent ionic composition, Eh, and pH from the indicated tests (BB12, BB3A, BB19, and BB15B). (a) SO_4^{2-} stability diagram for NaCl brine leaching system, T = 25°C, P = 1.013 bars, a[Fe^{3+}] = $10^{-4.47}$, a[H2O] = 1, a[Cu^{2+}] = $10^{-3.06}$, a[K^+] = $10^{-0.57}$, a[Na^+] = $10^{0.34}$, a[Cl] = $10^{0.38}$, a[SO_4^{2-}] = $10^{-1.33}$. (b) SO_4^{2-} stability diagram for $AlCl_3$ brine leaching system, T = 25°C, P = 1.013 bars, a[Fe^{3+}] = $10^{-4.29}$, a[H2O] = 1, a[Cu^{2+}] = $10^{-3.05}$, a[K^+] = $10^{-0.63}$, a[Na^+] = $10^{0.33}$, a[SO_4^{2-}] = $10^{-2.64}$, a[Cl] = $10^{0.39}$, a[Al^{3+}] = $10^{-0.89}$. (c) Same as Figure 5b with Alunite suppressed.

CONCLUSIONS

This study investigates the performance of different industrial brine types for Cu recovery from a low-grade copper sulfide ore. The study is motivated by an increase in the global demand for copper. The main findings are:

1. In our experiments, industrial brines lead to a Cu recovery of 56–91 per cent, as opposed to a Cu recovery of 35 per cent in freshwater.
2. Ferric iron (at a concentration of 0.1 mol/L) serves as a strong oxidant and leads to higher copper recovery. Dissolved chloride and a low pH alone cannot dissolve copper sulfide mineral fully even in the presence of oxygen.
3. According to thermodynamic predictions, the introduction of Al^{3+} may lead to the formation of $AlSO_4^+$ species, thus lowering sulfate activity and the tendency for K-jarosite formation. Therefore, phase replacement concepts such as $AlSO_{4+}$ and alunite formation to replace iron hydroxysulfates (such as jarosite) can be applied to increase copper recovery.
4. The presence of Al^{3+} suppresses the formation of stable iron hydroxysulfate and jarosite and thus ensures the continuous availability of Fe^{3+} for chalcopyrite dissolution as Eh and pH vary.

ACKNOWLEDGEMENTS

The Melbourne Research and George Lansell Memorial Scholarships provided funding for this study. The analytical instrumentation used in this study was provided by the University of Melbourne's Trace Analysis for Chemical, Earth, and Environmental Sciences (TrACEES) Platform. Much appreciation to Dr. Kodjo Afewu and the anonymous IMPC reviewer for their discussions and comments on this paper.

ABSTRACT

Understanding the mineralogy and liberation of gold particles in an ore is key to the development and optimisation of gold processing operations, being cyanidation or gravity separation. This can be achieved through basic historic geological information, gold deportment studies, chemical speciation and metallurgical test works. The present study assessed the nature of the occurrence of gold particles (mineralogical composition, liberation, associations and surface chemistry) and its effect on the process route (cyanidation and gravity separation) of a typical paleo placer gold ore deposit within the Tarkwaian Rock system. The investigative approach used involved chemical assay, quantitative X-ray diffraction (QXRD) and quantitative evaluation of minerals using scanning electron microscopy (QEMSCAN). The ore samples (A, B, C, D, E, F) used were obtained from six active pits of a gold mine working on this orebody. The results of the mineralogical analysis revealed that the ore is highly oxidised and comprised quartz (>80 per cent) and Muscovite mica (>6 per cent) as the major mineral phases in all the samples. Trace amounts of hematite, kaolinite and todorokite were also identified in all the samples. The chemical analysis showed presence of gold (Au) in all the samples with samples B (3.62 g/t) and C (3.96 g/t) containing the highest concentrations. Trace amounts of copper (Cu), iron (Fe), sulfur (S), aluminium (Al), arsenic (As) were also detected in all the ores. The QEMSCAN mineralogical liberation and gold association results revealed that the gold grains were relatively coarser in all samples (P_{80} > 80 µm Au in size) except F (P_{80} < 32 µm Au in size). Gold grains were highly liberated especially in sample B with the majority of the locked gold grains forming complex associations. All the samples responded well to cyanidation and gravity separation except samples C and F, respectively.

INTRODUCTION

Historically, gold production in Ghana is believed to date back over 2500 years, with Ghana, formerly called the Gold coast (Pigois *et al,* 2003; Fisher, Dagdelen and Turner, 2005). Primarily, the gold has been mined from two sources:

1. Hematite-and-magnetite-bearing, modified paleo placer deposits in Tarkwaian quartz-pebble conglomerates (Sestini, 1973; Strogen, 1988; Hirdes and Nunoo, 1994; Hirdes, Senger and Adjei, 1994; Fisher, Dagdelen and Turner, 2005).
2. Structurally controlled, epigenetic lode, or orogenic gold deposits hosted in rocks of the Birimian Supergroup (Milési *et al,* 1992; Appiah, 1991; Mumin, Fleet and Chryssoulis, 1994; Blenkinsop *et al,* 1994; Groves *et al,* 1998, 2000; Allibone *et al,* 2002a, 2002b; Pigois *et al,* 2003).

Until recently, there was considerable debate over whether the paleo placer deposits in the Banket Series of the Tarkwaian System were derived from the lode deposits hosted in Birimian rocks or whether they predated the deformation events in which the Birimian-hosted gold lodes formed (Kesse, 1985; Hirdes, Davis and Eisenlohr, 1992; Milési *et al,* 1991, 1992; Pigois *et al,* 2003). Whilst much attention has been given to the assessment of the regional geological structures and origin of the gold, especially in paleo placer deposit, little is known about their chemistry, mineralogy and metallurgical characteristics that are necessary for designing processing route and/or optimising gold processing operations.

Designing, developing and optimising gold processing operations depend on comprehensive gold (Au) deportment studies such as physical, chemical, mineralogical and metallurgical assessments. This is done to obtain a full understanding of the nature and variability of gold in the ore and its respond to metallurgical extraction.

The most efficient gold extraction processing route is directly related to the inherent mineralogical features of the gold ore being processed (Zhou and Cabri, 2004; Chryssoulis and Cabri, 1990; Marsden and House, 2006; Chryssoulis and McMullen, 2005; Agorhom, Skinner, and Zanin, 2012, 2013; Agorhom *et al,* 2012). It is therefore necessary to accurately characterise the mineralogical nature of the ore to be processed, thus, characterisation of the gold metal phases, grain size, speciation, liberation, association and the associated gangue minerals. This information can be obtained using automated mineralogical analytical techniques such as quantitative evaluation of minerals by scanning electron microscopy (QEMSCAN) and mineral liberation analyser (MLA).

Although these techniques are able to provide the necessary information required to optimise gold extraction, the trace occurrence of gold in most ores makes them difficult to analyse. Therefore, the results of Au deportment studies are affected by representivity (representativeness) of the samples being analysed and the variation in gold grade (Coetzee *et al,* 2011).

Studies have shown that information gleaned from the mineralogical and Au deportment analyses provide the grounds for the extractability of gold from the ore to be tested using metallurgical techniques such as direct cyanidation, gravity separation, flotation and diagnostic leaching (Lorenzen and Tumilty, 1992; Lorenzen and Van Deventer, 1993; Lorenzen, 1995; Marsden and House, 1992; Henley, Clarke and Sauter, 2001; Goodall, Scales and Ryan, 2005; Celep *et al,* 2009; Botha *et al,* 2004; Tshiongo, Mbaya and Maweja, 2011; Esmkhani *et al,* 2013; Kasaini *et al,* 2008; Agorhom *et al,* 2012; Agorhom, Skinner and Zanin, 2013). This study makes use of bulk chemical assay, quantitative X-ray diffraction (QXRD) and QEMSCAN for the identification and characterisation of gold-bearing minerals in paleo placer gold ore of the Tarkwaian system of Ghana. The aim of the study was to conduct gold mineralogical, liberation and association to better understand and forecast possible leaching and recovery challenges.

MATERIALS AND METHODS

Materials

The paleo placer gold ore samples were obtained from six active pits at different reefs of a gold mining company operating within the Tarkwaian belt of Ghana. The samples from the six pits were designated as sample A, B, C, D, E and F respectively. Approximately 360 kg of rock samples in total was taken, crushed and milled to 80 per cent passing 106 µm.

The milled ore was blended and split into 3 kg representative subsamples due to the variable nature of gold in the ore (Figure 1). During the blending and splitting process, 200 g subsamples were taken from each pit samples for head grade elemental and QXRD analyses.

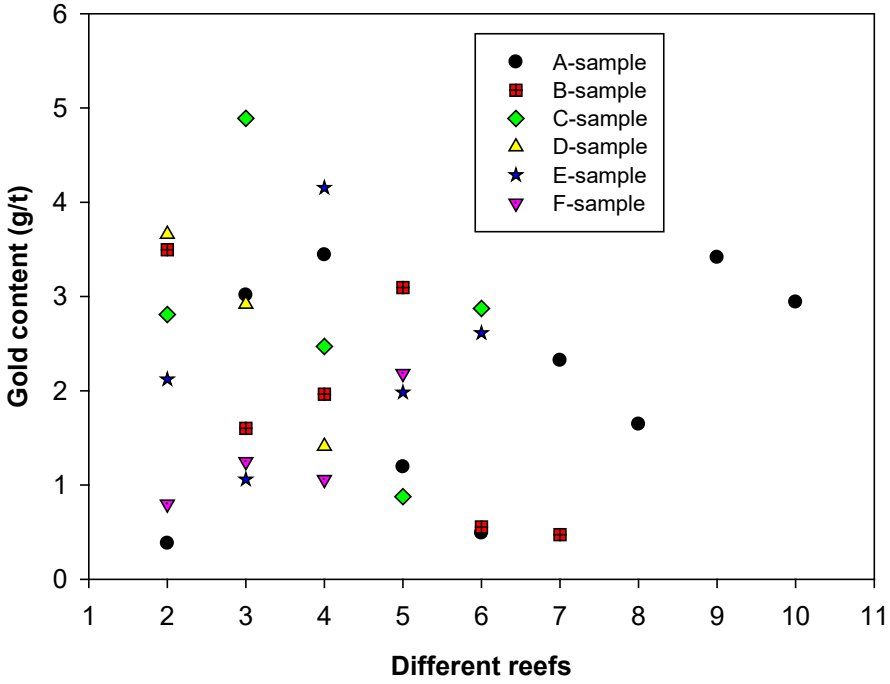

FIG 1 – Gold content (g/t) in the samples at different reefs of the different pits.

Methods

Elemental analysis

The elemental compositions of the ore samples were determined using bulk chemical assay and acid digestion with atomic absorption spectrometry (AAS), Inductively Coupled Plasma (ICP) optical emission spectrometry (OES) (S, Al, Ca, Fe, K, Mg, P, Si) and inductively coupled plasma (ICP) mass spectrometry (Ag, As, Cu, Pb, Sb, Te) finishing.

Quantitative X-ray diffraction analysis (QXRD)

Quantitative XRD identifies all detectable crystalline phases and their abundance is quantified and expressed as a table of normalised mineral abundances. The samples from pits A to F were micro milled for 10 minutes, with ethanol as the grinding liquid. The resultant sample was lightly pressed into a back-packed sample holder. The XRD trace was collected under the following instrument conditions (Table 1):

TABLE 1

X-ray diffraction analysis conditions.

XRD system	PANalytical X'Pert Pro PW3040 diffractometer, 40 kV, 40 mA
Filter	Iron
Radiation	CoKa (I = 1.789 Å)
Angular range	5° to 80° 2θ
Angular speed	0.04426° 2θ/second
Step size	0.0167°
Divergence Slit	¼°
Anti-scatter Slit	½°
Spinning	0.50 second per revolution

Mineral identification was undertaken using the X'Pert High Score Plus search/match software. Rietveld quantitative analysis was performed on the XRD data using the commercial package, SIROQUANT™ V3 from Sietronics Pty Ltd.

Quantitative evaluation of minerals by scanning electron microscopy (QEMSCAN)

QEMSCAN analysis using particle mineral analysis (PMA) and trace mineral search (TMS) mode of analysis was conducted on the panned concentrate as shown in Figure 2. Twenty five (25) kilograms of each sample was subjected to two-stage gravity concentration (Knelson concentration followed by hand panning) to upgrade gold particle for easy identification and statistical analysis using TMS. Eight polished sections were prepared from each panned concentrate (heavy pan fraction).

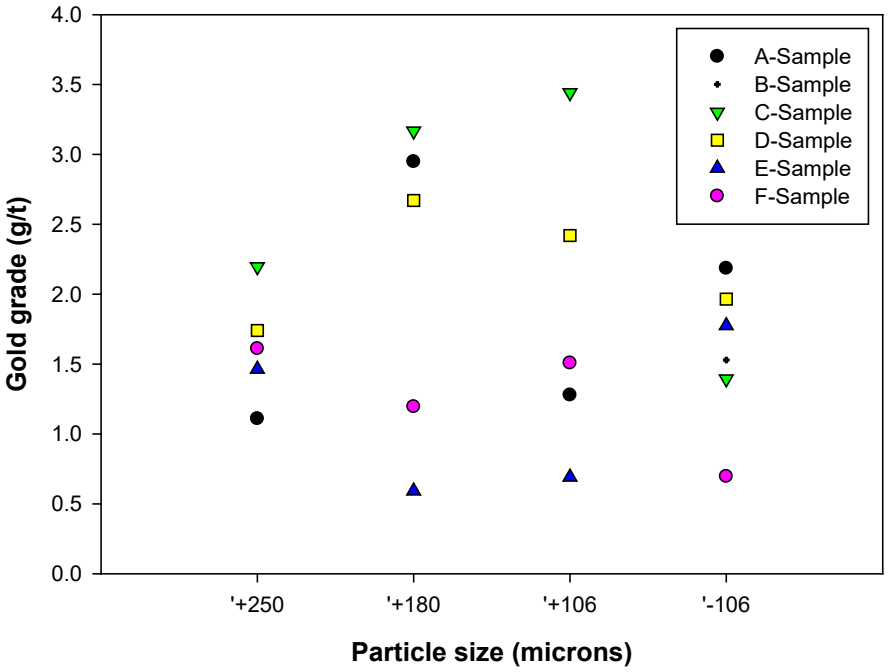

FIG 2 – Variation of gold grades in the ore samples from the different pits (A-F).

The block was ground, polished and coated with carbon prior to QEMSCAN analysis. QEMSCAN PMA and TMS modes were used on the samples and the 'Gen v3' SIP used to classify the data.

Modification were made to the SIP to account for Thorium and metals detected in the samples. The data was processed using iDiscover v.5.3 'Field stitching', 'Particulator', Area>1 filter, 'touching particles' and 'Boundary phase' processors were applied.

QEMSCAN data was used to display the grain size distribution curve of a mineral (eg Au) or group of minerals (eg Au/Ag mineral). A particle comprises of mineral grains. QEMSCAN average particle and grain size is an estimate of the diameter of the particle in a population. PMA was used for particle size estimation while TMS was used for estimating the grain size of the trace minerals or elements, gold and silver or Au/Ag minerals.

Laboratory Cyanidation test

A laboratory cyanidation test program was conducted to investigate the impact of the different gold mineralogy on Au leaching and recovery as well as the process route for the different ore samples. 1 kg each of the composite samples and the Knelson gravity tails for the different pits at approximately 80 per cent passing 106 µm were leached. Each sample was put into a 5 L leach bottle and Tarkwa tap water was added to prepare a pulp of 54 wt. per cent solids. The pulp power of hydrogen (pH) was adjusted to 10.5 with lime and initial free cyanide (CN) strength set to 250 ppm. Leaching was conducted for 24 h with the bottle rolling to agitate and aerate the pulp. No further reagents (lime and CN) were added during the leaching period. At completion, the sample was filtered and pregnant solution sampled and assayed for Au. Residue solids were washed and assayed for Au as well.

RESULTS AND DISCUSSION

Elemental composition

Gold (Au), which is the metal of interest, occurs in all the ores with concentrations within the ranges of 0.88–3.96 g/t. Whilst samples from pits B and C recorded the highest concentrations of 3.62 g/t and 3.96 g/t, respectively, the ore from pit F contained the lowest gold concentration, 0.88 g/t. Gangue elements/metals such as copper (Cu), sulfur (S), aluminium (Al), iron (Fe), arsenic (As) are also present in trace amount whilst silicon (representing silicate minerals) element occurs in high concentration in the ores from all the pits.

The high amount of silicon is linked to the high amount of quartz often reported in the Tarkwaian ore zone (Pigois *et al*, 2003; Fisher, Dagdelen and Turner, 2005). Studies have shown that the presence of these gangue elements, especially, Cu, S and Fe, significantly affect gold cyanidation process by increasing the consumption of cyanide and oxygen (Habashi, 1967; Dai and Jeffrey, 2006).

These base metals were consistently low in all the samples suggesting that cyanide consumption due to the speciation of these metals would be low under standard leaching conditions.

Size-by-size Au Analysis

The results for the size-by-size Au analysis for the all the samples obtained from the six active pits indicate that Au occurs in all size fractions, particularly in the -106 µm for all the samples, on the average of 70 per cent. A plot of Au grade and the particle size (Figure 2) indicates that Au grade varies across all size ranges regardless of the sample type.

It can be clearly seen that there does not exist a strong correlation between gold content and the particle size for the different samples. For example, sample B contains high Au grades in all size fractions except in the -106 µm where sample A had the highest grade. The variations of Au grades in all the samples indicate that proper blending procedure is required if a consistent feed grade is to be ensured in plant feed material. Otherwise, a gravity separation may be required to provide a consistent feed grade to the carbon-in-leach (CIL) circuit.

Mineralogical characterisation

Quantitative mineralogy of the ore samples (QXRD analysis)

The XRD was used to determine and quantify the general mineralogical composition of the ore samples from all the six active pits.

The XRD analysis was conducted on the composite head samples from the different reefs within each pit and the results are presented in Table 2. The results show that all the samples predominantly consist of quartz, varying between 83 and 90 wt. per cent.

TABLE 2

Quantitative modal mineralogy of the samples using QXRD.

Mineral (wt.%)	Composition	A	B	C	D	E	F
Quartz	SiO_2	88	90	90	90	83	89
Hematite	Fe_2O_3	2	2	3	3	2	2
Mica	$K(Fe^{2+},Mg)_3Al(Si_3Al)O_{10}(OH)_2$	8	8	7	6	12	9
Kaolinite	$Al_2Si_2O_5(OH)_4$	2	0	<1	1	3	<1
Todorokite	$(Na,Ca,K)Mn_6O_{12}$ 3-4.5H_2O	0	0	1	1	0	<1
Total		100	100	100	100	100	100

Muscovite mica is the most dominant phyllosilicate gangue mineral constituting between 6 and 12 wt. per cent. Kaolinite also varied between 1–3 wt. per cent and its presence is an indication of

the degree of superficial weathering of the orebody. This is particularly significant for the ore sample from pit E. The higher amounts of muscovite mica and kaolinite in sample E may pose rheological problems during processing. Fe-oxides, predominantly hematite is the most common non-silicate gangue mineral identified in all the ore samples, varying between 2 and 3 wt. per cent. Trace amount of todorokite was detected in all the samples (maximum 1 wt. per cent). The gangue mineralogy of the samples from the various pits is consistent and shows a true reflection of Tarkwaian sediment composition (Pigois *et al*, 2003; Fisher, Dagdelen and Turner, 2005).

Gold mineralogy, liberation and associations (QEMSCAN analysis)

The grades of Au in all the samples were quite low and highly variable, varying between 0.88 g/t (sample F) and 3.96 g/t (sample D) (Figure 2).

Au deportment and statistical identification analysis for low-grade Au ores are often problematic due to the difficulty in identifying statistical significant number of Au grains (Goodall, Scales and Ryan, 2005; Agorhom, Skinner, and Zanin, 2012). Moreover, presence of high amount of coarse Au grains also makes it difficult and this was the case in this study. Therefore, for easy identification of Au particles/grains, all the samples were upgraded through two-stage gravity concentration before subjecting the samples to QEMSCAN analysis.

Particle and grain size distribution

The particle sizes of the identified minerals were all below 200 µm in all the samples. Eighty per cent (80 per cent) of the identified minerals varied between 166 and 197 µm with sample B showing the smallest mineral particle size (ie P_{80} = 166 µm).

Gold grain size analysis performed using TMS showed that the 80 per cent of all the Au grains varied between 32 and 109 µm. For samples A to E, majority (>55 per cent) of the gold grains were higher than 40 µm. Gold grains higher than 40 µm are 69 per cent, 58 per cent, 55 per cent, 75 per cent and 0 per cent for samples A, B, C, D, E, and F, respectively. Fine Au grains were found in the pit F ore sample (<40 µm). This shows that gravity circuit may be required to enhance gold recovery by providing consistent gold grade, stable reagent consumption and management, and minimise high gold in process and hence faster leaching kinetics at the CIL circuit (Henley, 1975).

Au/Ag mineral liberation and locking studies

The liberation results showed that 67 per cent of the identified Au grains was completely (over 100 per cent) liberated in ore sample B (Table 3). However, in all the samples, the liberation of the gold grains varied between 44 and 94 per cent. Highest liberation was achieved in ore sample B while ore sample F showed the lowest Au grains liberation. The level of Au grains liberation increased at the targeted grind size (P_{80} = 106 µm) in the order of:

Sample F < Sample A < Sample C < Sample D < Sample E < Sample B.

The locking/mineral association analysis is shown in Table 4. The locking or association of the Au/Ag minerals showed that Au grains in pit A and F samples show a bimodal distribution. That is, between 58 and 44 per cent of the Au grains were fully liberated whereas 41 and 51 per cent formed complex aggregates with other mineral phases. This shows that finer grind may be required to increase liberation of gold from the association minerals in these ore samples for enhanced direct cyanidation. About 1 to 5 per cent of the identified Au grains were either associated or locked in Fe-Ox/OH or titano Fe-Ox/OH mineral phases (Table 4).

Gold surface chemistry

The surface chemistry speciation of the gold grain identified in the various samples was also examined using SEM/EDX. Generally, about 8 to 11 gold grains were scanned for the surface chemistry analyses as shown in Figure 3. The speciation of gold particles in the ore is simple as majority of the identified Au particles were relatively pure Au-alloy chemistry (above 90 per cent) (Figure 3).

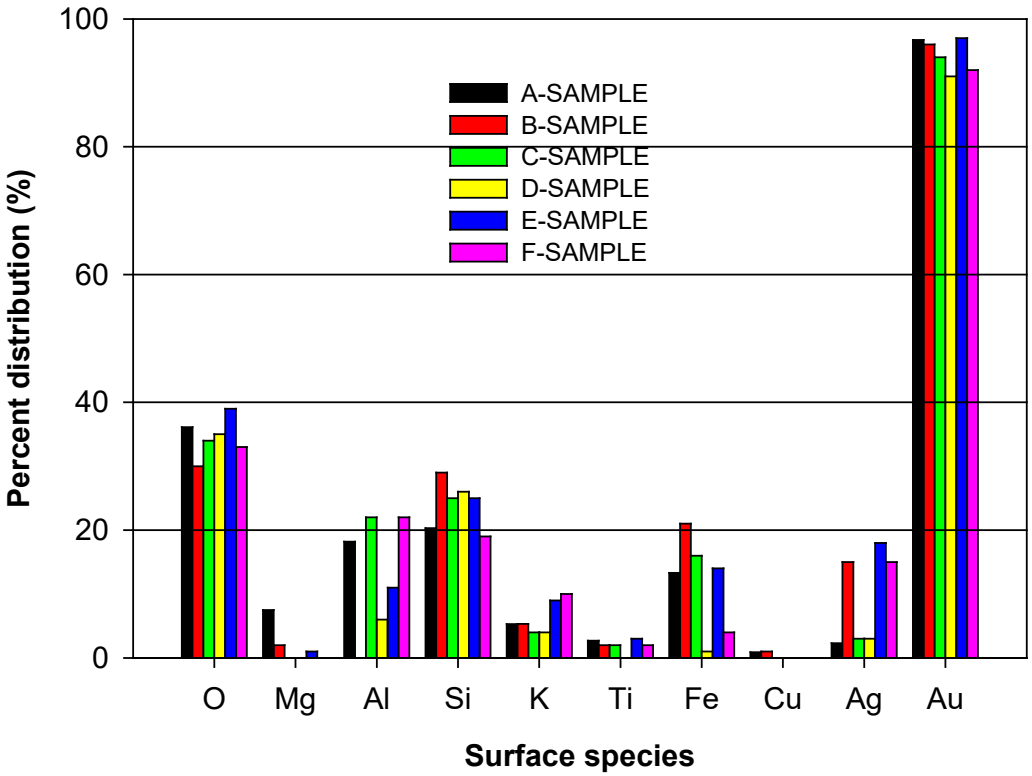

FIG 3 – Surface chemistry speciation of the identified gold grains in the ore as identified by SEM/QEMSCAN.

The relatively coarse gold particles exhibit pure Au-alloy while the fine particles exhibit variable Au-chemistry comprising O, Mg, Si, Al, K, Ti, Fe, Cu and Ag. This is because most of the relatively fine gold particles occur as fine inclusions within complex aggregates of Fe Ox/OH, Ti-Fe Ox/OH and silicates.

In terms of sample-by-sample analysis, the Au particles found in the ore sample from pit F were highly contaminated compared to the other samples. Some amounts of Ag, alumina-silicates and iron oxide/hydroxides were identified as the main Au surface contaminants, especially for the fine gold particles. The nature of the gold particles in the F ore sample as fine, low liberation and highly variable surface chemistry indicate that Au cyanidation will be difficult for this ore (Venter, Chryssoulis and Mulpeter, 2004). It is therefore recommended that the proportion of this ore in the leach feed should always be low compared to the others.

Gold leaching and recovery

Based on the mineralogical and liberation results obtained, gold extraction and leaching behaviour was studied for all the samples using gravity separation and cyanidation. Table 5 highlights the results for both gravity concentration and cyanidation test works.

TABLE 5

Gold recovery data for both the gravity separation and cyanidation using 250 ppm CN for 24 h.

Sample ID	Gravity concentration (1)		Gravity tails CN (2)		(1) + (2) = (3)	4
	Au Rec (%)	Con Au (g/t)	Au Rec (%)	Tails Au (g/t)	Overall, Au Rec (%)	Direct CN Au Rec (%)
A	55.0	65.05	90.4	0.04	95.7	91.4
B	49.0	46.99	90.8	0.05	95.3	91.9
C	33.4	39.29	89.8	0.09	93.2	96.9
D	43.2	52.42	88.0	0.12	93.2	94.9
E	51.1	74.24	89.4	0.06	94.8	94.0
F	51.2	24.94	88.5	0.06	94.4	86.8

CN – cyanidation.

The results show that the gravity concentration achieved between 33.4 per cent and 55.0 per cent of gold recovery for all the samples at the grind size of 106 µm. Notably, Sample A produced the highest gold recovery of 55 per cent almost the same as the amount of gold liberated (Table 5) whilst sample E yielded the highest gold concentrate grade of 74.24 g/t. Additionally, the cyanide leaching of the gravity tails also produced a very good recovery for all the samples studied (88–90 per cent).

For the direct cyanidation, it was found that Au recovery in all the samples varied between 88.6 per cent and 96.9 per cent (Table 5). The Au leaching in all the samples gave recovery efficiency in the order of C (96.9 per cent) > D (94.9 per cent) > E (94.0 per cent) > B (91.9 per cent) > A (91.4 per cent) > F (86.9 per cent) which is consistent with the nature of Au liberation and association in the samples. For example, the low Au recovery exhibited by sample F can be attributed to the low liberation and high locking of the Au particles (Table 5) coupled with varied surface chemistry of the identified gold particles in the sample. Overall, direct cyanidation of the ore from the pits A, B and F achieved lower recoveries compared to the two-stage extraction route (ie gravity concentration of the samples followed by cyanide leaching of the gravity tails). However, for pits C, D and E there was no appreciable change in gold recovery under the tested conditions.

CONCLUSIONS

Paleo placer Au ore process mineralogy through basic elemental analysis and quantitative mineralogy complimented with gravity concentration and direct Au cyanidation has been conducted. The grades of gold in all the samples were erratic, hence blending is required to maintain consistent plant feed grade. Over 88 per cent of the ore samples composed of quartz as the major gangue minerals with muscovite mica and hematite as the minor gangue minerals. Trace amounts of kaolinite and todorokite were also detected. Although sulfide minerals were rarely detected in both the head composite and QEMSCAN samples, small amounts of Cu (17–25 ppm) and S (50–150 ppm) were identified in all the ore samples. Majority of the identified Au particles were relatively coarse in all samples except F (particles less than 32 µm). Au particles were highly liberated (66–94 per cent) in the ore from pits B, C, D and E samples than the A and F samples.

The remaining gold grains form complex aggregates with silicates and iron oxide minerals. The coarse gold particles were relatively pure (Au > 90 per cent) as compared with the fine gold particles (Au > 32 µm), especially for the pit F sample. Key Au surface contaminants such as silver, copper, alumina-silicates and iron oxides were detected by the SEM/EDX scan. Cyanidation of the composite sample from each of the pits (@ 250 ppm, 24 h) showed recoveries varying between 86.9 and 96.9 per cent, with pit F sample giving the lowest recovery (86.9 per cent). Pit C sample gave the highest recovery of 96.9 per cent. A comprehensive gravity concentration gold leaching kinetics based on blending these pit samples should be considered.

It must however be emphasized that good use of mineralogical characterisation techniques (XRD and PSD), to assist with flow sheet development are not 'new' but, this study provides a good basis for early stage project assessment and would be of benefit at the conceptual/scoping study level and process optimisation.

ABSTRACT

A promising source for the extraction of rare metals and REEs in Russia is the eudialyte ores of the Lovozero deposit, which do not contain active uranium components. The eudialyte ore reserves of the Lovozero Massif are considered virtually unlimited and therefore have the potential to become a primary source of a number of rare and rare earth metals.

The goal of this study was to comprehensively examine the effect of the parameters of high-power nanosecond electromagnetic pulses (HPEMP) and dielectric barrier discharge (DBD) on the leaching performance of eudialyte concentrate and the selective separation of zirconium and REEs from productive solutions.

Using scanning electron microscopy and infrared spectroscopy, the mechanism behind the intensification of acidic dissolution of eudialyte as a result of pretreatment with energy impacts was described. During the HPEMP treatment, weakening and destruction of the eudialyte surface was observed, which at the substructural level is expressed in the deformation and local destruction of $Si_{10}O_{27}$, Si_9MO_{30} resulting in formation of microcracks. During the DBD treatment, the formation of characteristic defects was observed in the form of imprints of dielectric breakdown microchannels and individual mineral fragments.

Pretreatment of eudialyte concentrate using HPEMP made it possible to increase the recovery of zirconium into the pregnant solution of leaching by 3.4–4.3 per cent (from 86.6 per cent to 90.9 per cent) and by 4.1 per cent (from 86.6 per cent to 90.6 per cent) when using DBD. The increase in the total recovery of REEs was 1.2–1.8 per cent (from 87.7 per cent to 89.2 per cent).

The effect of pH values, solution temperature, initial concentrations of valuable components on the successive recovery performance of zirconium and REEs from the pregnant solutions nitric from the acid leaching of eudialyte concentrate by chemical precipitation was examined. The possibility of selective separation of the zirconium product and rare earth elements with a zirconium recovery of 99.95 per cent and a REE recovery of 87.5 per cent was established. REE loss with the zirconium product was 8.0 per cent and 4.5 per cent with the spent pregnant solution.

INTRODUCTION

The eudialyte ores of the Lovozero deposit in Russia's Murmansk Region are a promising mineral resource for the production of zirconium and rare earth metals (REE) (Kryukov *et al*, 2012; Samsonov and Semyagin, 2014). Multiple pyro- and hydrometallurgical processing options for eudialyte concentrates have been proposed in the literature based on multistage decomposition by acids and alkalis (Zakharov *et al*, 2005, 2011a, 2011b; Lebedev, 2003; Lebedev *et al*, 2003; Davris *et al*, 2017). The central challenges involved in the hydrometallurgical processing of eudialyte are associated with the significant (40–60 per cent) share of silicon (Johnsen *et al*, 2003; Bogatyreva *et al*, 2018a, 2018b). During acid leaching, silicon passes into solution in the form of silicic acid, which undergoes a polycondensation process with the formation of polymers of various composition and structure, including stable gels, which reduces the recovery of valuable components, decreases the filtration performance, and complicates the further processing of solutions by extraction and sorption-based methods (Jha *et al*, 2016; Ma *et al*, 2018a, 2018b). Potential solutions to the challenges involved in the hydrometallurgical processing of ores high in silicon include exposing mineral suspensions to energy impacts (ultrasound, high-voltage pulses, plasma and electrochemical treatment etc), which improves the unlocking and breakage performance of fine-grained mineral complexes and the recovery of non-ferrous and precious

metal micro – and nanoparticles in the downstream ore processing circuits (Chanturia *et al*, 2019a, 2019b).

The zirconium and REE grades of the resulting leaching pregnant solutions of eudialyte concentrate do not exceed 1–10 g/L (Vaccarezza and Anderson, 2018; Voßenkaul *et al*, 2016; Johnsen *et al*, 2003), in which connection the study of the method of sequential chemical deposition of zirconium and REEs, characterised by its process simplicity and low operating costs, is highly relevant. This method makes it possible to obtain precipitates of Zr and REEs readily soluble in slightly acidic solutions, suitable for further processing.

The goal of this study was to comprehensively examine the effect of the parameters of high-power nanosecond electromagnetic pulses (HPEMP) and dielectric barrier discharge (DBD) on the structural and chemical properties of the eudialyte surface and the leaching performance of eudialyte concentrate and the selective separation of zirconium and REEs from pregnant solutions.

EXPERIMENTAL

Materials

The studies were carried out on samples collected from an experimental eudialyte concentrate batch from the Lovozero Mine and Concentrator with a particle size of -630+63 μm (97.7 per cent), containing 8.34 per cent of zirconium oxide and 2.5 per cent of REE oxides. The main impurities in the concentrate are individual grains of feldspar, nepheline, loparite, aegirine, and intergrowth thereof (up to 10 per cent). The share of twin loparite crystals, fragments thereof, and golden brown lamprophyllite crystals is substantially lower (~3 per cent). Accessory minerals include secondary zeolites (natrolite, gonnardite) (Chanturia *et al*, 2019a).

Experimental conditions

Eudialyte concentrate was leached in a reactor, which is the key unit of the lab-scale plant designed by IPKON RAS for unlocking concentrates of non-ferrous, rare, and rare-earth metals through the use of thermal, electrochemical, and ultrasonic impacts on the mineral suspension (Chanturia *et al*, 2020). Leaching conditions were as follows: temperature — 80 (40)°C, exposure — 1 hour, S:L ratio — 1:20, agitation intensity — 550 min^{-1}, nitric acids — 450 g/L.

After leaching, the suspension was filtered, the precipitate was washed with distilled water and dried. The composition of the precipitate was analysed using the inductively coupled plasma mass spectroscopy (ICP-MS) (ICPE-9000, Shimadzu) and X-ray fluorescence (XRFA) (ARL ADVANT'X, Thermo Scientific) methods; the solutions were analysed using the inductively coupled plasma atomic emission method (ICP-AES) (Elan-6100, PerkinElmer). Surface micromorphology of the eudialyte was examined by analytical scanning electron microscopy (SEM) (LEO 1420VP, Carl Zeiss). X-ray diffraction analysis (XRD) of the concentrate was carried out using an ADP-2 diffractometer (NPO Burevestnik). To record the IR spectra of eudialyte mineral particles, a Fourier spectrometer (IRS) (IR-Affinity, Shimadzu) and a diffuse reflection add-on unit (DiffuseIR, Pike Technologies) were used. Changes in the elemental composition of the eudialyte surfaces were examined by X-ray photoelectron spectroscopy (XPS) using a Versa Probe II spectrometer (ULVAC-PHI). AFM measurements were made in the air under standard conditions with 256×256 points resolution at Ntegra Prima scanning probe microscope (NT-MDT, Zelenograd). Polished mineral sections of 10×10×4.5 mm were fixed with conducting duplex scotch in order to prevent generation of an uncontrollable static surface charge. In all the measurements it was imperative to scan an initial specimen to detect surface alterations acquired in the course of specimen preparation and to exclude artifacts in data processing.

The recovery (Zr, REEs, and impurities) was calculated by the Equations 1–2.

$$\varepsilon_{i,L} = \frac{C_{i,N} \times V_N + C_{i,W} \times V_W}{C_{i,L} \times V_L} \times 100\% \quad (1)$$

$$\varepsilon_{i,S} = (1 - \frac{C_{i,P} \times m_P}{C_{i,L} \times V_L}) \times 100\% \quad (2)$$

Where $\varepsilon_{i,L}$, $\varepsilon_{i,S}$ is the recovery of the component during precipitation, calculated for the liquid and solid phases, respectively; $C_{i,L}$, $C_{i,N}$, $C_{i,W}$ are the grade of the component in the initial pregnant solution, solution after neutralisation, and wash solution, respectively; V_L, V_N, V_W are the volume of the initial pregnant solution, solution after neutralisation, and wash solution; $C_{i,P}$ is the grade of the neutralisation precipitate; m_P is the mass of the precipitate. All experiments were repeated three times, and the results were averaged with a relative error of ±3 per cent. The calculations were verified by the mass balance of each element in the solid phase and liquid phase with a relative error of ±5 per cent.

The mineral samples were treated with high-power nanosecond electromagnetic pulses (HPEMP) and low-temperature dielectric barrier discharge (DBD) plasma in air under standard conditions using dedicated experimental set-ups (IPKON RAS, NPP FON LLC, Ryazan), consisting of high-voltage pulse generators and electrode systems (discharge cells). In the HPEMP generator, a voltage converter converts 220V AC (50 Hz) to DC to charge the capacitive energy storage device of the nanosecond pulse generator. When treating the samples with HPEMP, the following pulse parameters were set: video impulse type; pulse leading edge duration ~3–8 ns; pulse duration ~30–50 ns; pulse voltage amplitude not less than 70 kV; electric field strength in the interelectrode space not less than 10^7 V/m; distance between electrodes 7 mm; pulse frequency 375 Hz; sample treatment time (t) 30, 60, and 90 s. Before the electromagnetic treatment, the mineral samples were moistened with distilled water at a S:L ratios of 6:1.

Mineral sample treatment by low-temperature pulsed (sub-nanosecond) dielectric barrier discharge plasma in air at atmospheric pressure was carried out under standard conditions for the following parameters using discharge-initiating pulses: pulse leading edge duration 250–300 ns; pulse duration 8 μs; voltage amplitude on the electrodes in the barrier discharge cell 20 kV; pulse frequency 16 kHz; sample treatment time (t) 10–90 s, eudialyte concentrate sample treatment time 30 s. The dimensions the DBD discharge cell significantly exceeded the length of the interelectrode gap, which was ~5 mm. The gas temperature in the impact area of the discharge cell did not exceed the temperature of the dielectric barrier and remained of the order of room temperature during the treatment.

RESULTS AND DISCUSSION

The effect of energy impacts

Based on the SEM data, the original eudialyte grains have a conchoidal fracture characteristic of this mineral, forming a concave profile of smooth surface areas separated by sharp uneven edges (Figure 1a). The non-thermal action of HPEMP caused damage to the surface of a significant share of the mineral grains with the formation of new relief forms: depending on the treatment time (t), from parallel-fractured at t = 30 s (Figure 1b) to polygonal-fractured at t = 60 s and 90 s (Figure 1c and 1d).

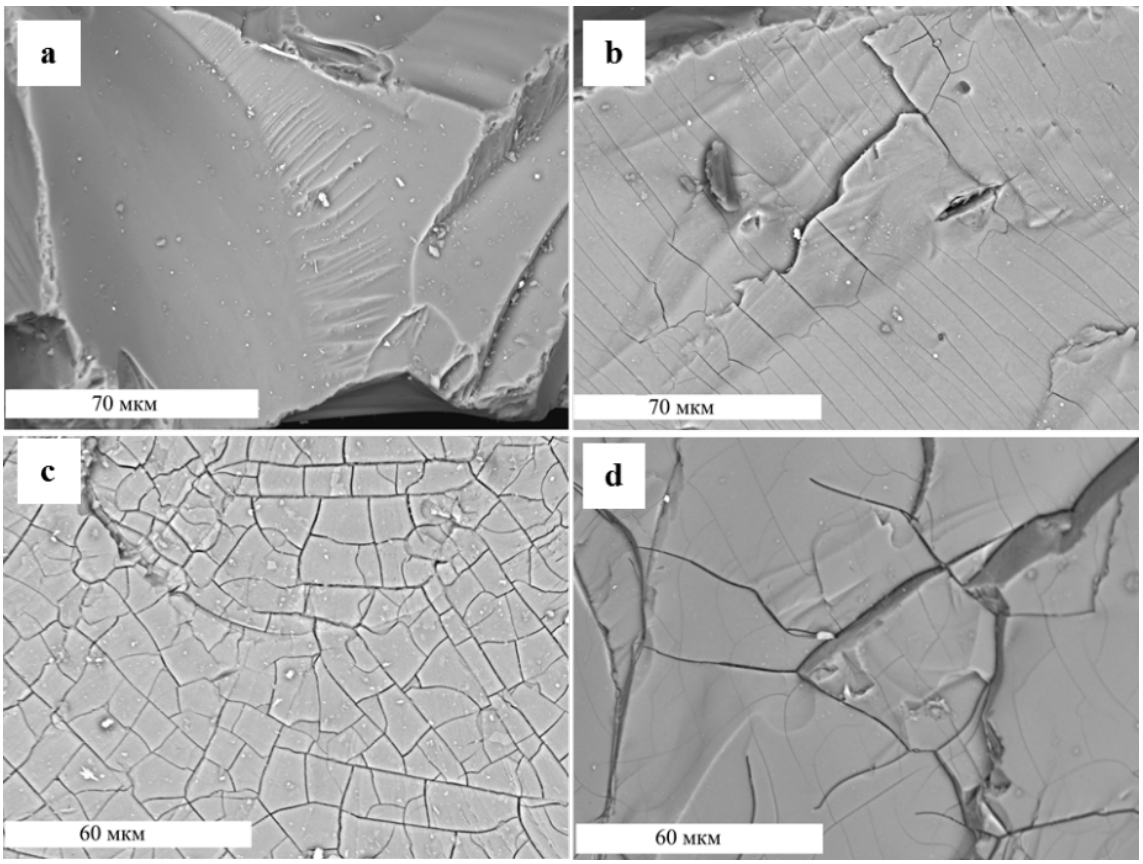

FIG 1 – SEM images of the eudialyte original grain (a) and the mineral surface after HPEMP treatment for t = 30 s (b), 60 s (c) and 90 s (d).

A distinctive feature of the micromorphology of eudialyte grains after treatment under DBD conditions under all conditions applied is the formation of a different number of imprints from electrical breakdown microchannels no larger than 3–4 μm (Figure 2). Despite the fact that, in most of the grains, there are only single manifestations thereof, among the studied samples, individual particles containing a significant number of such defects were found (Figure 2a). Surface microfracturing, typical of samples after exposure to HPEMP, is less developed or practically absent when exposed to a barrier discharge.

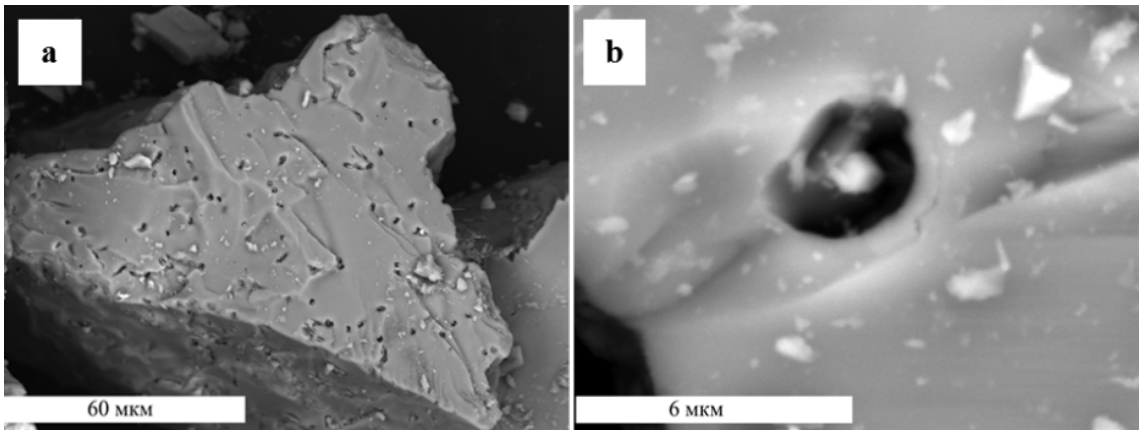

FIG 2 – Electrical breakdown microchannel imprints on the eudialyte surface after DBD treatment.

A detailed study of the areas between the microchannel imprints made it possible to reveal a modified, compared to the original (Figure 3), mineral surface, composed of closely adjacent new formations sized 400 nm or less.

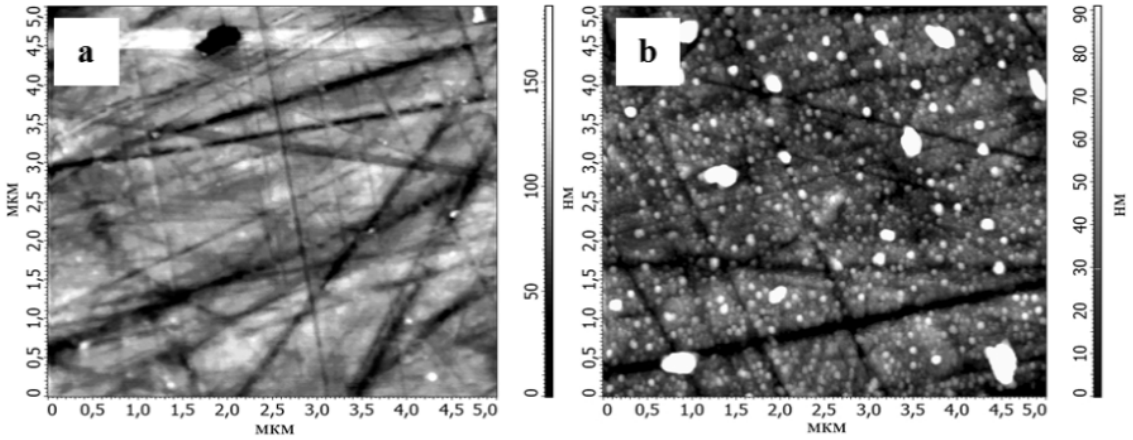

FIG 3 – AFM images of the original eudialyte surface (a); and that after a DBD treatment (t = 60 s) (b).

The interaction of eudialyte grains with a nitric acid solution after preliminary exposure to HPEMP leads to a smoothing of the surface upon dissolution, initially, of the surface cracked layer. As a result, the appearance of the particles becomes close to the original.

Our observations are in good agreement with those described in Chanturia *et al* (2019a) in terms of the predominantly tangential (layered) mineral dissolution mechanism in a HNO_3 solution. The findings of our morphological study of the grains after exposure to DBD and interaction with a HNO_3 solution are, in general, similar to those under exposure to HPEMP. Nevertheless, an insignificant number of eudialyte grains with deep cracks was observed, including separation of entire mineral fragments.

The IR spectral signatures of the original and electromagnetic pulse treated (HPEMP and DBD) eudialyte are presented in Figure 4. Our examination of the obtained spectral signatures showed that in the region of stretching vibrations of the Si–O bond of the initial sample, five absorption bands were identified: 940 cm^{-1}, 980 cm^{-1}, 1010 cm^{-1}, 1070 cm^{-1} and 1135 cm^{-1}. In the sample treated with HPEMP for t = 30 s, the 940 cm^{-1} band is smoothed, and at a longer exposure (t = 60, 80–90 s) transforms in a shoulder at about 900 cm^{-1}, and a mild shoulder appears at 1100 cm^{-1}.

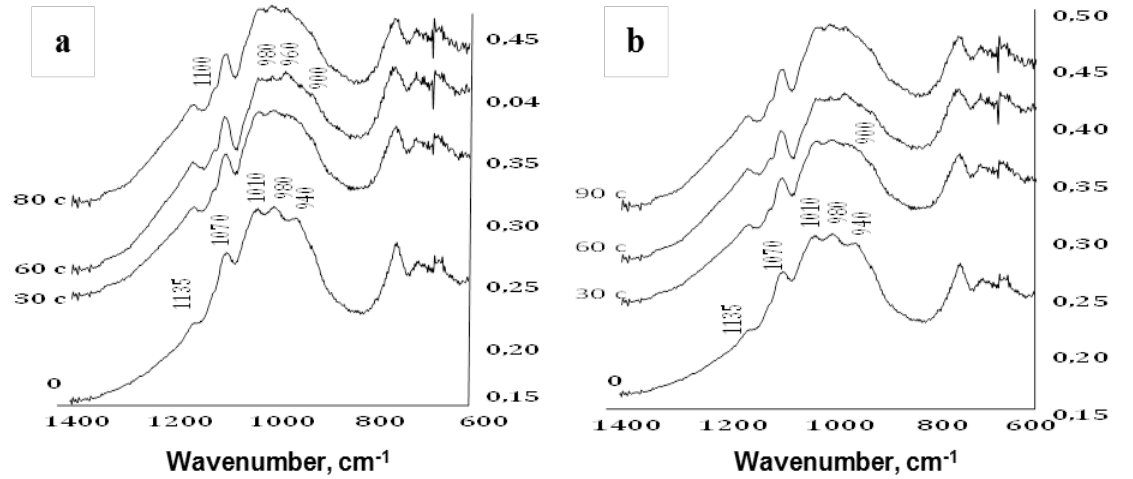

FIG 4 – IR spectra of eudialyte before and after (a) HPEMP and (b) DBD treatments.

As reported in Rastsvetaeva *et al* (2020), the presence of a band at 940 cm^{-1}, indicates a high content of ten-membered $Si_{10}O_{27}$, Si_9MO_{30} clusters in the structure of the mineral. Taking this into account, the observed changes in the spectral signatures can be associated with destruction of the silicon-oxygen bonds.

Thus, it can be assumed that when the surface of mineral particles interacts with high-intensity pulsed electric fields, the surface of eudialyte undergoes structural changes, which are manifested in the IR spectra of the mineral, and are the result of deformation and/or local destruction of eudialyte's silica-oxygen lattice.

High-power electromagnetic pulses have a significant destructive effect on the structural state of the eudialyte surface, which causes the activation of the process of dissolution of mineral particles in nitric acid and improves the performance of acid leaching of eudialyte concentrate, based on a chemical analysis of cakes and calculation of leaching indicators taking into account the material balance (Table 1).

TABLE 1

Effect of the high-power electromagnetic pulse impact parameters on the nitric acid leaching performance of eudialyte concentrate.

Treatment conditions	REE recovery, %						
	Zr	Ce	Hf	La	Nd	Y	∑REE
No treatment	86.6	87.5	84.9	86.2	88.4	89.7	87.7
HPEMP (30 s)	89.9	88.4	89.9	87.2	89.9	92.4	89.5
HPEMP (60 s)	90.9	88.2	90.7	85.7	90.1	92.8	89.4
HPEMP (90 s)	90.2	87.6	89.5	85.8	89.4	92.3	88.9
DBD (30 s)	90.6	87.9	89.4	85.9	89.9	92.8	89.2

In general, pre-treatment with HPEMP made it possible to increase the recovery of zirconium into the pregnant leach solution by 3.4–4.3 per cent, while with the use of DBD, the increase in recovery was 4.0 per cent. The maximum increase in zirconium recovery (4.3 per cent) was achieved as a result of treating the concentrate with HPEMP for t = 60 s, which is comparable to the performance obtained with a short-term (t = 30 s) exposure to a barrier discharge (4.1 per cent). The increase in the total recovery of rare earth elements was 1.2–1.8 per cent.

Selective recovery of zirconium and REE from pregnant solutions

The chemical composition of the resulting pregnant solution is characterised by a zirconium grade of 2.6 g/L and a REE grade of 0.6 g/L, where the dominant REEs are Ce, Y, La, and Nd. Together with valuable components (Zr and REE), Na, Ca, Fe, Al, Mn, Sr, Ti, Mg and K pass into solution when leaching the eudialyte concentrate.

Separation of Zr and REE with neutralisation of the pregnant solutions was carried out in two stages – at the first stage, neutralisation of nitric acid with the recovery of Zr with Al and Fe impurities was achieved by increasing the solution pH from -0.74 to 4.8–5.0 using calcium carbonate. In the second stage, precipitation of the *REE* from the solution was achieved by increasing the pH of the solution to 6.0–6.4 using sodium carbonate.

Figure 5 shows the relationship between the recovery of Zr, Al, Fe into the solid precipitate and the pH of the environment under isothermal conditions (20°C). It can be seen from the presented results that the precipitation performance increases with increasing pH, and at a pH of 4.0, 99.9 per cent of zirconium, 100 per cent of aluminium, and 43.8 per cent of iron is precipitated. It was found that the recovery of other impurities (Na, Mn, Sr, Ti, Mg and K) did not exceed 15–35 per cent, and the total loss of rare earth elements to the precipitate was approximately 8 per cent.

A further increase in pH to 4.8–5.0 leads to a sharp increase in REE loss to 40.0 per cent due to co-precipitation with Zr, which is probably associated with the onset of precipitation in the form of carbonates. At the same time, due to a decrease in the solubility of $CaCO_3$, its specific consumption increased by a factor of 1.6 from 375 to 600 g/L.

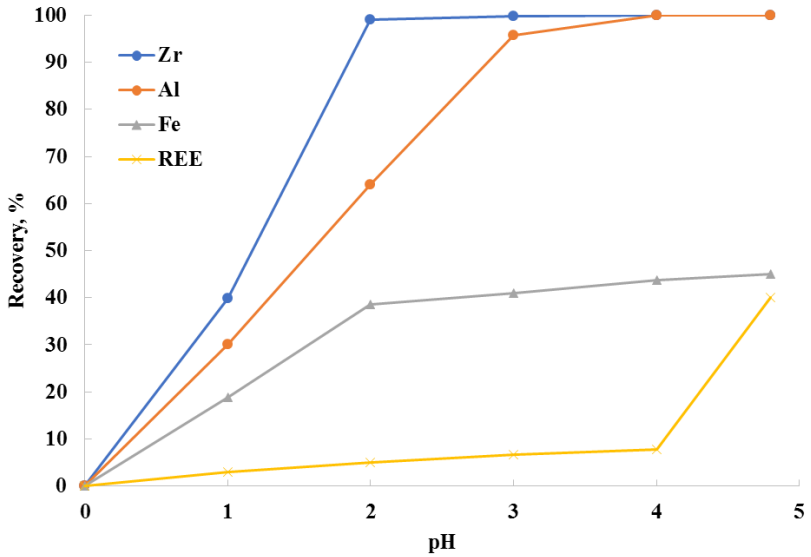

FIG 5 – Effect of (a) the solution pH on element recovery to residue and (b) specific consumption of calcium carbonate on the solution pH. Solution temperature was 20°C.

Thus, the separation of zirconium from REE occurred at pH 4.0. Further chemical precipitation of REE compounds should be carried out using more soluble compounds, such as sodium carbonate and sodium hydroxide.

The results of the second stage of the experiment showed that at a specific consumption of sodium carbonate of 6 g/L (pH 6.1), the highest REE recovery of 95.5 per cent into the solid phase was achieved. When the pH of the pregnant solution is increased to 6.0 using sodium hydroxide, the highest REE recovery into the precipitate was at 59.1 per cent, which suggests the recovery of a significant share of the REEs into the solid phase in the form of carbonates.

Table 2 shows the results of chemical analysis of residues performed by the X-ray fluorescence method. High content of CaO (30–40 per cent) is confirmed by the SEM and IR spectroscopy data on the predominance of calcium carbonates in the residue. Significant losses on ignition (up to 53.5 per cent) are due to the predominance of both calcium carbonates and calcium nitrate tetrahydrate in the residues. The content of ZrO_2 and total REE oxides in first stage residue is 6.96 and 0.06 per cent respectively, second stage residue – 0.21 and 2.82 per cent, which is consistent with the data on the efficiency of valuable component recovery from the liquid phase. Note that relatively low contents of Zr and REE are associated with both their low concentrations in the primary pregnant solution and a significant amount of residues. However, unlike the original eudialyte concentrate, the residues are readily soluble in weakly acidic solutions, which makes it possible to produce solutions with a high concentration of valuable components for subsequent processing.

TABLE 2

Chemical composition of the solid phase of I and II deposition stage.

Component	Content, %		Component	Content, %	
	I stage	II stage		I stage	II stage
CaO	30.50	40.29	SrO	0.09	0.18
Na_2O	0.17	4.01	ZrO_2	6.96	0.21
Al_2O_3	2.26	0.59	HfO_2	0.09	< 0.02
K_2O	0.04	0.08	∑REE oxides	0.06	**2.82**
TiO_2	1.20	< 0.02	Cl	0.04	0.07
SiO_2	0.26	0.18	LOI (400°C)	24.08	11.67
Fe_2O_3	3.49	0.21	LOI (950°C)	53.55	50.02

Since the temperature of the pregnant solution in the process of nitric acid leaching is 80°C, the effect of the initial temperature of the pregnant solution on the performance of zirconium and REE precipitation at the first stage was examined. Theoretically, temperature should have a significant effect on the rate of chemical reactions, for example, according to the Van't Hoff empirical rule, for every 10°C increase in temperature, the rate constant of a homogeneous elementary reaction increases by a factor of 2 to 4. However, the analysis of our results showed that the initial temperature of the solution in the range of 20 to 80°C did not affect the precipitation of valuable components, and the recovery of zirconium into the precipitate was 99.84–99.99 per cent, that of REEs 7.61–7.93 per cent. This fact is probably due to the initially high rate of the chemical reaction of neutralisation and the long duration of the treatment (2 hours), during which the temperature is reduced to 30–35°C.

It was found that the recovery of zirconium does not depend on the initial content in the studied concentration range and was 99.64–99.97 per cent. At the same time, an increase in the initial REE grade from 0.15 g/L to 1.2 g/L increased the loss to the precipitate from 0.29 per cent to 8.48 per cent, which is most likely due to the co-precipitation of REEs with impurity metals, whose concentrations also increase. The results obtained are consistent with those reported in the literature (Soltani *et al*, 2018; Chen *et al*, 2020).

CONCLUSIONS

According to SEM and IR spectroscopy results, the mechanism behind the intensification of the acid dissolution of eudialyte as a result of pretreatment with HPEMP and DBD is associated with the disintegration and breakage of the mineral surface and is expressed at the substructural level as the local disintegration of $Si_{10}O_{27}$, Si_9MO_{30} structural units with subsequent formation of microcracks, as well as the direct formation of characteristic defects in the form of electrical breakdown current microchannel imprints and individual mineral fragments.

Our results showed the fundamental possibility of using high-power electromagnetic pulsed impacts (HPEMP and DBD) to intensify the acid leaching of eudialyte concentrate with relatively low electricity consumption (0.1–1.0 kW*h/t). Pre-treatment of mineral samples with HPEMP made it possible to increase the recovery of zirconium into the pregnant leach solution by 3.4–4.3 per cent, and by 4.1 per cent when using a DBD treatment. The increase in the total REE recovery was 1.2–1.8 per cent.

The study demonstrated the high performance of chemical sequential precipitation of zirconium and REEs from a pregnant solution resulting from nitric acid leaching of eudialyte concentrate.

It was established that an increase to 4.0 in the pH value of the initial pregnant solution at the first stage of precipitation with calcium carbonate supports a zirconium recovery of 99.95 per cent into the solid phase with the associated recovery of impurity metals – aluminium (100 per cent) and iron (43.8 per cent). The total loss of REEs to the zirconium product did not exceed 8 per cent. The subsequent increase of pH to 6.1 using sodium carbonate enables a REE recovery of 87.5 per cent into the solid phase, while the total recovery from the solution was 95.5 per cent.

Valuable components in the resulting precipitates are concentrated mainly as complex hydroxides and carbonates, giving 6.96 per cent of ZrO_2 and 2.82 per cent of REE oxides. The resulting products are easily soluble in weakly acidic solutions, making downstream processing possible, which will be the focus of our research in the future.

ACKNOWLEDGEMENTS

The authors are grateful to Candidate of Geology and Mineralogy E.V. Koporulina for her assistance in carrying out the experimental studies.

ABSTRACT

With the extensive exploitation and gradual depletion of high-grade copper reserves, the mining industry is paying more and more attention to the hydrometallurgical extraction of copper from low-grade and arsenic bearing copper ores. Hydrometallurgical processing, such as heap leaching, column leaching and bioleaching, provide a viable alternative to the traditional pyrometallurgy due to its harmony with the environment, moderate capital investment, and low operating costs. However, the slow leaching kinetics of enargite (Cu_3AsS_4) and chalcopyrite ($CuFeS_2$) remain problematic for commercial leaching practice. The formation mechanism and the nature of the passivating layers during leaching is still a matter of debate in hydrometallurgical research. In this study, the dissolution mechanism of enargite and chalcopyrite in sulfuric acid solution was investigated using a range of electrochemical and spectroscopic analysis methods. Electrochemical oxidation of enargite demonstrated an obvious passivation region from 500 to 750 mV (Ag/AgCl). The formed passivation film was found a n-type semiconductor behaviour, which is different from the original enargite with a p-type behaviour. The results of X-ray photoelectron spectroscopy (XPS) suggested that a nonstoichiometric film $Cu_{(3-x)}As_{(1-y)}S_4$ (x>>y) accumulated on the electrode surface, which accounted for the obvious decrease in current density in the passive potential region. For chalcopyrite, three important potentials of 550, 680 and 730 mV which are related to the formation and dissolution of passivation film were observed based on the cyclic voltammetry (CV) and potentiodynamic polarisation. Raman and X-ray absorption near edge structure (XANES) spectra studies of the chalcopyrite electrodes after being treated under these three potentials indicated a metal-deficient sulfide of $Cu_{1-x}Fe_{1-y}S_2$ (y>>x) might be responsible for the passivation phenomenon. Hence, it is concluded that the passivation of enargite and chalcopyrite are similar which are caused by metal-deficient sulfide surfaces although the compositions of the metal-deficient sulfide are different.

INTRODUCTION

Currently, it has been estimated that around 80 per cent of copper was produced by pyrometallurgy, however, this processing method requires ores with high-grade. With the gradual decreasing trend of high-grade copper ores and the more complex ore mineralogy, it will become more difficult to process low-grade and complex copper ores by the traditional pyrometallurgy. For example, chalcopyrite ($CuFeS_2$), the most abundant copper sulfide on the earth's crust, has become one of the most important copper sources with the extractive method transforming from traditional pyrometallurgy to hydrometallurgical methods due to the gradual depletion of high-grade ores and the need for processing low-grade ores. Meanwhile, many of the low-grade copper ores contain arsenic-bearing sulfide phases, for example, enargite (Cu_3AsS_4), which is commonly found in the copper deposits of some mining countries. Although, pyrometallurgy can efficiently extract copper from high-grade copper ores, it is unsuitable for processing the low-grade and arsenic-bearing copper ore because of the high energy cost and emissions of environmentally toxic arsenic gas during smelting.

Hydrometallurgy has been proved to be more advantageous than pyrometallurgy for processing the low-grade and complex copper ores (Safarzadeh *et al*, 2013). Additionally, aqueous arsenic species are more controllable by precipitated and stabilised methods in hydrometallurgical processing. However, the refractory character of chalcopyrite and enargite during leaching poses a major challenge for researchers (Hackl *et al*, 1995; Viramontes-Gamboa *et al*, 2010). Chalcopyrite and

enargite are more refractory in acidic media as compared to other copper sulfides, such as bornite and chalcocite in various acid systems with or without bacteria during which the leaching kinetics of copper is extremely low (Corkhill *et al*, 2008; Li *et al*, 2013; Padilla *et al*, 2010; Riveros and Dutrizac, 2013). The slow leaching behaviour of chalcopyrite and enargite is related to the formation of a passivating layer whose composition and formation mechanism are still unknown (Lattanzi *et al*, 2008; Watling, 2013). Elemental sulfur (S^0), jarosite and a metal-deficient surface layer have been suggested to be responsible for the slow leaching kinetics.

It has been suggested that the oxidative dissolution of metal sulfides in solutions occurs via an electrochemical mechanism by several researchers (Ghahremaninezhad *et al*, 2010; Guo *et al*, 2017; Karimi *et al*, 2017; Liu *et al*, 2017; Tu *et al*, 2017). Various electrochemical techniques have been used to gain a better understanding of the mechanism underlying the leaching process of metal sulfides, such as chalcopyrite, pyrite, and sphalerite. In the present study, electrochemical methods were employed to systematically investigate the oxidation of chalcopyrite and enargite in 0.1 mol/L sulfuric acid. Meanwhile, the oxidised surface chemistry was studied by various surface analytical techniques with the hope to provide complementary information for interpretation of the passivation mechanism.

EXPERIMENTAL

Electrodes preparation

High-quality natural enargite and chalcopyrite obtained from Wright's Rock Shop (USA) were used for electrode fabrication. The ores were cut into approximately cubic shapes and connected to copper wire by silver paint on the back. The electrode contacts were protected from the solution by mounted in epoxy, leaving only one face of the electrode with an area of approximate 0.25 cm^2 exposed to the solution.

Electrochemical experiments

The electrochemical experiments were carried out using a PARSTAT 2273, Princeton Applied Research (USA) on a conventional three-electrode electrolytic cell at approximately 20°C. An Ag/AgCl, KCl (sat.) electrode (0.204 V versus SHE at 20°C) was used as the reference electrode and all further potentials quoted in this study are with respect to it if not otherwise mentioned. A Pt wire was used as the auxiliary electrode. All solutions were prepared in 18 MΩ water (MilliQ, Millipore) and deaerated by bubbling high-purity N_2. Cyclic voltammetry, potentiodynamic curves, chronoamperometric polarisation and Mott-Schottky were performed to study the behaviours of the electrodes. EIS tests at different potentials were conducted in the frequency range of 10^{-2} to 10^4 Hz with a peak-to-peak amplitude of 10 mV. ZSimpWin 3.20 (2004) software was used to fit the impedance data.

Surface chemical analysis methods

XPS measurements of the oxidised electrodes were performed using a Kratos Axis ULTRAX-ray photoelectron spectrometer (Kratos Analytical Ltd., UK) incorporating a monochromatic Al Kα X-rays (1486.6 eV) at 150 W (15 kV, 15 mA). Survey (wide) scans were obtained at a pass energy of 160 eV over 1060−-40 eV binding energy (BE) range with 1.0 eV steps and a dwell time of 100 ms. Multiplex (narrow) high-resolution scans were carried out at a pass energy of 40 eV with 0.05 eV steps and a 250 ms dwell time. Base pressure in the analysis chamber was $<5.0 \times 10^{-7}$ Torr during sample analysis. Spectra analysis and peak fitting were carried out using CasaXPS software (Version 2.3.14).

Raman spectrometry was performed using a RenishAW Invia Raman Microscope (USA) with a 514 nm laser source. The spectrometer was calibrated using silicon as a standard before the test. To protect the sample from being damaged by the laser, a low laser intensity of 1 mW was used throughout the experiment. The Raman data was collected in the wavenumber range between 800 and 100 cm^{-1}, with a step width of 0.1 cm^{-1}.

The S K-edge XANES spectra were collected at beam-line 4B7A, Beijing National Synchrotron Radiation Facility (BSRF) using fluorescence mode. The spectrum was scanned in the energy region

between 2450 to 2520 eV at a step width of 0.1 eV. Freshly polished enargite, elemental sulfur, covellite and jarosite were used as standards materials. XANES data was processed with the ifeffit software package.

RESULTS AND DISCUSSION

Electrochemical study of enargite and chalcopyrite

Potentiodynamic polarisation, Mott-Schottky and EIS of enargite

Potentiodynamic curve and Mott-Schottky plot of a freshly polished enargite electrode in 0.1 mol/L sulfuric acid solutions are shown in Figure 1. It can be seen from Figure 1 that a passive region was evident from the 0.50 to 0.75 V at a scan rate of 0.5 mV/s, which is related to the formation of a passivation surface layer (Equation 1) (Ásbjörnsson *et al*, 2004; Lattanzi *et al*, 2008). In this region, the electrode current increased slowly and even decreased with the increase of the applied potential above 0.5 V. When the potential increased from 0.75 V to 0.90 V, the electrode transferred into a trans-passive state. Within this small potential window, the measured current started to increase gradually, which is likely related to the partial dissolution of the passive film shown as Equation 2 (Elsener *et al*, 2007). As the anodic potential reached 0.90 V, the surface layer dissolved completely and the electrodes entered an active area Equations 3 and 4 (Lattanzi *et al*, 2008).

$$\mathrm{Cu_3AsS_4} \rightarrow \mathrm{Cu_{(3-x)}As_{(1-y)}S_4} + x\mathrm{Cu^{2+}} + y{\mathrm{AsO_3}}^{3-} + 2x\mathrm{e^-} + 3y\mathrm{e^-}\ x >> y \quad (1)$$

$$\mathrm{Cu_{(3-x)}As_{(1-y)}S_4} \rightarrow \mathrm{As_{(1-y-z)}S_4} + (3-x)\mathrm{Cu^{2+}} + z{\mathrm{AsO_3}}^{3-} + (3z+6-2x)\mathrm{e^-} \quad (2)$$

$$\mathrm{As_{(1-x-z)}S_4} \rightarrow 4\mathrm{S^0} + (1-\mathrm{y}-z){\mathrm{AsO_4}}^{3-} + 3(1-y-z)\mathrm{e^-} \quad (3)$$

$$\mathrm{Cu_3AsS_4} + 4\mathrm{H_2O} \rightarrow 3\mathrm{Cu^{2+}} + {\mathrm{AsO_4}}^{3-} + 4\mathrm{S^0} + 8\mathrm{H^+} + 11\mathrm{e^-} \quad (4)$$

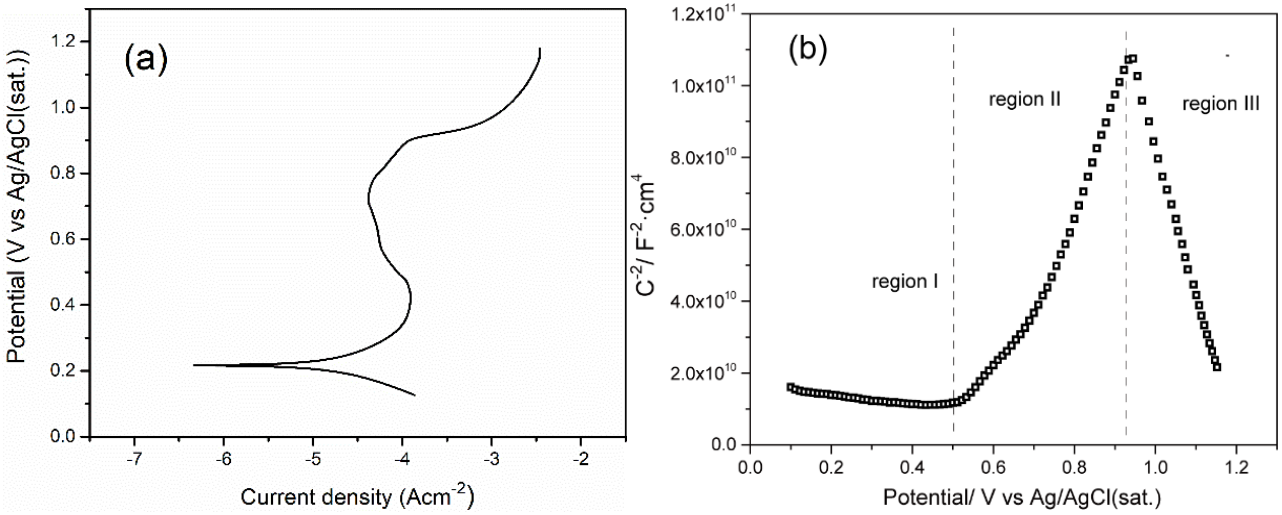

FIG 1 – Potentiodynamic polarisation of enargite electrode (scan rate: 0.5 mV s^{-1}) and Mott-Schottky plots for enargite electrode in 0.1 mol/L sulfuric acid.

The Mott-Schottky plot demonstrates three typical regions, regions I, II and III with different slopes. The negative slopes in regions I and III are attributed to p-type behaviour, while the positive slope in region II is indicated to the n-type behaviour of the passive films (Fattah-alhosseini and Vafaeian, 2015). For the potential region II, the potentiodynamic curve presented in the previous section show a thick passive film formed on the surface of the electrode when the applied potential higher than 400 mV. The positive slope in region II corresponding to the formation of passive film indicating this passive film is an n-type semiconductor thus explains the break of Mott-Schottky plot at 500 mV. It has already been mentioned from the above potentiodynamic study that enargite actively dissolved in the potential above 900 mV as suggested by Equation 4. Thus, the observed p-type semiconductor of enargite electrode in Figure 1b in the potential region of above 900 mV is directly associated with the properties of the enargite.

Figure 2 shows the measured and fitted Nyquist plots at different potentials obtained by the corresponding equivalent circuits. The fitted value of the elements in the equivalent circuit of Figure 2b and 2c are shown in Table 1. It can be seen from Figure 2a that the EIS spectrum obtained at OCP and 400 mV demonstrated a flattened semicircle followed by a straight line which is related to the existence of a Warburg impedance. Thus a circuit of R(QR)(C(WR))) shown in Figure 2b was used to fit the measured data at OCP and 400 mV. With an increase of applied potential to 600 mV, the electrochemical impedance increased significantly, indicating a passive film formed and the thickness of this passive layer increased according to Equation 1. It is also worth mentioning that the diffusion process characterised by a Warburg impedance disappeared at the potential of 600 mV shown in Figure 2a, which might be associated with the dense passive layer formed under this potential inhibiting the diffusion of oxidation products away from the enargite electrode. Thus a circuit of R(QR)(CR) shown in Figure 2c was used to fit the measured data at 600 mV. For the enargite oxidation at 800 mV, the electrode entered a trans-passive region. The acquired impedance spectra under this potential decreased significantly compared with that at 600 mV. The substantially different impedance values at these two potentials imply that different faradic processes were occurred. The results can be explained by the oxidation model of the $Cu_{(3-x)}As_{(1-y)}S_4$ layer being oxidised to another surface layer due to the increasing depletion of surface copper as suggested by Equation 2.

CV and potentiodynamic polarisation of chalcopyrite

The results of CV and potentiodynamic polarisation are shown in Figure 3. Four anodic peaks and two cathodic peaks were detected (Figure 3a). The peak A1 may be due to the initial dissolution of

iron from the crystal lattice of chalcopyrite (Equation 5) to form $Cu_{1-x}Fe_{1-y}S_2$ (y >> x) and it has been confirmed by several researchers that iron is more preferentially dissolved than copper from the crystal lattice of chalcopyrite (Ghahremaninezhad *et al*, 2013; Nava *et al*, 2008; Yang *et al*, 2015). A2 around 700 mV could be ascribed to partial oxidation of chalcopyrite as shown Equation 6 and/or the oxidation of the surface layer of $Cu_{1-x}Fe_{1-y}S_2$ (y >> x) (Equation 7) (Ghahremaninezhad *et al*, 2013; Yang *et al*, 2015). The formed surface layers of $Cu_{1-x}Fe_{1-y}S_2$ and $Cu_{1-x-z}S_2$ are suggested to be responsible for the passivation of chalcopyrite dissolution. When the potential further increased to over 0.8 V, this layer dissolved with the oxidation of ferrous iron to ferric iron and the oxidation of sulfur to sulfuric acid (Equation 8) (Ghahremaninezhad *et al*, 2010).

$$CuFeS_2 \rightarrow Cu_{1-x}Fe_{1-y}S2 + xCu^{2+} + yFe^{2+} + 2(x + y)\, e^- \; y >> x \quad (5)$$

$$Cu_{1-x}Fe_{1-y}S_2 \rightarrow Cu_{1-x-z}S_2 + zCu^{2+} + (1 - y)\, Fe^{2+} + 2(z + 1 - y)\, e^- \quad (6)$$

$$CuFeS_2 \rightarrow 0.75CuS + 1.25S^0 + 0.25Cu^{2+} + Fe^{2+} + 2.5e^- \quad (7)$$

$$CuFeS_2 + 8H_2O \rightarrow Cu^{2+} + Fe^{3+} + 2SO_4^{2-} + 16H^+ + 17e^- \quad (8)$$

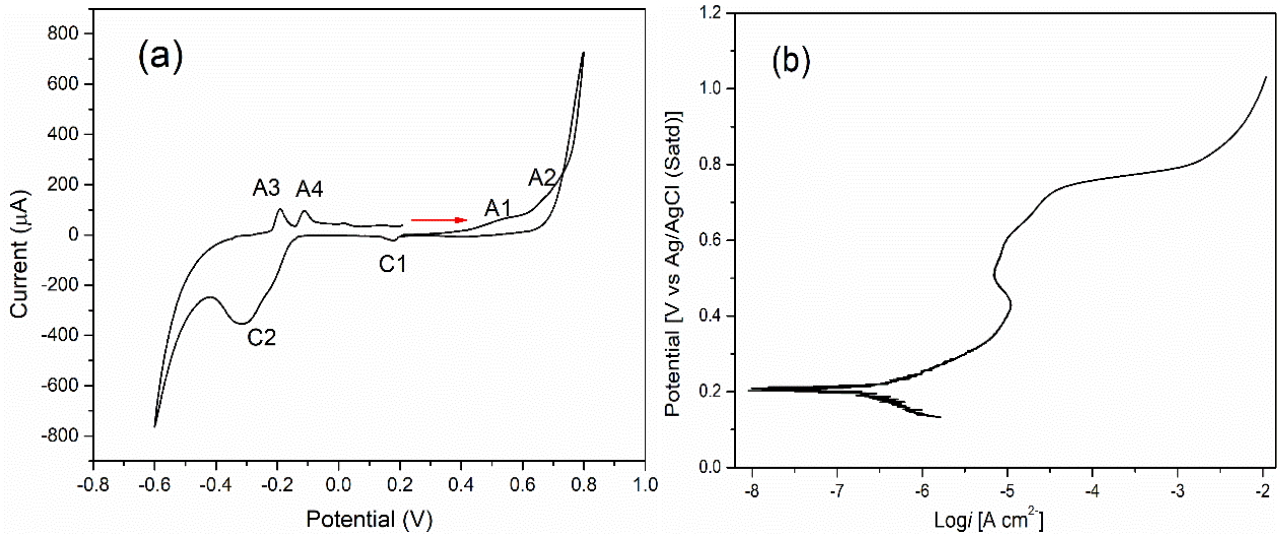

FIG 3 – (a) Cyclic voltammograms of chalcopyrite electrode (The scan was initiated from $E_{OC}P$ (0.215 V) in the positive direction at a scan rate of 10 mV s^{-1}) and (b) potentiodynamic polarisation of chalcopyrite electrode (scan rate: 0.5 mV s^{-1}) in 0.1 mol/L H_2SO_4 solution.

In the inverse scan, C1 may be attributed to the reaction of cupric ions with CuS or elemental sulfur, producing chalcocite (Liang *et al*, 2011). When the potential value was lower than −100 mV, peaks C2 observed. The peak C2 possibly is related to the reduction of covellite and/or chalcopyrite. Thus, the anodic peaks of A3 and A4 might be corresponded to the oxidation of the reduced products of peaks C1 and C2. Further explanation of these peaks is not in the scope of this study because these peaks are irrelevant to the dissolution and passivation of chalcopyrite.

Figure 3b shows the result of potentiodynamic curve of chalcopyrite at a scan rate of 0.5 mV s^{-1}. The result shows that the potentiodynamic profile is similar to that observed by Ghahremaninezhad *et al* (2010). A passive region is evident from the OCP to 630 mV. In this region the current was low and surface reaction was very slow. According to the CV curve, it is assumed that some nonstoichiometric or secondary metal sulfide mineral formed in this region as shown in Equation 5. From 630 to 700 mV, the current rose rapidly with the increase of potential. In this region, the surface reaction was fast due to the oxidation of the formed surface layer (Equation 6) and the partial oxidation of chalcopyrite (Equation 7).

Surface chemical analysis of enargite and chalcopyrite

XPS of electrochemical oxidised enargite surface

The spectra of S 2p of the oxidised enargite electrodes with the increase of applied potential in Figure 4 show significant differences compared with the freshly polished enargite. The spectra of

S 2p were fitted to interpret the sulfur oxidation states and to identify the oxidation products. The fitted analysis results are presented in Table 2.

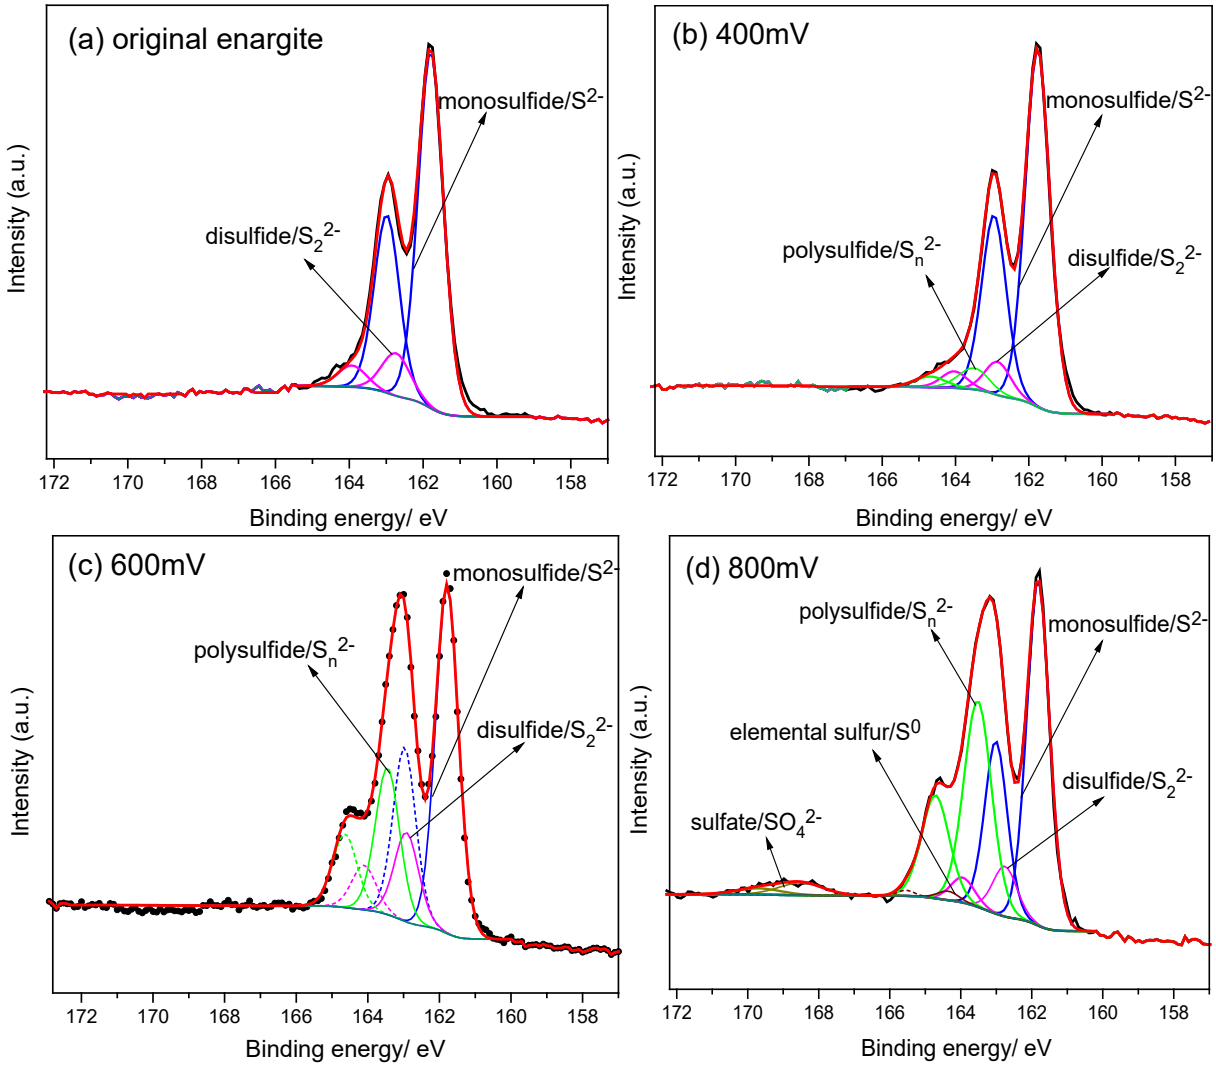

FIG 4 – S 2p XPS spectra for freshly polished enargite electrode surface (a) and the electrodes obtained after dissolution at 400 (b), 600 (c) and 800 mV (d).

TABLE 2

XPS analysis of the relative proportion of different sulfur species present on the enargite electrode.

	S^{2-}	S_2^{2-}	S_n^{2-}	S^0	SO_4^{2-}
Original	88.1	11.9	-	-	-
400 mV	87.2	8.4	4.4	-	-
600 mV	64.7	7.7	27.6	-	-
800 mV	58.2	9.1	28.6	1.3	2.8

Figure 4c illustrates the S 2p XPS spectra of freshly polished enargite surface, with the peak at 161.8 eV and 162.9 eV corresponding to the S $2p_{3/2}$ and S $2p_{1/2}$ peaks for monosulfide sulfur (S^{2-}) in enargite. Compared to the untreated enargite, it is clear that sulfur species with higher oxidation states formed on the surface of the electrode after oxidation with the increasing potential. Examining the spectra for S 2p at potentials of 400 and 600 mV revealed the presence of three distinct sulfur species: the S $2p_{3/2}$ peaks located at 161.8, 162.8, and 163.5 eV. An additional peak has been fitted at 164.4 eV for the S $2p_{3/2}$ at the potential of 800 mV. The S $2p_{3/2}$ species at 161.8 and 162.8 eV corresponds to the monosulfide (S^{2-}) and disulfide (S_2^{2-}) in enargite. Assignment of the S $2p_{3/2}$ peaks

identified at 163.5 and 164.4 eV is not straightforward. However, analysis based on binding energy suggests it would appear reasonable for the peak at 163.4 eV to be assigned to metal deficient sulfide or polysulfides (S_n^{2-}) that, for the latter, fall in the range 162.0−163.6 eV and the peak at 164.4 eV is likely due to S^0.

Raman spectroscopy and XANES of chalcopyrite

Raman spectroscopy was applied to study the sulfur species of chalcopyrite electrode surface after being electrochemical oxidation under different potentials. Based on the previous CV and potentiodynamic polarisation studies, chalcopyrite electrodes were subjected to chronoamperomatic treatment under three important potentials: 550, 680 and 730 mV which are related to the formation and dissolution of passivation films. Raman spectra of original and oxidised chalcopyrite are shown in Figure 5. The Raman spectra of original chalcopyrite displayed three peaks of 292, 319 and 353 cm^{-1}, which resulted from lattice vibrations. At 550 mV, a broad peak around 470 cm^{-1} was found in the spectra, which could be assigned to a S–S bond of covellite (Yang *et al*, 2015). Furthermore, the broad shoulder shows the presence of polysulfides (Mycroft *et al*, 1990). The evidence of polysulfides and covellite supported Equations 5 and 6. The spectra of electrode oxidised at 680 mV shows several new peaks of 272, 415 and 452 cm^{-1} which are similar to the previous study by Parker *et al* (2008). They suggested that these peaks were produced by the irradiation of the oxidised surface which was a Raman-inactive phase with laser light. The photo-induced product yielded a Raman spectrum consistent with polymeric sulfur (S_μ) and they concluded that the parent compound is a metal-deficient sulfide having a remnant chalcopyrite lattice structure which further supported the Equations 5 and 6. At higher potential of 730 mV, more intensive peaks at 152, 220 and 474 cm^{-1} were observed, suggesting the accumulation of crystalline elemental sulfur (S_8) (Equation 7).

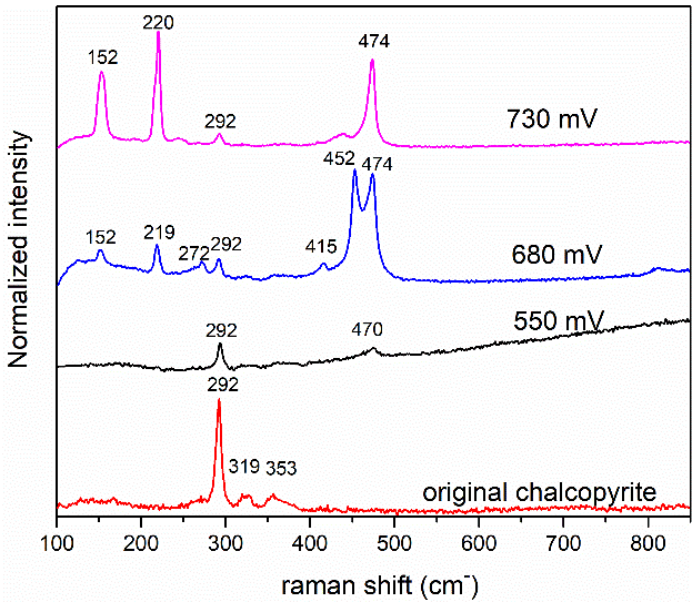

FIG 5 – The Raman spectra of original chalcopyrite surface and oxidised chalcopyrite electrode surfaces after chronoamperometry treatment at different potentials.

The S K-edge XANES spectra are shown in Figure 6. The original chalcopyrite shows a sharp absorption edge at 2.4698 KeV, which decreased as the increase of potential. On the other hand, a peak 2.4722 KeV, which suggests the oxidation of electrode surface, appeared after electrochemical oxidation, and rose with the increasing potential. According to the literature, this peak is higher than that of FeS_2 (S_2^{2-}) but slightly lower than that of elemental sulfur (S_8) (Xia *et al*, 2010). Coupled with the results of XPS study, it can be inferred that this peak indicates the formation of polysulfide (S_n^{2-}) and/or S_8 which are in line with the previous results of Raman spectroscopy.

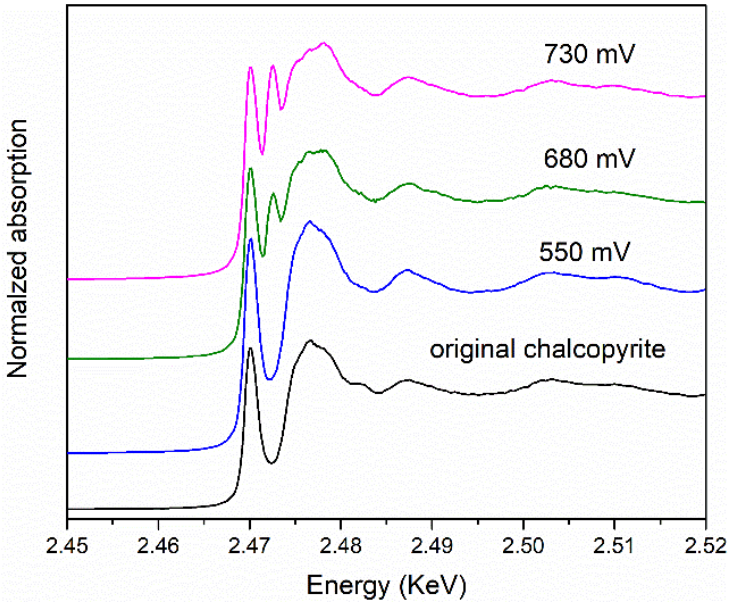

FIG 6 – The S K-edge spectra of the unreacted enargite and oxidised enargite electrode surfaces after chronoamperometry treatment at different potentials.

CONCLUSIONS

Electrochemical and surface analytical techniques were employed to investigate the oxidation of enargite and chalcopyrite in 0.1 mol/L sulfuric acid. Electrochemical oxidation of enargite demonstrated an obvious passivation region from 500 to 750 mV. A nonstoichiometric film $Cu_{(3-x)}As_{(1-y)}S_4$ (x>>y) likely accumulated on the electrode surface, which accounted for the obvious decrease in current density in the passive potential region. Results of XPS have shown a substantial change in the oxidation state of sulfur species on the surface of enargite at the passive and trans-passive region. For chalcopyrite, three important potentials of 550, 680 and 730 mV which are related to the formation and dissolution of passivation film were observed based on the CV and potentiodynamic polarisation. Raman and S K-edge XANES spectra studies of the chalcopyrite electrodes after being treated under these three potentials indicated a metal-deficient sulfide of $Cu_{1-x}Fe_{1-y}S_2$ (y >> x) might be responsible for the passivation phenomenon. Hence, it is concluded that the passive and transpassive dissolution of enargite and chalcopyrite are similar which are caused by metal-deficient sulfide surfaces although the compositions of the metal-deficient sulfide are different for these two cases.

ABSTRACT

To improve the understanding of the reactions and mechanisms occurring during the leaching of sulfide ores at high temperatures a range of advanced characterisation and sensing tools have been combined to provide a sophisticated and powerful methodology to examine sulfide leaching systems. These include advanced electrochemical methods, surface chemistry and materials characterisation techniques such as synchrotron X-Ray Absorption Spectroscopy (XAS), X-Ray Photoelectron Spectroscopy (XPS), Scanning Electrochemical Microscopy (SECM), and *in situ* X-ray diffraction (XRD), together with new robust solid state chemical sensors for *in situ* real time monitoring of key aqueous chemical parameters. The methodology was employed to investigate various sulfide mineral leaching processes. For example, oxidation of arsenopyrite at elevated temperature involves complicated multiple reactions and the process is strongly influenced by the solution conditions, component speciation and mineralogy. The methodology was used to study this system both *ex situ* and *in situ* to gain a detailed understanding of the complex chemical reaction mechanisms operating. These mechanisms are discussed in terms of the observed leaching efficiency. The application of this methodology enables complex sulfide leaching systems to be understood more fully such that process efficiency can be improved.

METHODS

The *in situ* XAS study was carried out in X-ray Absorption Spectroscopy (XAS) beamline at Australian synchrotron. The experiment set-up is shown as in Figure 1 (Chen *et al*, 2018). The solid sample and solution was filled in the quartz capillary with an OD of 1 mm and wall thickness of 0.1 mm. The position of capillary was controlled by a motor and accurately adjusted to fit in the X-ray path. For each leaching experiment the pressure of leaching was set as 28 bar using oxygen or air and the system was heated from room temperature to 200–225°C and then the cooled down to room temperature. A set of XAS data were collected at different temperatures during the heating-up and cooling down stages.

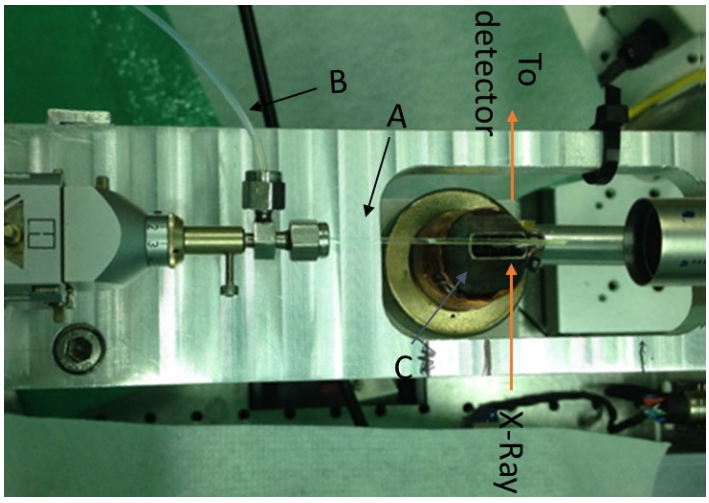

FIG 1 – The set-up of *in situ* XAS experiment (A: quartz capillary; B: gas line; C: hot air blower).

RESULTS AND DISCUSSION

The evolution of As solution species in arsenopyrite pressure leaching with oxygen is shown in Figure 2. At room temperature, the As k edge XANES spectra show a single strong peak at 11874.8 eV (Testemale *et al*, 2004), which indicated the presence of As(V) species. In Figure 2a with the increase of temperature, the spectra showed a clear trend of change. Increasing the temperature up to 80°C, the spectra showed similar features to that at room temperature, which indicated only As(V) was in the solution. When the temperature raised to 100°C, a dramatic change of spectra was seen. At 100°C, a peak at 1171.3 eV appeared which is corresponding to that of As(III) species (Ona-Nguema *et al*, 2010). With the further increase of the temperature, the As(V) peak decreased to a shoulder at 160°C and disappeared at 200°C. At the same time, the As(III) peak was increasing and became the only detectable peak at 200°C or above.

In the cooling phase, a reversed evolution of As speciation was seen (Figure 2b). The As(III) was the only As species in the solution at 220°C and 160°C. When the temperature was decreased to 100°C, a shoulder appeared which possibly indicated the presence of As(V). A clear presence of As(V) occurred at 50°C and most of the As presented as As(V) at room temperature.

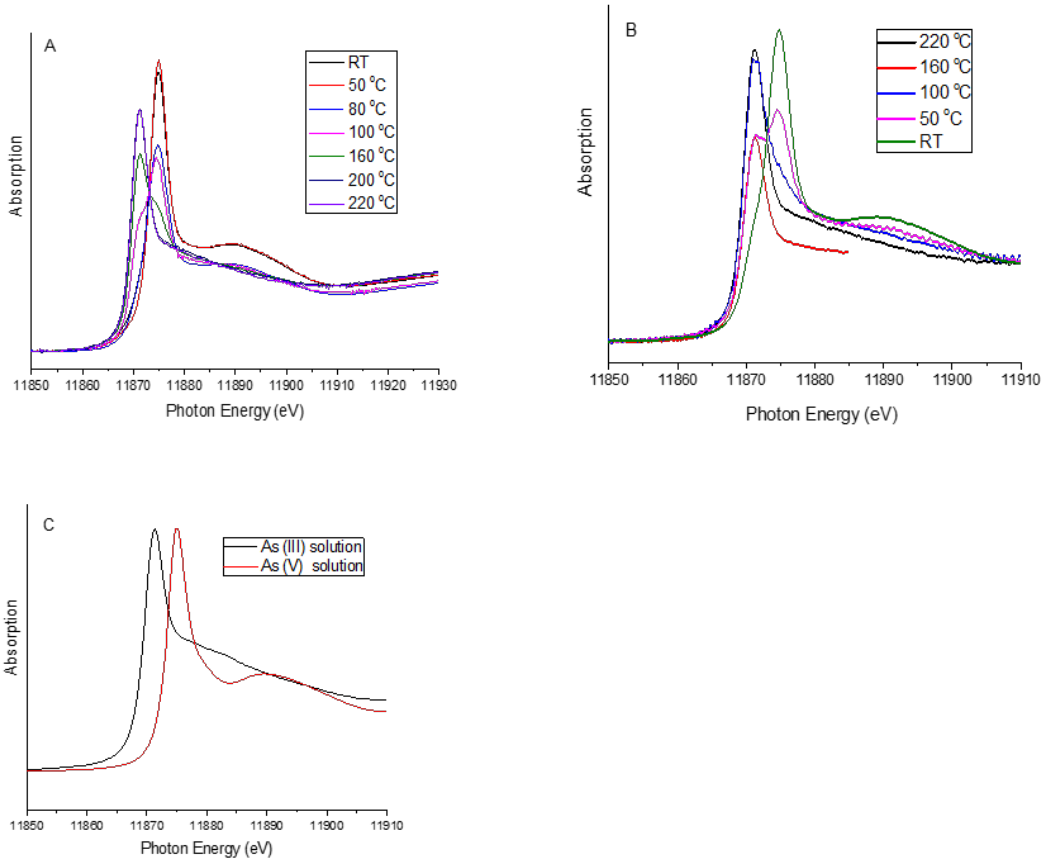

FIG 2 – The As K edge XANES spectra of arsenopyrite leaching solution at 28 bar oxygen (A, heating; B, cooling; C, As(III) (dissolved As_2O_3 in 0.5 M sulfuric acid) and As(V) (sodium arsenate standard solution).

To quantify the As(V)/As(III) ratio in the solution, the spectra was deconvoluted by curve fitting using arctangent curve representing absorption step and Lorentzian curve representing the As(V) or As(III) species (Takahashi *et al*, 2003). The As(V)/As(III) ratio could be directly represented by the area of the corresponding Lorentzian curve. In either heating phase or cooling phase, the curve fitting results are in line with the above qualitative interpretation. The fitting results show that As(V) was the only solution As species up to 80°C. At 100°C, the proportion of As(III) to As(V) was 31.7 per cent to 68.3 per cent, which then increased to 84.2 to 15.2 at 160°C. Only As(III) was found in solution at temperate at 200°C or above. During cooling, as only As(V) first showed up at 100°C, accounting to 12.3 per cent of the solution As and quickly increased to 50.5 per cent, when temperature lowered

to 50°C. At room temperature, As(V) returned to the predominant As species and comprised of 80.3 per cent of total solution As.

The arsenic species in solution during the arsenopyrite pressure leaching with the co-existence of pyrite or pyrrhotite have been also investigated. *In situ* XAS has confirmed that the arsenic in solution was present mostly as As(V) at low temperatures and As(III) at elevated temperatures, and the As(III) can be re-oxidised to As(V) during cooling process. The addition of pyrrhotite facilitated the reduction of As(V) and increased the stability of As(III) in the solution, which is possibly explained by the faster oxidation of pyrrhotite that created a more reductive environment, which was further confirmed by the S k-edge XANES study on the leached residue (Yang *et al*, 2020). On the other hand, the addition of pyrite favoured the presence of As(V) in the solution, which could be explained by the relatively slower oxidation rate or/and the catalysing reaction of pyrite on As(III) oxidation.

ACKNOWLEDGEMENTS

The authors would like to thank the support from the Australian Research Council grant (ARC LP160101760), CSIRO Research plus postdoctoral scheme and Zijin Mining Group. The *in situ* XAS study of arsenic species was carried out on the XAS beamline at the Australian Synchrotron, part of ANSTO, Victoria, Australia. The S k-edge XANES data were collected in the Beijing Synchrotron Radiation Facility (BSRF), Beijing, China. The authors appreciate the support provided by the beamline scientists and staff of the Australian Synchrotron and Beijing Synchrotron Radiation Facility.

ABSTRACT

The hydrometallurgical separation and enrichment processes provide an effective way to selectively recover metals from relatively dilute multicomponent sulfuric acid leach solutions. The multicomponent leach solution utilised in this study contained 0.3 g/L Cu, 0.34 g/L Ni, 0.13 g/L Co, and 2.96 g/L Fe, which was obtained after high-pressure oxidative acid leaching (HPOAL) of the copper-nickel smelter slag. The solvent extraction (SX), precipitation, and xanthate complexation processes were employed to recover and upgrade Cu, Ni, and Co from the leach solution. Batch SX tests were carried out using a countercurrent two-stage mixer settler extraction column, and LIX 984N (10 per cent v/v) as a copper extractant. Fundamental parameters influencing the extraction process such as pH, mixing speed, H_2SO_4 concentration, and organic/aqueous (O/A) phase ratio were investigated. For copper enrichment in solution, a combination of two extraction stages and two stripping stages were employed. Copper was successively separated from Fe, Ni, and Co under optimised extraction conditions (pH 2, 400 rev/min, O/A 0.25, and 20 min contacting) and stripping conditions (175 g/L H_2SO_4, 400 rev/min, O/A 4, and 20 min contacting). About 97 per cent of copper was extracted with low co-extraction of Fe, Ni, and Co of about 5.90 per cent, 1.47 per cent, and 2.53 per cent, correspondingly. A final Cu-rich solution containing 23 g/L Cu was obtained with a very low Fe concentration of 0.05 g/L. Additionally, for iron removal from the Ni/Co raffinate solution, more than 99 per cent of iron was precipitated at pH 4 by the addition of a calcium carbonate ($CaCO_3$) suspension, with low co-precipitation of nickel and cobalt of around 3.68 per cent and 2.27 per cent, respectively. Furthermore, about 83.6 per cent of nickel and 99.4 per cent cobalt were co-precipitated from the solution by potassium amyl xanthate (PAX) solution at pH 6. The Ni and Co xanthate complexes were thermally decomposed and recovered as cobalt oxide (CoO) and nickel sulfide (NiS) solids.

INTRODUCTION

Hydrometallurgical processes have recently been playing an efficient role in the extraction of valuable metals from metallurgical waste, low-grade ores, and complex ore materials. This includes the high-pressure leaching of slag waste from pyrometallurgical operations to recover the entrained valuable metals such as nickel, copper, and cobalt. Even though the high-pressure leaching of slag has comprehensive metal recoveries (Baghalha, Papangelakis and Curlook, 2007; Huang *et al,* 2015; Li, Perederiy and Papangelakis, 2008), due to the low metal content in the waste material, the generated leach solutions are relatively dilute in metals concentrations. Consequently, this necessitates multiple metal enrichment stages and impurity removal steps to obtain an industrial standard solution suitable for electrowinning. Furthermore, in a multicomponent leach solution, several metal separation processes in sequence may be necessary to realise the maximum value of each metal. The separation of metal ions and the removal of impurities from leach solutions is very important in enabling efficient operation in the upstream processes to achieve high purity metals by electrowinning.

Acidic pressure leaching solutions of copper-nickel smelter slags commonly contain low content of Cu, Ni, and/or Co, with impurities of Fe, Ca, and/or Mg. The solvent extraction process is generally used in the selective extraction of copper from leach solutions. Hydroxyoxime extractants, such as LIX 984N (aldoxime-ketoxime mixture) are often used for the extraction of copper from the solution because of their high stability and excellent copper selectivity properties (Schlesinger *et al,* 2011;

Shakibania *et al,* 2020). The separation of nickel and cobalt is commonly done by solvent extraction utilising organic extractants such as Cyanex 272 (bis(2,4,4-trimethylpentyl) phosphinic acid), and D2EHPA (di-2-ethylhexyl phosphoric acid). However, increased content of impurities in solution has been noted to cause difficulties in the separation of nickel and cobalt (Huang, Li and Chen, 2007; Kursunoglu, Ichlas and Kaya, 2017). Therefore, alternative methods for the separation of nickel and cobalt are currently being explored. Shirayama and Uda (2015) utilised the difference in Ni and Co oxidation/reduction rate to selectively reduce Ni and separate it from Co in an acidic aqueous solution. Vakylabad, Darezereshki and Hassanzadeh (2021) selectively extracted nickel and cobalt from the leach solution by a xanthate complex at room temperature, owing to the strong hydrophobic properties of nickel and cobalt xanthates.

Several other studies have investigated a combination of different techniques to separate and enrich metals from multicomponent leach solutions (Banza, Gock and Kongolo, 2002; Huang, Li and Chen, 2007; Keber *et al,* 2020; Kursunoglu, Ichlas and Kaya, 2017; Parhi and Sarangi, 2008; Sridhar and Verma, 2011). Huang, Li and Chen (2007) developed a technique for the recovery of copper, nickel, and cobalt from leach solutions, employing solvent extraction for the separation of Cu, and used the Na_2S precipitation method to further recover Ni and Co in solution. Selective precipitation is known to have good selectivity for metal removal and fast reaction rates (Godirilwe *et al,* 2021; Perez *et al,* 2020). Banza, Gock and Kongolo (2002) also incorporated the iron precipitation method in between sequential solvent extractions of Cu followed by that of Ni and Co. Therefore, a combination of separation processes has proven to be effective for the recovery of valuable metals from a multi-component solution.

This study is focusing on the processing of the acidic pressure leaching solution to recover Cu, Ni, and Co from the solution. Three hydrometallurgical processes of solvent extraction (SX), precipitation, and xanthate complexation processes were used to selectively separate and enrich metal ions of Cu, Ni, and Co, and remove the Fe impurity from the pregnant leach solution (PLS). The solvent extraction method using a countercurrent two-stage mixer settler extraction column and LIX 984N as a copper extractant was employed to separate copper from other metals (Ni, Co) and Fe impurity as well as upgrade the copper concentration in the PLS. A multistage counter-current extraction column has been proven to effectively extract metals from dilute solutions (Takahashi and Nii, 1999). Iron impurity in the raffinate solution, which is known to have detrimental effects on the upstream processes, was removed by precipitation using calcium carbonate ($CaCO_3$) emulsion from the solution prior to nickel and cobalt recovery. In this study, the xanthate complexation method using potassium amyl xanthate (PAX) displays an effective route to recover nickel and cobalt from the solution.

EXPERIMENTAL

Reagents and material

Solvent extraction and stripping of copper were carried out using a simulated pregnant leach solution (PLS) obtained from the optimised high-pressure leaching of copper-nickel slag. The metal concentration in the PLS is displayed in Table 1, showing dilute metal concentrations of nickel, copper, and cobalt. The multicomponent leach solution contained 0.3 g/L Cu, 0.34 g/L Ni, 0.13 g/L Co, and 2.96 g/L Fe and was used for optimisation tests during solvent extraction experiments. The simulated sulfate solution was prepared by dissolving analytical grade salts of $NiSO_4 \cdot 6H_2O$ (99 per cent purity), $CuSO_4 \cdot 5H_2O$ (99 per cent purity), $CoSO_4 \cdot 7H_2O$ (98 per cent purity), and $Fe_2(SO_4)_3 \cdot nH_2O$ (78 per cent purity) all from Nacalai Testique, Inc, Japan, in distilled water. The pH adjusting solutions were prepared by dissolving analytical grade sodium hydroxide pellets (97 per cent purity, Nacalai Testique, Inc) in distilled water, and diluting concentrated sulfuric acid (98.08 per cent purity, Nacalai Testique, Inc) with distilled water. A commercial-grade LIX 984N (BASF, Ireland) and diluent Isoper M were used in this study. An analytical grade $CaCO_3$ powder (98 per cent purity, Nacalai Testique, Inc) was dissolved in water to prepare the emulsion used for iron removal. A 28 per cent analytical grade ammonia solution (NH_3) (FUJIFILM Wako Pure Chemical Co., Ltd, Japan) was used for washing the Ni/Co xanthate precipitate. Chemical-grade PAX (Potassium amyl xanthate, $C_5H_{11}OCSSK$) from Wako Chemicals, Japan, was dissolved in distilled water to be used for the complexation of nickel and cobalt.

Metal concentration in the simulated pregnant leach solution from the HPOAL stage.

Element	Fe	Ni	Cu	Co
Concentration, g/L	2.96	0.34	0.30	0.13

Procedure

Solvent extraction of copper

Batch solvent extraction tests were carried out using a countercurrent two-stage mixer settler extraction column illustrated in Figure 1. Copper was selectively extracted using LIX 984N (10 per cent v/v) with Isoper M as a diluent. The initial pH of the PLS was measured to be 1.0, and the pH was adjusted between 1.0–2.5 using a 1 M NaOH solution. For each extraction test, 400 ml of solution and 100 ml of diluted extractant (O/A = 0.25) were simultaneously fed by a pump into the extraction column at about 15 ml/s. The agitation speed was adjusted to the desired set point. Once the extractant has been filled into the extraction column, the respective pump was stopped to avoid air bubbles in the extraction column. The mixing and settling were allowed for 20 minutes to achieve steady-state and clear phase separation. The copper-loaded organic phase was then collected at its respective outlet leaving behind the copper barren aqueous phase (raffinate), which was collected afterward at the aqueous phase outlet. The raffinate solution was analysed using MP-AES to determine the metal concentration and compute the extraction efficiency. Fundamental parameters influencing the extraction process such as pH and mixing speed were investigated.

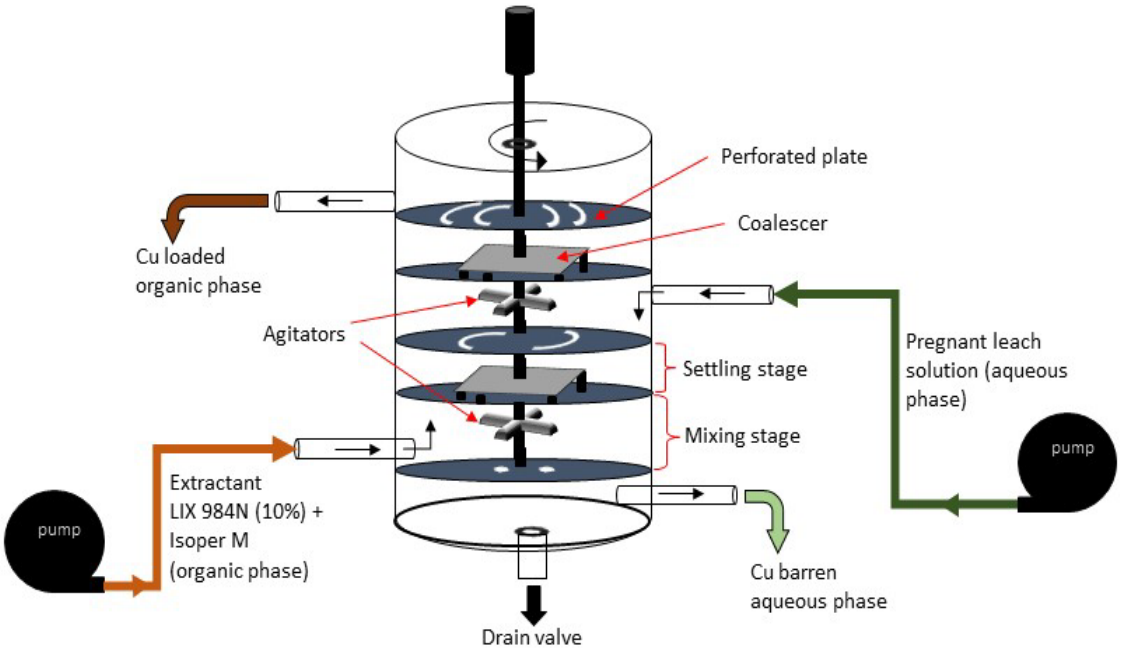

FIG 1 – Experimental set-up of a 2-stage mixer-settler extraction column.

The copper-loaded organic was subjected to stripping experiments using a sulfuric acid solution. The stripping column had a similar set-up as the extraction column. A desired volume of the sulfuric acid solution (50–175 g/L H_2SO_4) and the copper loaded organic was pumped into the stripping column at 15 ml/s and mixed at an agitation speed of 400 rev/min. After 20 minutes contacting, the barren organic and the stripped solution were collected separately from their respective outlets. The strip solution was analysed using MP-AES for copper concentration and determination of the stripping efficiency. Fundamental parameters influencing the stripping efficiency of copper such as H_2SO_4 concentration, and organic/aqueous (O/A) phase ratio were investigated. For copper enrichment in solution, a combination of two extraction stages and two stripping stages were employed. An illustration of the extraction and stripping procedure is shown in Figure 2.

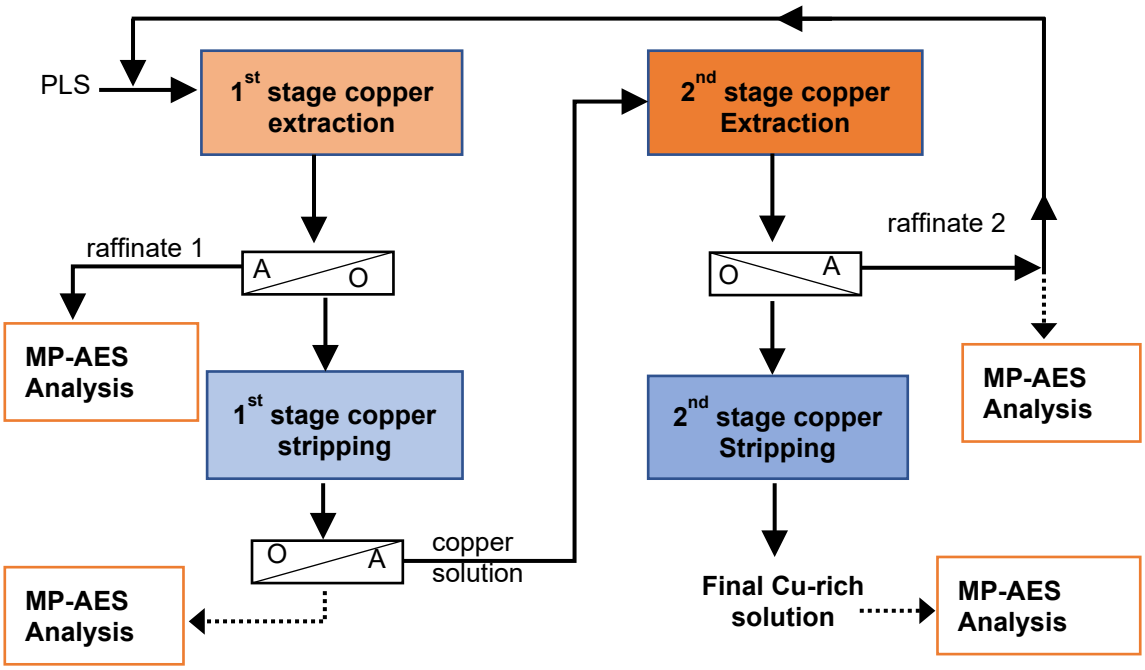

FIG 2 – An illustration of the extraction and stripping procedure of the pregnant leach solution obtained from high–pressure oxidative acid leaching of slag.

Iron removal

The raffinate solution obtained from the first extraction stage contained 0.303 g/L nickel, 0.125 g/L cobalt, and 2.52 g/L iron and was further processed for iron removal. A prepared calcium carbonate emulsion of 200 g/L was added to the raffinate solution in a dropwise manner, to achieve a pH of 4. The raffinate solution was then heated to 65°C using a magnetic stirrer operating at 500 rev/min. Once the temperature reached 65°C the reaction time was set to 20 minutes. The resulting precipitate and the residual solution were cooled and filtered, and the solution was taken for MP-AES analysis for the elemental analysis to determine the precipitation efficiency. The Fe precipitate solids were dried and analysed for mineral composition using XRD while part was dissolved using aqua regia for chemical analysis of the precipitated solids.

Complexation of nickel and cobalt

A PAX solution of 55g/L was prepared and added in a dropwise manner to the 50 ml solution of the raffinate. The pH was investigated between 5.5–8.0, from the initial pH of the raffinate solution (pH 4). The solution mixture was then heated to 50°C using a magnetic stirrer operating at 400 rev/min. The complexation reaction was allowed to proceed for 2 h, after which the solution was cooled and filtered. The residual barren solution was analysed using MP-AES to determine the amount of nickel and cobalt remaining in the solution and accordingly calculate the complexation efficiency. The Ni/Co xanthate precipitate was dried overnight, weighed, and roasted in a muffle furnace at 220°C for 1.5 hrs. After the calcination process was complete, the calcined products were removed and cooled to room temperature before being analysed using XRD for mineral identification. Part of the calcined product was dissolved using aqua regia and analysed for elemental composition using MP-AES.

Separation of nickel and cobalt

The Ni/Co xanthate precipitate was washed with 10 ml of ammonia solution and shaken for 15 minutes using a shaker at room temperature. The solution was filtered and taken for MP-AES analysis to determine the amount of nickel dissolved, while the remaining cobalt xanthate was dried before the calcination process. The cobalt xanthate precipitate was roasted in a muffle furnace at 220°C for 1.5 hrs. After the calcination process, the products were cooled to room temperature and analysed using XRD for mineral identification. Part of the calcined product was dissolved using aqua regia and analysed for elemental composition using MP-AES.

RESULTS AND DISCUSSIONS

Solvent extraction of copper

Effect of stirring speed

The stirring speed was investigated in the range of 200–400 rev/min to find the optimal operating conditions for the extraction of copper from the pregnant leach solution. The results are displayed in Figure 3, showing that as the stirring speed of the column extractor is increased, the copper extraction also increases, with the highest percentage extraction of 98.28 per cent at 400 rev/min. A high stirring speed increases the contact between the organic phase and the aqueous phase thus resulting in the formation of the Cu–LIX984N complex and thus enhancing the extraction of copper from the leach solution. Takahashi and Nii (1999) also noted that the mass transfer coefficient of the organic phase is dependent on the agitation speed. On the other hand, iron carryover to the organic phase had an increasing trend as the stirring speed was increased, which is mostly by entrapment in the organic phase (Schlesinger *et al,* 2011).

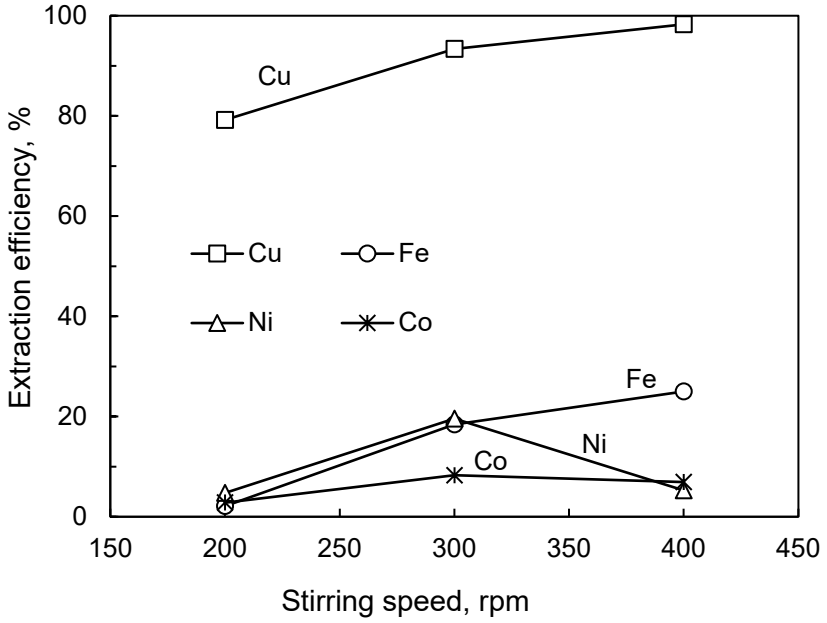

FIG 3 – The extraction behaviour of metals versus the stirring speed. Conditions: O/A ratio 0.25 (100 ml to 400 ml), pH 2.5, solutions flow rate 15 ml/s, and residence time 20 min).

Effect of pH on copper extraction

The pH was investigated in the range of 1–2.5 on metal extractions, and the results are displayed in Figure 4. As the pH was increased, the amount of copper extracted from the pregnant leach solution likewise increased, reaching a high of 98.28 per cent when the pH was 2.5. Banza, Gock and Kongolo (2002) also found that the favourable pH for copper selectivity using LIX 984 was 2.5. The amount of Fe extracted with copper remained below 6 per cent when the pH was 2 or lower, however, when the pH was increased to 2.5, the amount of Fe co-extracted with copper sharply increased from 5.90 per cent to about 25 per cent which is undesirable due to the consequential effects iron has in the upstream processes such as in the electrowinning process. Co-extractions of cobalt and nickel remained low at all the investigated pH values at 2.53 per cent and 1.47 per cent respectively. Therefore, a pH of 2 was chosen as the optimal condition for the extraction of copper (97 per cent) from the pregnant leach solution due to the good separation efficiency of copper from iron, nickel, and cobalt.

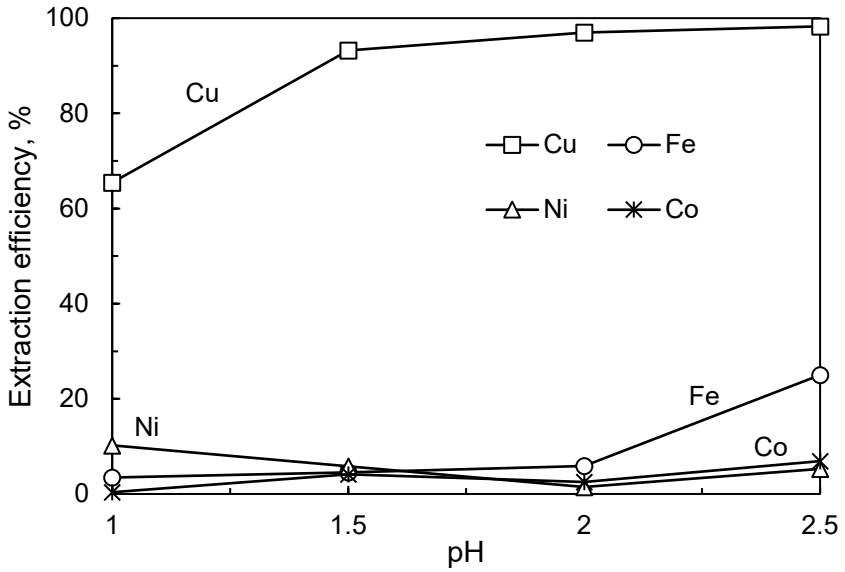

FIG 4 – The extraction behaviour of metals as a function of pH. Conditions: O/A ratio 0.25 (100 ml to 400 ml), agitating speed 400 rev/min, solutions flow rate 15 ml/s, and residence time 20 min).

Effect of sulfuric acid concentration on stripping

The effect of sulfuric acid on the stripping of copper from the organic phase was investigated in the range of 50 g/L to 175 g/L H_2SO_4 concentration (Figure 5). At lower acid concentration, 50 g/L H_2SO_4, copper stripping efficiency was low, and only 66 per cent was recovered from the organic phase while the amount of iron stripped from the organic phase was high at 89 per cent. As the concentration of sulfuric acid increased, so as the separation efficiency between copper and iron. Utilising a sulfuric acid concentration of 175 g/L, a high copper stripping efficiency of 97.28 per cent was achieved, with a lower iron stripping efficiency at 15.63 per cent, yielding a separation efficiency of 81.65 per cent between copper and iron. Therefore 175 g/L sulfuric acid was selected as the optimum conditions for efficient copper stripping from the organic phase.

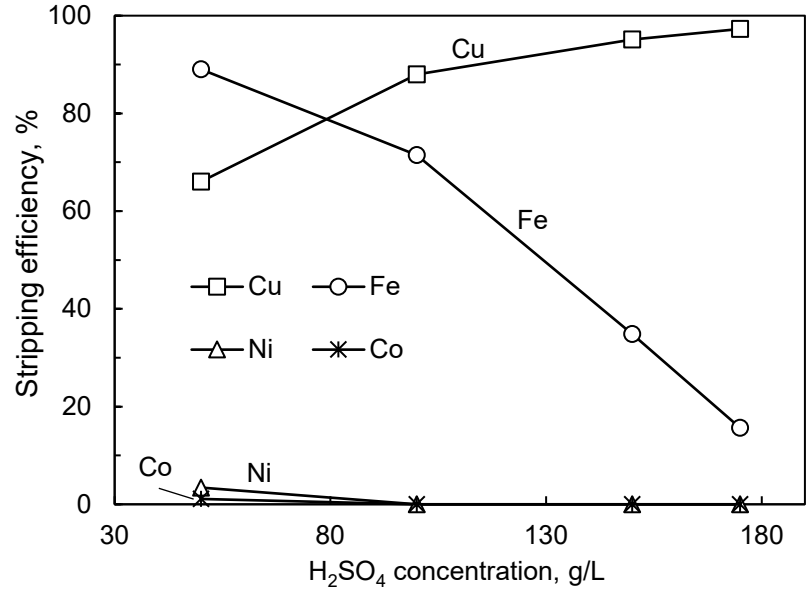

FIG 5 – The copper stripping behaviour of metals as a function of sulfuric acid concentration. Conditions: O/A ratio 0.25 (100 ml to 400 ml), stirring speed 400 rev/min, solutions flow rate 15 ml/s, and residence time 20 min).

Effect of organic/aqueous (O/A) ratio

The organic/aqueous (O/A) ratio was investigated to achieve a higher copper concentration in the stripped solution and the results are displayed in Figure 6. The copper concentration increased from

0.26 g/L to 4.18 g/L as the O/A ratio was increased from 0.25 to 4.0. The concentration of iron slightly increased as the O/A ratio was increased, reaching a high of 1.27 g/L at an O/A ratio of 4. The stripping efficiency of copper was not significantly affected by the increase in the O/A ratio but maintained a stripping efficiency above 86 per cent.

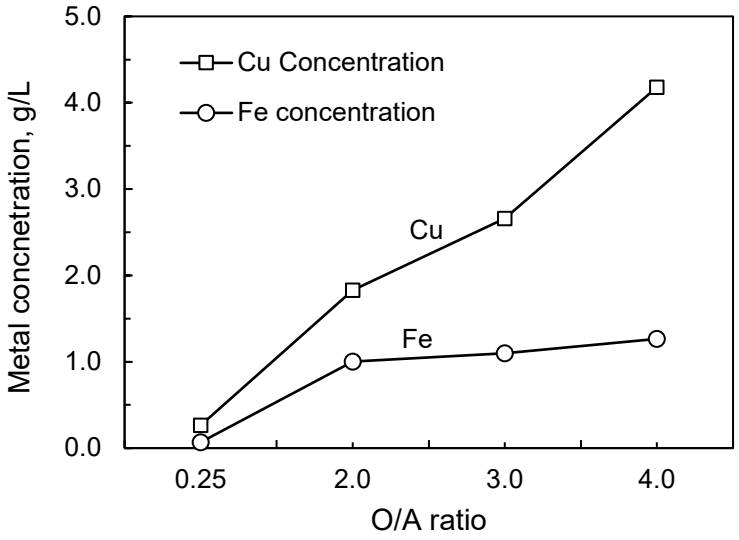

FIG 6 – The effect of the organic/aqueous (O/A) ratio on the concentration of metals in the stripped copper solution. Conditions: H_2SO_4 concentration 175 g/L, stirring speed 400 rev/min, solutions flow rate 15 ml/s, and residence time 20 min).

Two stages of copper extraction and stripping

Two stages of copper extraction and 2 stages of copper stripping were employed to further upgrade the copper concentration in the final stripped solution. The stripped solution obtained under the optimal copper stripping conditions (O/A ratio 4, H_2SO_4 concentration 175 g/L, stirring speed rev/min, solutions flow rate 15 ml/s, and residence time 20 min) was further contacted with a fresh LIX 984N extractant to carry out the second stage of extraction and stripping stages. The conditions of extraction and stripping in the second stages were kept the same as in the first extraction and stripping stages. The copper concentration was successfully upgraded from 4.18 g/L in the first extraction and stripping stages to 22.9 g/L in the second extraction and stripping stages. Moreover, iron concentration was further minimised in the final stripped solution, decreasing from 1.27 g/L to 0.05 g/L in the first and second stripped solution, respectively. The metal concentration of the raffinate (0.4 g/L Cu, 1.57 g/L) obtained from the second stage of copper extraction had a comparable copper concentration to the PLS, therefore it can be recycled back to be blended with the initial PLS feed.

Iron removal

The raffinate solution obtained from the first extraction stage contained 0.303 g/L nickel, 0.125 g/L cobalt, and a higher concentration of iron at 2.52 g/L. Before recovery of nickel and cobalt from the raffinate solution, iron was removed using a calcium carbonate precipitating reagent at a pH of 4. Excellent removal of iron (99.99 per cent) from the solution was achieved, with no residual iron detected by MP-AES. Low co-precipitation of nickel and cobalt was obtained at 3.68 per cent and 2.27 per cent, respectively. The precipitation of iron using calcium carbonate may form iron carbonate solids or a mixture of calcium-iron hydroxides (Bhattacharjee *et al,* 2005). An XRD analysis of the obtained precipitates was carried out and the result is displayed in Figure 7. The main mineral component is shown to be gypsum, while the iron mineral component could not be detected by XRD, indicating that the iron precipitate formed may exist in a colloidal structure, not in a crystalline structure. The precipitate was chemically analysed to contain about 12 wt% Fe.

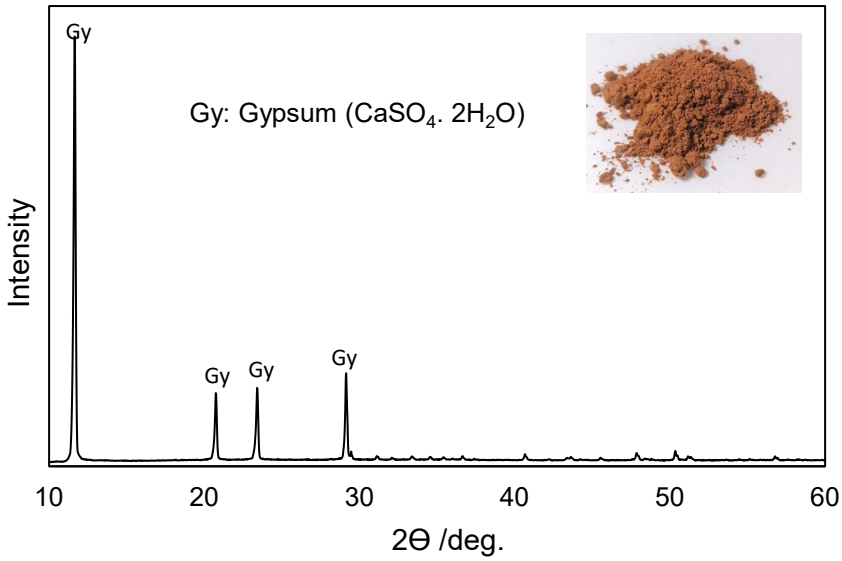

FIG 7 – An XRD pattern of the precipitate obtained after iron removal.

Xanthate complexation of nickel and cobalt

For the recovery of nickel and cobalt from the raffinate solution obtained from the first stage of copper extraction, a xanthate complexation method was used. Potassium amyl xanthate, PAX (potassium-O-pentyl dithiocarbonate), was used as a complexing agent to form complexes of nickel and cobalt xanthates. Nickel and cobalt xanthates form insoluble metal xanthates which are hydrophobic (Yamasaki *et al,* 1963), making it possible to remove nickel and cobalt as xanthate precipitates from the solution. The xanthates' solubility product constant (K_{sp}) is an essential physicochemical parameter affecting the selective extraction of metals in hydrometallurgical methods (Darezereshki *et al,* 2021). Therefore, factors such as the solution pH significantly influence the K_{sp}. Figure 8 shows the complexation behaviour of nickel and cobalt under different pH conditions using PAX as a complexing agent.

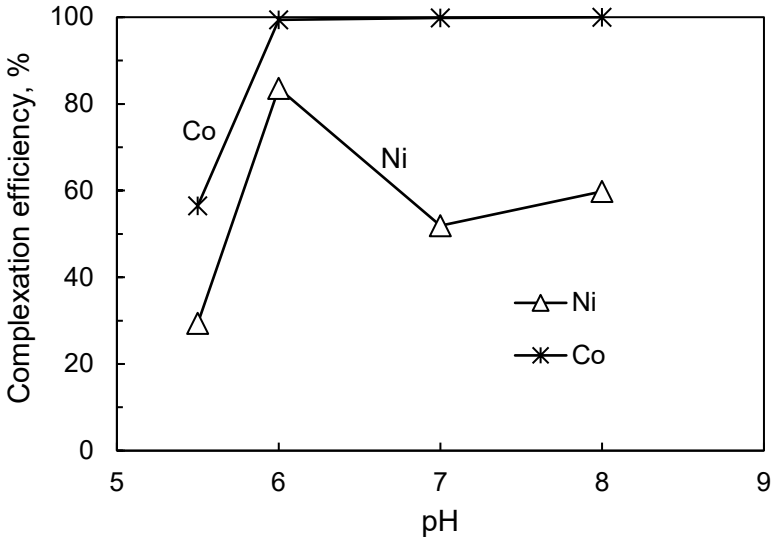

FIG 8 – The effect of pH on the Ni/Co complexation using PAX. Conditions: 50°C, 2 h, 400 rev/min.

The results show that as pH was increased beyond 6, cobalt was completely complexed out of the solution forming cobalt xanthate precipitate. The highest complexation efficiency of nickel achieved was 83.6 per cent at a pH of about 6, while a further increase in pH resulted in a decline in the formation of nickel xanthate. At high pH values, hydroxide ions have been noted to compete with xanthates for metal ions (Zhang *et al,* 2018), and since nickel xanthate is less stable than cobalt xanthate due to its lower K_{sp}, it can easily dissociate resulting in a lower complexation efficiency. Therefore, pH of 6 was selected as the optimum condition for effective complexation of nickel and

cobalt using PAX reagent. The complexation of cobalt and nickel from solution using PAX is suggested to follow reactions (1) and (2) (Vakylabad, Darezereshki and Hassanzadeh, 2021). The balanced reactions (1) and (2) indicate that a PAX dosage corresponding to a xanthate/(Ni+Co) molar ratio of 2 is required to achieve comprehensive complexation of Ni and Co from solution.

$$Ni^{2+} + 2CH_3(CH_2)_4OCS_2K \rightarrow Ni(CH_3(CH_2)_4OCSS)_2 + 2K^+ \quad (1)$$

$$Co^{2+} + 2CH_3(CH_2)_4OCS_2K \rightarrow Co(CH_3(CH_2)_4OCSS)_2 + 2K^+ \quad (2)$$

Separation of nickel and cobalt

For the separation of nickel and cobalt, the difference in their solubility product (K_{sp}) was explored. Since nickel xanthate has a lower solubility product (K_{sp}) than cobalt xanthate (Co (1.0 × 10–13) and Ni (1.4 × 10–12)) (Vakylabad, Darezereshki and Hassanzadeh, 2021), nickel xanthate can therefore be easily dissolved. Additionally, nickel is known to form stable complexes with ammonia (Yang *et al,* 2020), therefore, ammonia solution (NH_3) was used to selectively leach the nickel xanthate complex while cobalt xanthate remained in solid form. The dissolution of nickel xanthate complex using ammonia solution was anticipated to follow the reaction (3). Cobalt was not detected in the wash solution by MP-AES analysis, confirming that almost all cobalt xanthate remained in solid form due to its higher K_{sp}. However, the leaching efficiency of nickel xanthate was marginal, showing only 51 per cent nickel xanthate dissolution when washed with ammonia solution, yielding a nickel ammine solution of 1.6 g/L Ni. The low leaching efficiency of nickel is attributed to the easy hydrolysis of NH_3 to NH_4^+ in an aqueous solution, thereby resulting in insufficient ammonia complexation with Ni^{2+} in the solution (Yang *et al,* 2020).

$$Ni(CH_3(CH_2)_4OCSS)_{2\,(s)} + 6NH_{3(aq)} \rightarrow Ni(NH_3)_6{}^{2+}{}_{(aq)} + 2CH_3(CH_2)_4OCSS^-{}_{(aq)} \quad (3)$$

Thermal decomposition of cobalt xanthate precipitate was carried out in a muffle furnace at 220°C for 1.5 hrs. The XRD pattern of the calcined product is shown in Figure 9. Cobalt xanthate decomposed to form cobalt oxide (CoO) product, which was chemically analysed to be 25 wt% Co. Due to a high nickel carry-over from the ammonia washing stage, nickel xanthate was transformed into nickel sulfide (NiS) as detected by XRD. The nickel content in the calcined product was chemically analysed to be 10.5 wt% Ni.

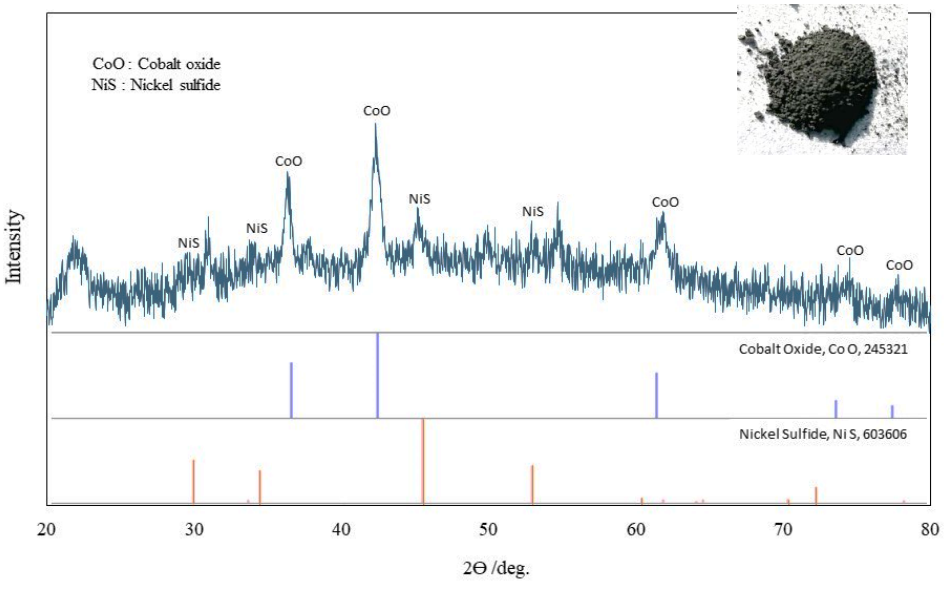

FIG 9 – An XRD pattern of the calcined product obtained after nickel and cobalt xanthates thermal treatment.

CONCLUSION

This study presents a combination of various separation techniques to selectively separate metal ions from the pregnant leach solution (PLS) and upgrade the content of the metals from the dilute PLS. The general findings obtained from the three main processes (solvent extraction, precipitation, and xanthate complexation) investigated can be concluded as follows:

1. Solvent extraction
    - About 97 per cent of copper can be selectively extracted from the PLS at pH 2, with minimum co-extractions of Fe, Ni, and Co, using LIX 984N (10 per cent v/v) extractant. A 175 g/L sulfuric acid solution can effectively strip copper from the organic extractant.
    - Utilising a combination of two extraction stages and two stripping stages, copper concentration in the PLS was remarkably upgraded from 0.3 g/L Cu to 23 g/L Cu with a very low impurity content concentration of 0.05 g/L Fe and no Ni and Co co-extraction in the second stage.
2. Iron removal
    - More than 99 per cent of iron was precipitated at pH 4 by the addition of a calcium carbonate ($CaCO_3$) suspension, with low co-precipitation of nickel and cobalt of around 3.68 per cent and 2.27 per cent, respectively.
3. Xanthate complexation
    - Utilising potassium amyl xanthate (PAX) solution, a pH of around 6 can effectively complex about 83.6 per cent of nickel and 99.4 per cent cobalt from the raffinate solution forming stable Ni and cobalt xanthate precipitates.
    - Due to a higher solubility constant (K_{sp}) of cobalt xanthate, more than 99 per cent Co successfully remained as cobalt xanthate precipitate during the selective dissolution of nickel xanthate using ammonia solution.
    - Thermal treatment of nickel and cobalt xanthate precipitates at 220°C for 1.5 h converted Ni and Co to be recovered as CoO and NiS solids.

This study demonstrates that dilute leach solutions obtained after the extraction of valuable metals from waste materials or low-grade materials can be significantly upgraded by employing various hydrometallurgical processes to qualify them for upstream processing. Therefore, the utilisation of waste materials, such as smelter slag, as a secondary source of valuable metals can be considered viable. More so in the future, as the demand for base metals continues to increase, similarly the metal prices will significantly increase, making the processing of waste and/or low-grade metal sources economically feasible.

ABSTRACT

An alternative leaching system for rare earth element recovery from monazite is under development. The initial stage utilises oxalic acid to convert the rare earth phosphate into an oxalate salt through dissolution and reprecipitation and it is the efficiency of this stage that governs the overall recovery achieved. It has previously been proposed that lixiviant consumption is the primary limitation in this process.

This work further investigates a range of conditions in an attempt to further elucidate the factors influencing the achievable conversion in this stage. It has been shown that the pH may be governed by multiple reactions both consuming and producing acid (thus the mild change over time). The importance of proper mixing and potential to operate at lower temperature with only moderate impact on kinetics has also been demonstrated. Staged/sequential leaching is more effective in fresh solution as opposed to restoring the lixiviant concentration with subsequent reagent addition, suggesting some impact of solution composition. However, contrary to previous findings, subjecting the leach residue to fresh solution resulted in significant decline in leach rate and overall dissolution. This may be because a greater proportion of conversion was achieved in stage 1 in this work than in previous investigation. This may indicate that eventual passivation or the presence of some more refractory REE minerals limits dissolution. Iron dissolution was relatively consistent upon exposure to fresh solution, displaying the ability of the solution to continue to leach the goethite component of the concentrate.

INTRODUCTION

Rare earth elements (REEs) are a crucial component of many technologies, particularly those relating to renewable energy generation (Baolu *et al*, 2017). As such the demand is growing rapidly and is projected to continue growing into the future as these technologies become more prevalent in society. These elements are considered critical not only because of their utilisation, but the risk to supply given the vast majority of global reserves and production originates from China (Chen *et al*, 2018). As such, exploitation of resources outside China have received significant attention. Increasingly, alternatives to conventional processes are being considered for challenging orebodies and waste streams to maximise REE resource utilisation.

Studies conducted at Curtin University have considered the use of various organic acids for disintegration of phosphate mineralisation containing the rare earth elements (REE) (Lazo *et al,* 2017). These minerals are attacked and disintegrated by treatment with these acids, with oxalic acid showing considerable promise in this regard, offering the potential to provide an alternative option for REE production. While investigations have centred on treatment of existing concentrates that are amenable to conventional sulfuric acid bake and water leach technology, the ultimate objective for this process is more likely a niche application where ore or concentrate that is not particularly suited or responsive to conventional treatment or where significant non-recoveries are experienced.

Oxalic acid treatment attacks and breaks down rare earth phosphate mineral structures, releasing phosphorus to solution. The reaction indicated, using RE to signify rare earth element, was proffered as that given in Equation 1 (Lazo *et al*, 2017).

$$2REPO_{4\,(s)} + 3H_2C_2O_4\,(aq) \longrightarrow RE_2(C_2O_4)_{3\,(s)} + 2H_3PO_{4\,(aq)} \quad (1)$$

The insolubility of REE oxalates results in precipitation and collection with the mineral residue. Phosphoric acid is also generated in this reaction.

The solids once separated from the acidic solution are further processed to recover REE, which in this case has successfully used ethylene diamine tetra acetic acid (EDTA) with solution pH elevated to around ten to achieve solubilisation. The use of EDTA alone without the oxalic acid treatment was claimed to not significantly solubilise REE components. It is worth noting that the extent of REE solubilisation in EDTA closely corresponded with the degree of solubilisation of phosphorus in the oxalic acid treatment step. Hence, phosphate concentrations provided a reasonable predictor for the degree of REE release from phosphate mineralisation in the previous endeavours.

Testing also demonstrated that insoluble rare earth hydroxides can then be formed and these, once resolubilised, would be suitable as feed to conventional solvent extraction. A high-level overview of proposed processing has been developed (Lazo *et al*, 2018), but significant efforts are required to develop a processing flow sheet upon which technical and economic valuation could be based.

A key finding from reviewing the initial endeavours is the complex nature of the oxalic acid leach system. Oxalic acid attacked the phosphate mineral at all temperatures. Iron was also dissolved from iron oxides during the oxalic acid treatment. At 25°C the reactions proceeded slowly with only about 13 to 14 percent phosphorus release over 24 hours, with very little iron reporting to solution. At 65°C, a greater extent of phosphorus was released than at 25°C, rising to approximately 30 percent, and iron dissolution too was far greater, closing in on 22 percent dissolution. A notable result was achieved at 85°C, with far greater iron dissolution near 39 percent but less phosphorus release than at 65°C. Overall, the initial results indicated only around 30 percent of the phosphate mineral was attacked by the oxalic acid solution in a single contacting in these series of tests. Iron dissolution increased in line with increased temperature.

Phosphorus and iron are the two major components identified as dissolved by the oxalic acid treatment. In the initial work, iron dissolution reactions were not put forward, but such could be contemplated as provided in Equations 2 and 3.

$$2Fe_2O_{3\,(s)} + 3H_2C_2O_{4\,(aq)} \longrightarrow Fe_2(C_2O_4)_{3\,(aq)} + 2H_2O \quad (2)$$

$$2FeOOH_{\,(s)} + 3H_2C_2O_{4\,(aq)} \longrightarrow Fe_2(C_2O_4)_{3\,(aq)} + 4H_2O \quad (3)$$

These imply an acid consumption response which should lead to increasing solution pH levels. Interestingly, changes in solution pH were less at 65°C and 85°C than at 25°C. Contrary to expectations, the greatest increase in solution pH occurred at the lower temperature of 25°C, the testing with the lowest extent of iron release to solution. Hence, the only minor changes in acidity did not conform particularly well with the iron reactions presented.

The complexity of the system requires greater attention to the mechanisms that limit recovery, these could be soliubility limits of dissolved species, consumption of the lixiviant, passivation through REE reprecipitation, pH alterations or a combination thereof.

OTHER INVESTIGATIONS USING OXALIC ACID OR PHOSPHORIC ACID

The complex nature of the oxalic acid leach system implied by the response in the initial testing directed the need to investigate and establish the types of reactions and behaviours of other minerals seen in other works with this acid. As phosphoric acid is an implied product of the oxalic acid leach, it was deemed appropriate to also investigate the use of this acid in other mineral processing applications. An assortment of materials have been subjected to experimentation using these acids, with some of these investigations as listed in Tables 1 and 2 for oxalic acid and phosphoric acid respectively.

A common theme relating to phosphoric acid treatment of phosphate rock was reprecipitation of phosphorus from solution as temperature was elevated. This is a proposed procedure for recovery of REE. Elevation of temperatures from ambient to around 90°C was described as a route for isolation of REE, either by concentration to mineral residue for subsequent recovery (Bandara and Senanayake*,* 2019; Li *et al*, 2021; Soltani *et al*, 2019; Stone *et al*, 2016) or by direct precipitation from solution as an isolated REE residue (Wu *et al,* 2019a*,* 2019b). Re-formation of REE phosphates, essentially reversing the phosphorus dissolution implied in Equation (1) was the proffered explanation. A representation of such re-precipitation is provided in a simplistic reaction (Equation 4).

$$RE^{3+} + H_3PO_4 \longrightarrow REPO_{4\,(s)} + 3H^+ \quad (4)$$

Phosphoric acid solution is also capable of attacking iron oxides with formation of both ferric and ferrous phosphate complexes (Hernandez-Hernandez *et al*, 2015). Both ferrous and ferric ions are

typically soluble in phosphate solution, with a range of compounds and complexes possible, such as $FePO_4$, $FeHPO_4^+$ and $FeH_2PO_4^{2+}$, or $Fe_3(PO_4)_2$ and $Fe(H_2PO_4)_2$ for instance. Dissolution of iron oxides in phosphoric acid solution could be expected to be acid consuming reactions.

Iron oxide reactions in oxalic acid have also been investigated. A pertinent finding was that hematite in oxalic acid solution, typically at elevated temperatures, results in a reductive leach reaction described by Equation 5 (Lee *et al*, 2006*,* 2007).

$$H^+ + Fe_2O_3 + 5HC_2O_4^- \longrightarrow 2Fe(C_2O_4)_2^{2-} + 3H_2O + 2CO_2 \quad (5)$$

Disintegration of the iron oxide resulted in ferrous oxalate as well as the generation of carbon dioxide, thus destroying oxalate. It was indicated that both hematite and maghemite reacted in this manner, while goethite and lepidocrocite reacted through acid consumption and generation of soluble ferric ion. The reductive leach would result in ferrous ion formation and ferrous oxalate is typically described as insoluble. However, the authors predictive modelling indicated soluble ferrous oxalate with iron concentrations up to 0.1 M in solutions with pH less than 2.

The potential for acid generation from iron dissolution, ferrous ion formation and stable ferrous oxalate solution species was also identified in other sources (Veglio *et al*, 1999). These results speak to the observed pH changes during oxalic acid leaching of the samples in question, as well as highlighting the complexation and reprecipitation of iron oxalate species as possible limitations to REE dissolution, along with oxalate loss as carbon dioxide. The array of metals dissolved in the process of converting the REE phosphate to oxalate may also play a role in oxalic acid consumption, limiting access of the leach solution to remaining monazite in the sample or modification of the pH and Eh.

This paper further investigates the impact of temperature, additional oxalic acid entering the system over time and monitors other metals in solution in an attempt to elucidate the reactions occurring in the system.

EXPERIMENTAL

The approach to flow sheet development has been to conduct experiments that centre on examination of the response of the two main components, phosphorus and iron, which are solubilised in the oxalic acid contacting step. These have examined the influence of temperature on the reactions occurring, residence time and the degree of agitation provided, as measured by dissolution of these two components.

In the first instance, the same flotation concentrate as used in Lazo *et al* (2017) was treated in the work presented here. This was done to allow correlation with the previous results and provide an initial sample with consistent composition (given in Table 3).

TABLE 3

Elemental composition of concentrate as stated in Lazo *et al* (2017).

Element	Grade (wt%)
Ce	14.36
Fe	16.25
La	8.65
Nd	3.32
P	7.24

Leaching experiments were conducted in a 2.5 L stainless steel, baffled reactor with a water jacket to achieve and maintain temperature. A three blade impeller was driven by overhead stirrer at 550 rev/min, unless otherwise stated, was used to suspend the solids and ensure effective solid/liquid mixing. Standard experiments utilised a pH of 1, oxalic acid concentration of 0.8 M, solids concentration of approximately 100 g/L and reaction time of 24 hours. Experiments involved varying

several conditions: temperature (ambient to 65°C), stirrer speed (up to 705 rev/min), and retention time (up to 96 h).

Staged/sequential leaching experiments were also conducted, these involved two modes: introducing additional oxalic acid to the current leach solution and collecting a dry residue from one stage of leaching and subjecting it to fresh oxalic acid with the same initial conditions. These were used to examine whether the limitation is due to the solution factors (solubility limits of dissolved species or reagent consumption) or solid factors (passivation). Samples were collected over time and immediately filtered upon collection, these were analysed with ICP-OES using an Agilent Technologies 5100 instrument.

RESULTS AND DISCUSSION

Leaching of two main components, phosphorus and iron, obtained in the previous test work with a flotation concentrate are presented in Figure 1. The values for the earlier results have been extrapolated from the original graphs (Lazo *et al*, 2017). These curves are presented along with the results of the first test conducted in this series of experiments. All the work was conducted on flotation concentrate reportedly having particle size P_{80} of 83 µm.

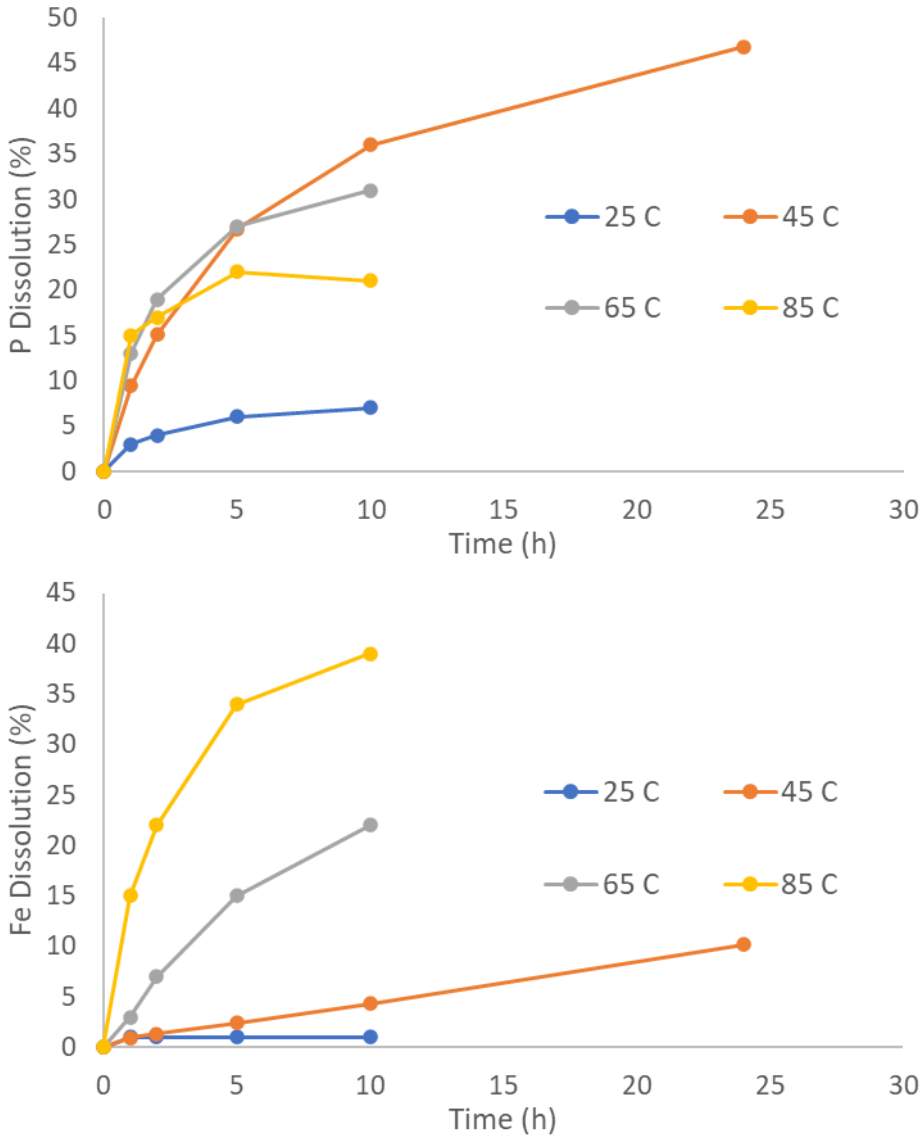

FIG 1 – Results from initial test with baffled tank reactor, 45°C, compared with previous results using different reactors at 25°C, 65°C and 85°C.

These results demonstrate that the baffled tank reactor is suitable for conducting the oxalic acid leaching process. Interestingly, the 45°C results for phosphorus dissolution in the initial two hour

window of operation were comparable to those achieved at both 65°C and 85°C in a different unbaffled reactor. After approximately five hours, the results demonstrated superior phosphorus release to solution than previously achieved at the two higher temperatures. The stalling of the reaction at 85°C in the initial test work after about four hours is evident.

While not initially as rapid, the P dissolution achieved at 45°C was comparable or surpassed that previously reached at both 65°C and 85°C. It's likely that the improved mixing in the baffled tank contributes to this result. Interestingly, while iron dissolution in the current experiment is much lower than seen at higher temperatures, it also continues linearly over an extended period of time rather than a decline in reaction rate over time previously observed. This suggests the rate controlling step is not affected in 96 hours at 45°C be that a reagent consumption or solubility-related phenomenon.

The next series of experiments were conducted with the intention of identifying the influence of temperature on the reaction, the potential to increase phosphorus release through the use of longer residence times, and to also have a preliminary understanding of the influence of the degree of agitation on leach performance. Results of this work are summarised in Table 4.

TABLE 4

Phosphorus and iron release from flotation concentrate in treatment with oxalic acid.

Test	rev/min	Hour	P Dissolution	Fe Dissolution
C1 45°C	545	1	10	1
		2	15	1

		5	27	2
		24	45	9
		48	50	18
		72	51	24

These experiments further demonstrate the superior performance of the baffled reactor, achieving better recoveries again at 65°C, however increasing stirring speed had no additional benefit to the outcome. Over the extended time period, again the initial rapid kinetics at 65°C the P dissolution slowed rapidly and converged with the 45°C reaction extent. This may be that the equilibrium limiting reaction extent is reached more rapidly, or that the much greater extent of iron dissolution (more than four times faster) limits leaching to a greater extent. Without data for a much greater period of time this is unknown.

Subsequent experiments were conducted to understand the impact of oxalate availability to the reaction over time. Conducting the leach at 30°C, additional solid oxalic acid was added to the system in excess to determine whether this was an appropriate method for continuing the leach. This was conducted commencing with a concentration of 0.8 M acid, adding a further 0.75 M after 24 hours and then another 0.5 M equivalent after 48 hours of reaction. These are presented in Figure 2 as subsequent stages at 30° (ie Stage 1: 0–24 h @ 0.8 M, Stage 2: 24–48 h @0.8 + 0.75 M and Stage 3: 48–72 h @ 0.8 + 0.75 + 0.5 M).

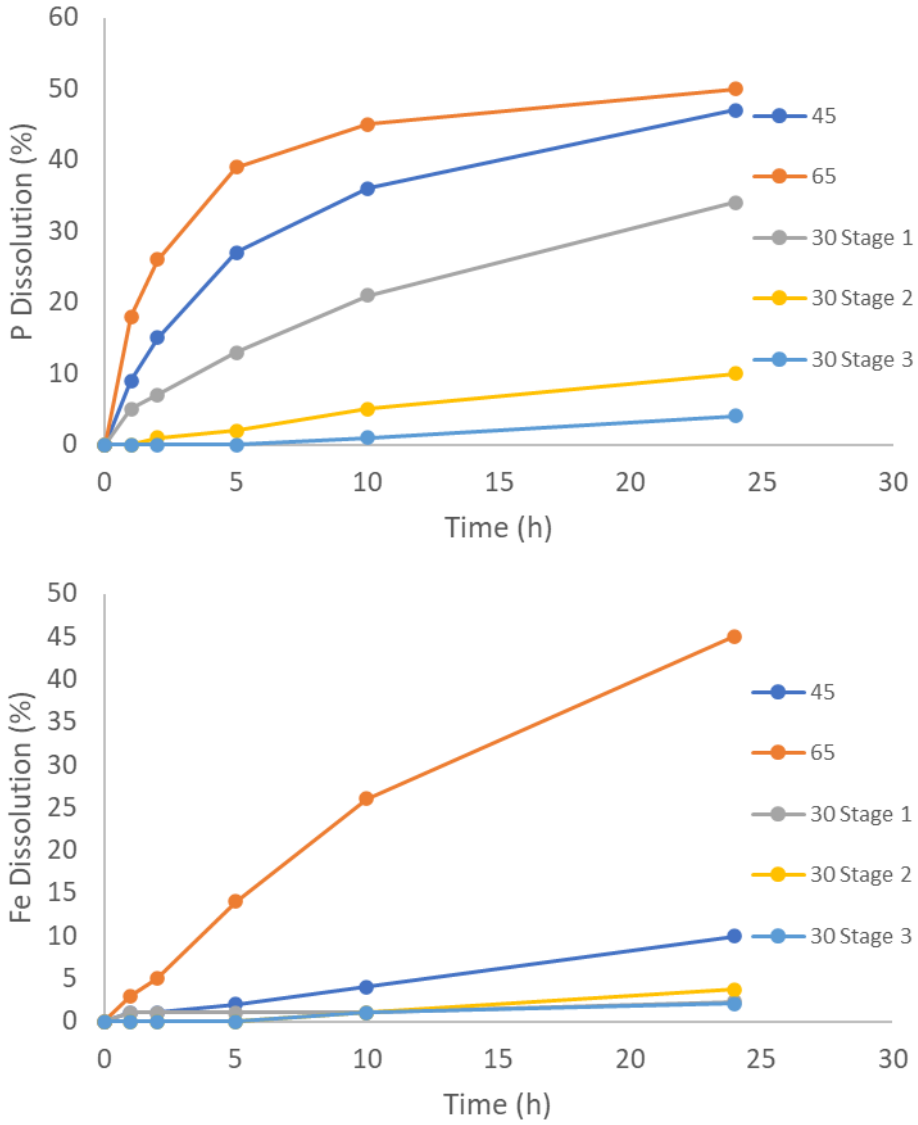

FIG 2 – Oxalic acid leaching at different temperatures and three stages at 30°C.

As anticipated, the leach at 30°C was slower again than that at 45°C and thus was more linear in rate over the 24 h. However, when additional oxalic acid was added, the subsequent 24 h periods showed significantly decreased reaction rates only achieving an additional 10 and 4 per cent P dissolution respectively. There are multiple potential reasons for this, the first being that saturation of the solution with respect to oxalic acid (solubility of ~1 M at ambient conditions) actually slows the

reaction, possibly through precipitation of other phases. Another possibility is the increasing dissolved ions in solution over time decreased the reaction extent, perhaps approaching solubility limits. However, if this is the case, then reactions at higher temperatures should have reached maximum recoveries faster and at lower overall P concentrations in solution.

A similar approach was conducted using the residue from prior tests at 45°C by re-immersing them in collected filtrate with additional make-up oxalic acid (0.8 M). This was again conducted multiple times (Figure 3). The major difference being that due to losses in solid-liquid separation the solids loading of each subsequent step decreased notably. These were effectively 100 g/L in stage 1, 75 g/L in stage 2 and 50 g/L in stage 3. While the premise of the experiment was the same the lower solids loading may promote a greater degree of leaching.

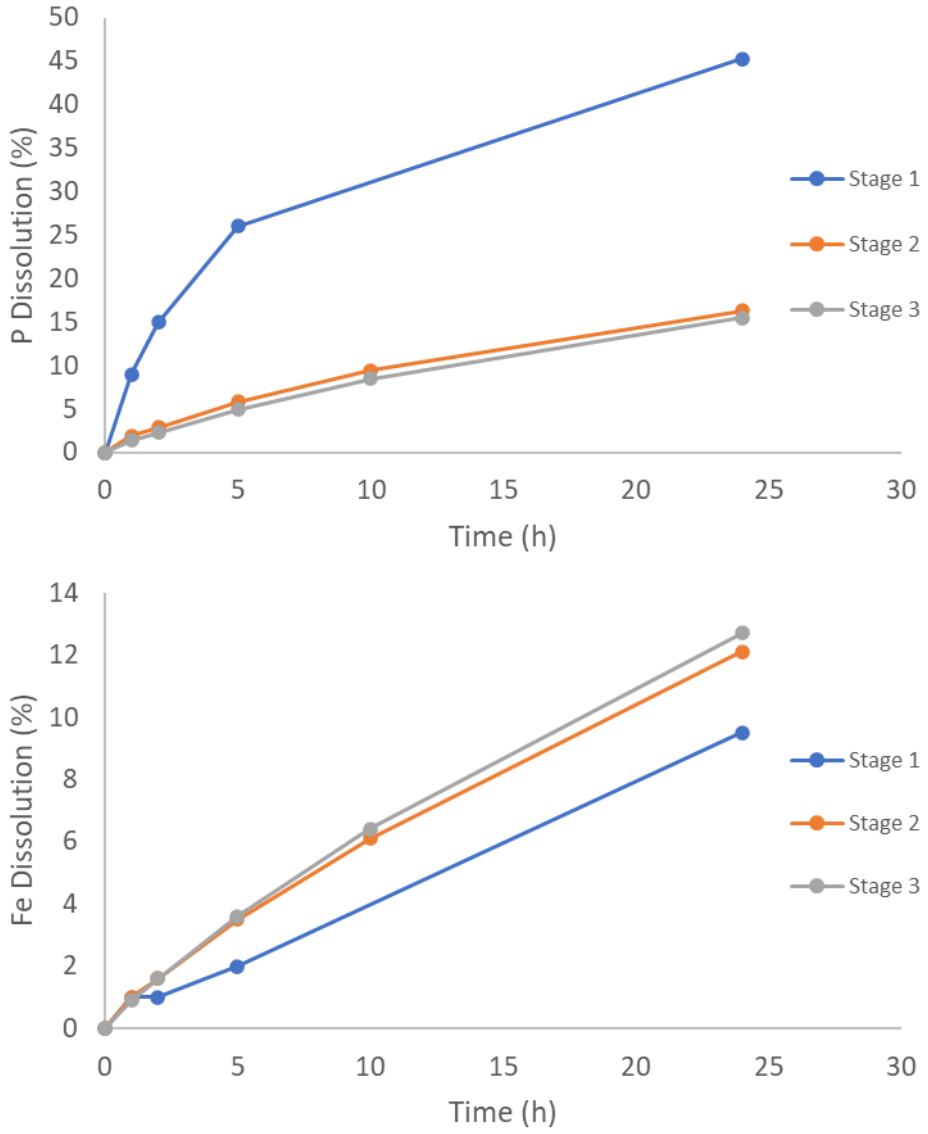

FIG 3 – Oxalic acid leaching in three stages at 45°C.

While a similar trend was observed in that there was a large decline in the P dissolution rate from stage 1 to stage 2, the further drop to stage 3 was minimal. As mentioned, this may be due to solids loading, or the elevated temperature. The overall P release achieved was in excess of 75 per cent, suggesting the 47 per cent reached in three stages at 30°C was unlikely due to increasing concentrations of dissolved ions. It may be somewhat related to the oxalate saturation, however, as the higher temperature promotes more rapid consumption of the lixiviant. This is underlined by the iron dissolution which is several times greater than that at 30°C. Interestingly, the iron dissolution rate increased marginally between the stages, again most likely due to the lower solids concentration of the slurry.

To further understand the impact of solids concentration, a single test was conducted at 200 g/L solids at 45°C (Figure 4). As expected, and in line with previous findings, the leach rate as a proportion of the P present in the sample mass decreased as did iron after some time. This aligns with the observation above regarding improved leach performance with lower solids loading.

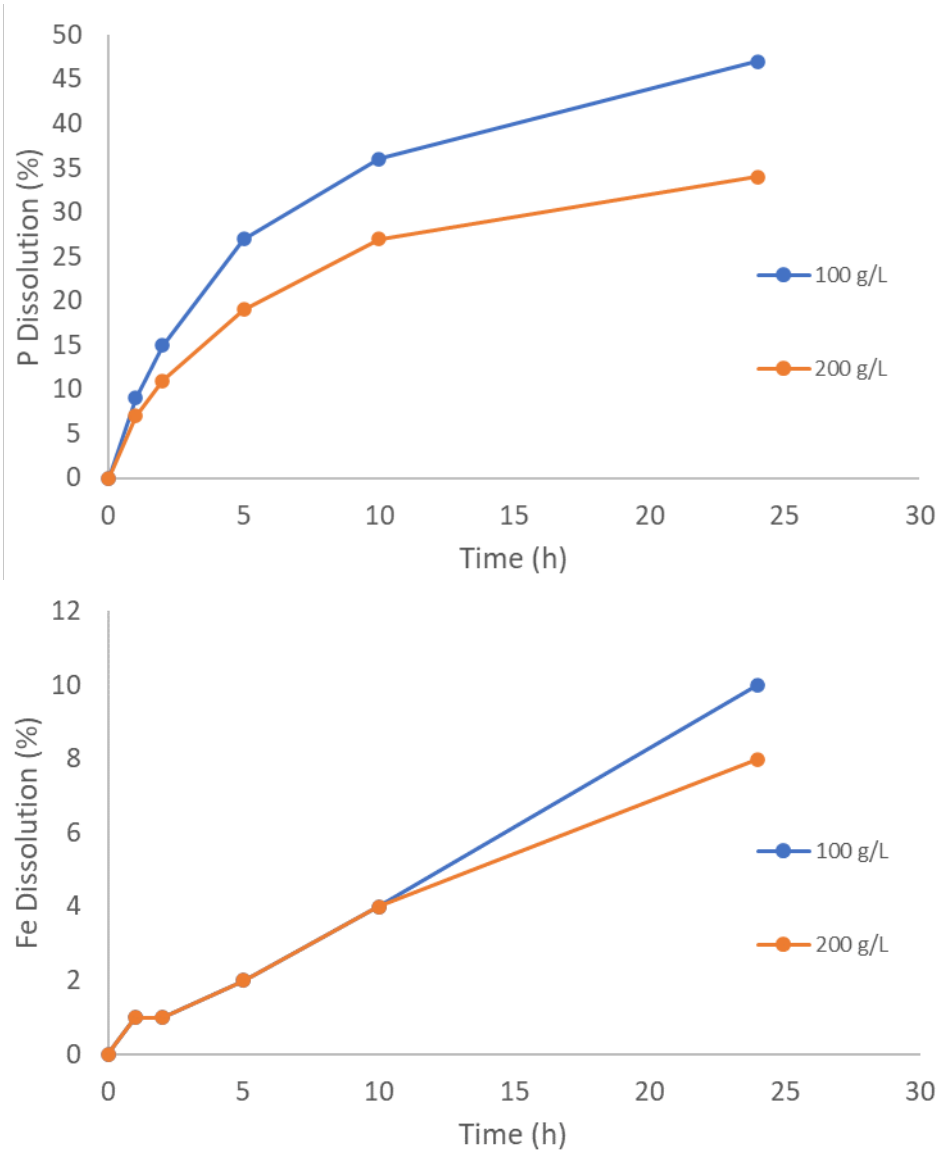

FIG 4 – Single stage oxalic acid leaching at different solids loadings at 45°C.

One aspect of leaching of interest that was observed during this work were the solution pH values. In these tests, once concentrate was added, the pH typically dropped and then tended to increase over time as the test continued. While problems were experienced in obtaining properly buffered values and drift commonly occurred between samples so that only the trends should be noted, the results are consistent with an acid generation type reaction occurring, this potentially relatable to iron dissolution as proffered above. Results are provided in Table 5. The largest pH decrease can be seen relating to the 65°C test, this having the greatest degree of iron dissolution.

TABLE 5

Solution pH trends during oxalic acid treatment.

Test	Hour					
	0	1	2	5	10	24
45°C C1 Stage I	1.0	0.9	0.9	0.9	0.9	1.1
65°C C2 Stage I	0.9	0.8	0.8	0.8	0.8	0.7
45°C C3 Stage I	1.0	0.9	0.9	0.9	1.0	1.0
45°C C4 Stage I	1.1	1.0	1.1	1.0		1.0
45°C C5 Stage II	1.0	0.9	0.9	0.9	0.9	1.0
30°C C6 Stage I	1.1	1.2	1.2	1.1	1.2	1.0
30°C C6 Stage II	1.0	0.9	1.2	1.1	1.2	0.9
30°C C6 Stage III	0.9	0.9	1.1	1.1	1.1	0. 9
45°C C7 Stage II	0.9	0.9	0.9	0.9	0.9	0.9
45°C C9 Stage III	1.0	1.0	1.1	1.0	1.1	1.1
45°C C8 Stage I	0.8	0.8	0.9	0.9	0.9	1.2

The zero hour pH measurement was prior to addition of concentrate.

REE concentrations in the oxalic acid solutions used in these tests remained at low levels. Maximums of around 20 ppm were seen for lanthanum and cerium in the 65°C test, otherwise they were typically less than 10 ppm. This is in line with the previous observations that REE oxalate precipitates were formed. Testing is underway with EDTA to confirm resolubilisation occurs and that the use of phosphorus concentrations are indicative of REE phosphate mineral disintegration through the oxalic acid contacting.

The results for several other elements in the first stage oxalic leach were obtained. Given the limited testing to date, some caution is warranted in examining the values presented, but there are interesting trends. These can be seen in Figure 5.

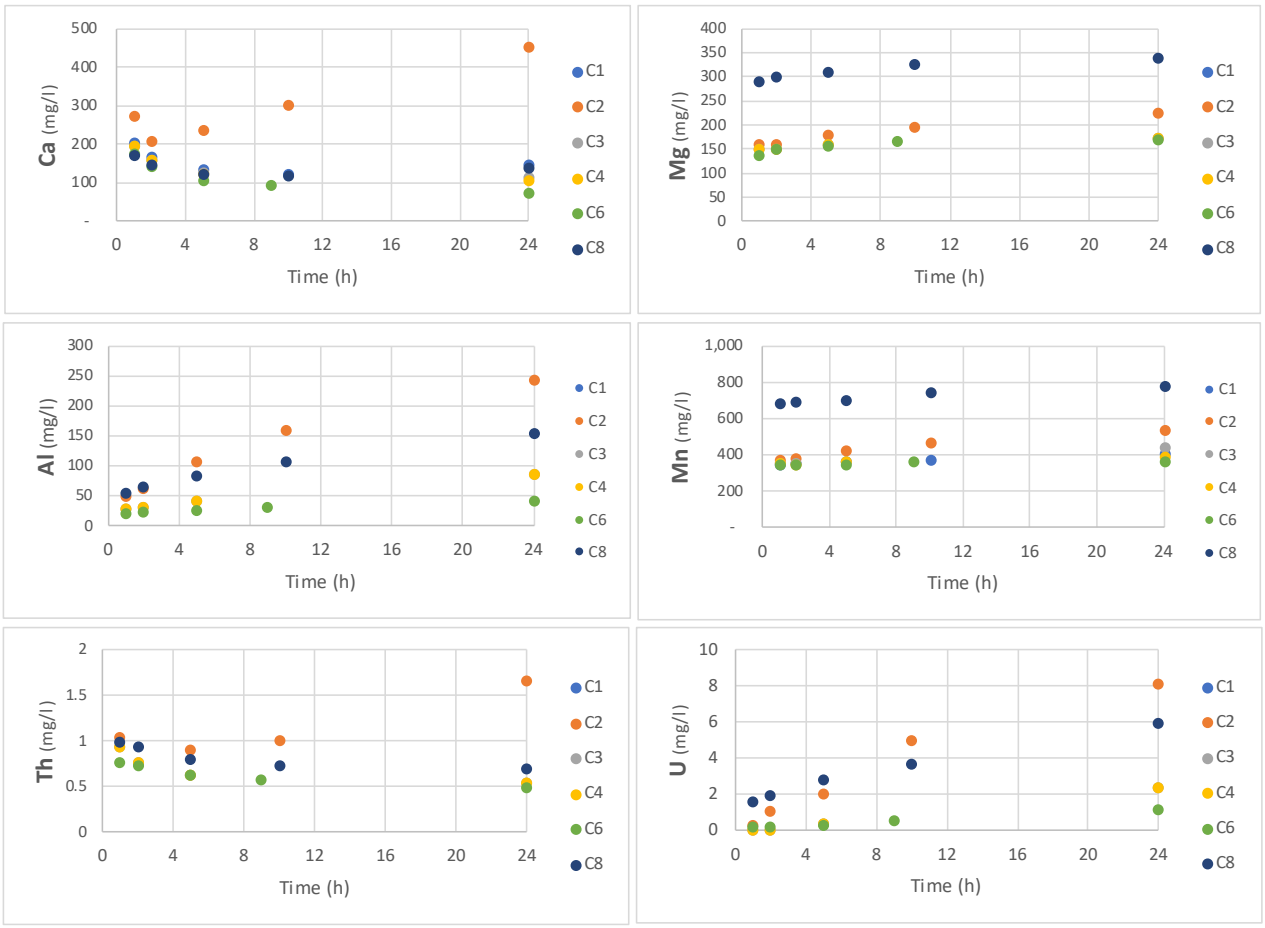

FIG 5 – Concentrations of various other elements in solution.

Calcium, magnesium and thorium rapidly reached moderate levels and then plateaus which agrees with the solubilities of their respective oxalate salts. Manganese displayed similar behaviour but should be moderately soluble in weak acids. There was a slight increase in dissolution over time suggesting a proportion of the Mn is being exposed slowly during leaching of other components of the concentrate, perhaps the iron phases. In any case, available Mn is rapidly leached in this system.

Aluminium dissolves relatively slowly but quite linearly over the leach duration in a similar vein to iron. Uranium display similar behaviour but at very low levels, indicating that the radioactive components may actually behave quite differently in the leach systems. While these present limited insight into rare earth conversion and phosphate dissolution, they are very important for environmental and safety concerns around radioactive material and impurity separation and byproduct generation as the overall composition of the leach solution wil govern how effective those approaches are.

CONCLUSIONS

Oxalic acid is capable of dissolving REE phosphate mineralisation present in a REE flotation concentrate, releasing phosphorus to solution while the REE remain in the residue. An operating temperature of 45°C produced favourable results with the experimental apparatus used here, essentially matching and in some cases bettering results achieved at higher temperatures in earlier work with an unbaffled reactor, at least for a single stage of leaching.

Results to date have been consistent with the requirement to operate with a multi-staged cross-flow leach approach, but have only realised around 77 percent overall phosphorus mineral decomposition as measured by phosphorus concentrations in solution. Efforts are underway to evaluate whether further improvements can be achieved.

Potential phosphorus release mechanisms and solubility limitations relating to temperature and phosphorus (phosphate) concentrations are in accord with findings elsewhere. Similarly, iron

dissolution through a combination of acid consumption and acid generation mechanisms appears to account for the reaction response, where this is in accord with results obtained in other works by various investigators.

ACKNOWLEDGEMENTS

INTRODUCTION

In the processing of refractory gold-bearing sulfides, pressure oxidation (POX) is commonly known for its role in liberating the gold in solid-solution via oxidation of the sulfide occlusions. For deposits that contain arsenic-bearing species including arsenian pyrite and arsenopyrite, POX serves an important secondary function in the fixation of arsenic, via the hydrothermal precipitation of stable arsenates such as scorodite and basic ferric arsenate sulfate (BFAS). There have been various investigations on the impact of different POX conditions on arsenic precipitation and the stability of the formed phases, but less is known about the changes to the arsenic carrier that occur in the curing stage, which follows directly from POX.

The primary function of curing is to coax the dissolution of sulfates to reduce lime consumptions during cyanide leaching, and the slurry is kept at elevated temperatures near 100°C to achieve this. While the arsenic-bearing phases are expected to undergo transformation during this stage, there has thus far been limited experimental evidence. In this study, the effect of curing time and curing temperature on the arsenic-bearing species and arsenic deportment in the POX product has been investigated. Leaching of the curing products was also conducted to examine the stability of the arsenic species in the solid precipitates.

METHODS

The synthetic feeds used in this study were prepared using mixtures of pyrite (FeS_2; ~98 per cent purity) obtained from Crystal World and arsenopyrite (FeAsS; ~93 per cent purity) obtained from the Renison Bell mine. Prior to curing, POX was first conducted for synthetic mixtures of pyrite and arsenopyrite at varying compositions to target iron-to-arsenic ratios between 1:1 to 10:1. This was performed to examine the different effect of curing on varying ore feeds. During POX, the samples were reacted for one hour under pure oxygen at a total pressure of 30 bar at varying temperatures between 180–220°C at pH 1.5. For each run, the POX product was cooled to the designated curing temperatures and the reaction vessel was depressurised before being cured as-is. A modified toxic characteristic leaching procedure (TCLP) was used as a simple measure of the stability of arsenic for comparison between the precipitates formed under the studied conditions.

RESULTS AND DISCUSSION

Effect of curing time

The effect of curing between 0 to 24 h at 90°C following POX was investigated for synthetic feeds with iron-to-arsenic rations between 1:1 to 10:1, with the product characteristics as shown in Table 1. Based on X-ray diffraction (XRD) studies, the POX temperature appeared to have no effect on the phases of the mineral product exiting the stage and entering curing. For the POX feeds with iron-to-arsenic ratios of 1:1 (pure arsenopyrite) and 2:1, BFAS was found to be the major product following POX prior to curing. For the 1:1 samples, BFAS remained as the major product following curing up to 18 h, after which scorodite was observed to be the major product up to a curing time of 24 h. The evolution of the arsenic-bearing species over 24 h of curing can be seen from Figure 1. This suggests that the formation of scorodite may proceed via transformation from BFAS rather than precipitation from solution, though the transition to scorodite was also associated with a significant increase in arsenic precipitation from solution. BFAS remains as a minor product, indicating that the transformation is incomplete and expected to continue at extended curing times. This transformation

was absent in the 2:1 samples studied here, with BFAS being detected as the major solid phase at up to 24 h of curing.

TABLE 1

Summary of the characteristics of the POX product under varying feed Fe:As ratios, POX temperatures, curing times and curing temperatures.

Feed Fe:As	POX temperature (°C)	Curing time (h)	As in solids product (%)	As in solution product (ppm)	As in TCLP extractant (ppm)
1:1	180	0	39.5	1207	12.4
		1	38.1	1733	9.8
		24	38.7	1290	4.5
	200	0	36.2	1784	12.5
		1	32.4	2126	15.1
		24	41.2	1186	5.4
	220	0	38.1	2192	10.2
		1	36.4	1624	7.0
		6	40.5	2299	6.6
		18	42.0	596	5.1
		24	41.4	391	6.6
		24 at 60°C	40.7	1594	5.2
		24 at 120°C	41.6	513	4.2
2:1	180	0	26.4	209	14.0
		1	26.5	483	6.1
	200	0	25.1	72	9.3
		1	22.8	216	4.4
		24	25.4	564	5.1
	220	0	27.7	130	12.2

	200	1	16.6	215	33.1
	220	1	17.8	181	140.8
10:1	180	1	9.1	177	220.7
	200	1	6.4	169	409.0
	220	1	9.7	122	304.5
		24	12.1	508	354.0

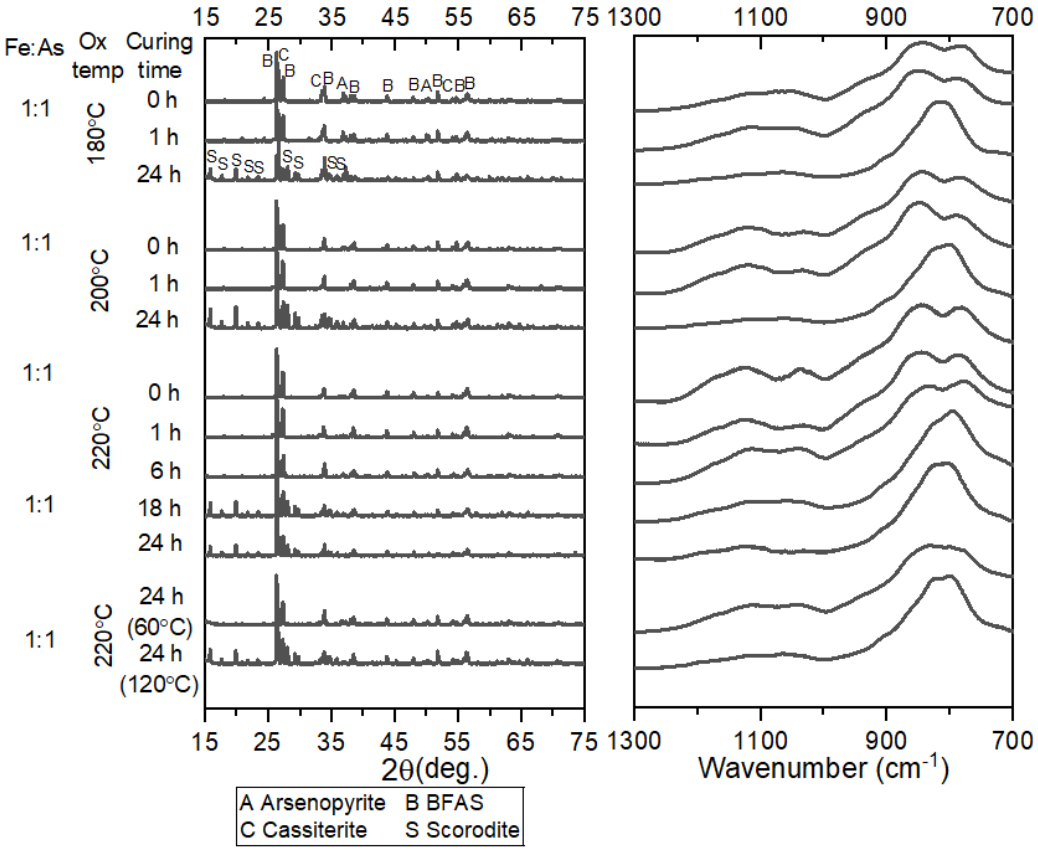

FIG 1 – XRD and normalised FTIR spectra for the product formed after curing at 0–24 h, following pressure oxidation of pure arsenopyrite (Fe:As of 1:1) at 180–220°C. Unless indicated otherwise, curing was conducted at 90°C.

An arsenic-bearing mineral could not be identified in the solids phase for most of the 4:1 samples and all 10:1 samples, potentially due to the low concentrations of the arsenic-bearing phases. X-ray photoelectron spectroscopy (XPS) suggests that the arsenic in these samples is present as adsorbed As_2O_5 species. There might also be low incorporation of the arsenic in hematite, as well as in sulfate minerals via substitution with arsenate groups. While curing for one hour did not result in any apparent changes to the arsenic-bearing phase, a general increase in the dissolved arsenic was observed, suggesting the dissolution of weakly-adsorbed arsenic species or unstable precipitates in the first hour.

Effect of curing temperature

The impact of curing at 60°C and 120°C was investigated for the 1:1 samples, at a curing time of 24 h. The formation of scorodite was observed following curing at 120°C, similar to 90°C, but the product remained as BFAS at 60°C after 24 h, as shown in Figure 1. Despite the absence of scorodite, the Fourier-transform infrared (FTIR) spectra for the sample after curing at 60°C is clearly different from the other BFAS samples, resembling a transformation in progress. While arsenical ferrihydrite is known to form near 70°C, this is unlikely here due to the low pH conditions. As the temperature regime would dictate the phase stability and rate of transformation, the formation of scorodite might occur at lower time scales at 120°C, though a follow-up study has yet to be conducted.

Arsenic stability

The formation of scorodite under extended curing times not only results in increased arsenic precipitation, but also improved the stability of the arsenic carrier. The arsenic extracted from the TCLP studies drops from approximately 10–15 ppm for the BFAS product to around 5 ppm following the transformation into scorodite, as shown in Table 1. This also suggests that the BFAS may be moderately crystalline, as other studies have achieved TCLP results below 5 ppm for BFAS. The extracted arsenic for the samples cured for 24 h at 60°C to 120°C were similar, with the 60°C sample

exhibiting low extractability despite the absence of scorodite. The TCLP arsenic extract for the 10:1 samples were substantially higher at 220–410 ppm despite initially containing less arsenic in the POX feed, suggesting that high feed ratios of arsenic-to-iron may be necessary to encourage the formation of stable precipitates.

ACKNOWLEDGEMENTS

The authors acknowledge the financial support provided by Zijin Mining and the Australian Research Council Linkage Project grant LP160101760 for this work. The authors are thankful to Nadia Zakhartchouk, Zahra Homan, Stephen Grist, Bebeto Lay, Sandro Longano, Susan Holden, Billy Murdoch, the Centre for Advanced Materials and Industrial Chemistry high-pressure research facility and the RMIT Microscopy and Microanalysis Facility. Special thanks to Selvakannan Periasamy, Ylias Sabri and Lydon Alexandrou for their assistance at various stages of this study.

The MTM copper process

R W Shaw[1]

1. FAusIMM, Director, Minetometal Pty Ltd, Melbourne 3054 Vic. Email: rwshaw3050@gmail.com

ABSTRACT

The MTM Process targets treating lower grade and/or problem concentrates that are not attractive to smelters. The process has been developed at laboratory scale for copper and is based on a related development for zinc that has been extensively developed both in the laboratory and through pilot testing.

The basis of the process is novel ammonia-ammonium chloride leach chemistry adapted to give high copper extraction whilst being selective over iron, arsenic and many other elements. The preferred flow sheet depends on location, especially infrastructure and utilities. These impact upon the leach and crystallisation stages more than copper reduction.

The drivers behind the development have been:

- Minimising CAPEX – no SX-EW steps, no acid plant.
- Flexibility on concentrate grade and impurities.
- Inert residue:
  - Sulfur fixed as calcium sulfate not acid or elemental sulfur.
  - Iron as iron oxide.
  - Arsenic as calcium arsenate and/or ferric arsenate.
- Break point in product at site – can be C.
- copper oxide and/or copper metal.
- Flexibility in energy source – can be any combination of wind:
  - Solar thermal and solar photovoltaics.
  - Biomass.
  - Coal.
  - LNG and/or natural gas.
- Recovery of gold and silver as well as copper.
- Suitable for smaller scale (<50,000 t/a) operations.

A process design for a 50 000 t/a plant has been developed sufficient to enable estimates for the CAPEX and OPEX. The CAPEX estimate of ~US$4060/installed annual tonne suggests the process will be lower CAPEX than alternative hydrometallurgical processes being developed for copper concentrates. This stems from having a much simpler leach circuit and through not requiring solvent extraction and electrowinning. The OPEX cost of ~US$517 is comparable to other hydrometallurgical processes and of the same order as historical treatment and refining charges.

Minetometal doubts that the process will be competitive with existing smelters for high quality concentrates but has niche opportunities for deposits which struggle to make readily marketable concentrates. The process chemistry has been confirmed at laboratory scale, but considerably more laboratory and pilot scale development are needed to bring the process to being ready for commercialisation. Minetometal aims to continue development and reach the commercial ready stage within the next 2–3 years.

INTRODUCTION

The MTM Copper Process has been developed to enable more economic copper production from a range of copper materials including sulfides. The process is particularly suited to problem deposits

where it has proven difficult to produce the high-quality concentrates required by conventional smelters. The process can treat low-grade concentrates and/or concentrates with problem impurities such as arsenic and radionuclides.

The current dominant process for producing copper metal from sulfide ores is to make a copper concentrate via comminution and flotation and then smelt the concentrates at high temperatures to make an impure blister copper. This is then electro refined to give high purity metal and to recover other valuable components especially gold and silver. The sulfur is converted to sulfuric acid for sale or for use in heap leaching.

The economics of the process are very dependent on the costs for building the smelter and the cost of transporting the concentrate to the smelter. The CAPEX of smelters is high, and these are invariably large installations which benefit from economies of scale. The transport costs and penalties imposed by the smelters for impurities and low copper grade are restrictive on the miners and force them to produce high-grade, high purity concentrates which may not be ideal for the overall deposits being mined.

There have been many attempts over the last 50 years to find an alternative low temperature process capable of making copper metal from a range of ores and concentrates without the high CAPEX needed for building a large smelter. These processes have also targeted processing problem ores and/or concentrates which are high in toxic heavy metals such as arsenic which many of the existing smelters will not accept as feed material.

Despite these concerted efforts none of the processes developed to date have achieved significant commercialisation. There has been some success with two medium scale plants being used to treat chalcocite which is the most readily leached of the copper sulfide minerals. Chalcopyrite is much more refractory and difficult to leach and to date there have only been a few small tonnage demonstration plants built.

The processes developed have mainly focused on using an oxidative acidic leach to dissolve the copper. A major drawback of these acid systems is that the iron also dissolves and must be precipitated. Another drawback is that the sulfur present most commonly reports as a sulfate which needs precipitation with lime to form an insoluble calcium sulfate that can be separated into the residue. This precipitation step is difficult and often consumes more than the stoichiometric lime requirement especially where the lime also precipitates acid required for the leach step.

Other challenges facing these processes is that solvent extraction followed by electrowinning are needed and these are both high CAPEX and OPEX operations. They are well established technology and widely used for heap leach operations where the costs are offset by not requiring a concentrator and the lack of choice as producing a concentrate is not possible.

Apart from the acid systems there have also been some attempts to use ammonia leaching over the past 100 years. A commercial plant was built using the Arbiter Process and another using a variation of this for partially leaching chalcocite concentrate at Escondida. These were not commercially successful and were uncompetitive with smelting. Their major challenges were the need for the high-cost solvent extraction – electrowinning steps and issues with ammonia recovery and managing sulfate build-up in the system.

OVERVIEW OF THE MTM COPPER PROCESS

The key to the process is using an ammonia-ammonium chloride lixiviant to selectively dissolve copper and then precipitating out high purity copper containing crystals. The crystals can then be reduced to copper metal by a hydrogen containing gas at quite modest temperatures. The process is based on known chemical reactions which have been reported previously and combining those into an overall cost-effective process. The advent of reverse osmosis for managing the water balance and increased use of plastics in construction are important advantages that were not available to many of the earlier workers.

Copper is known to be highly solubility in ammonia-ammonium chloride liquor and depending on the liquor concentration can reach over 100 g/L (Wei *et al,* 2010a). Figure 1 shows laboratory solubility data determined by Minetometal for different concentrations of ammonia in 50 g/L ammonium chloride liquor as a function of temperature.

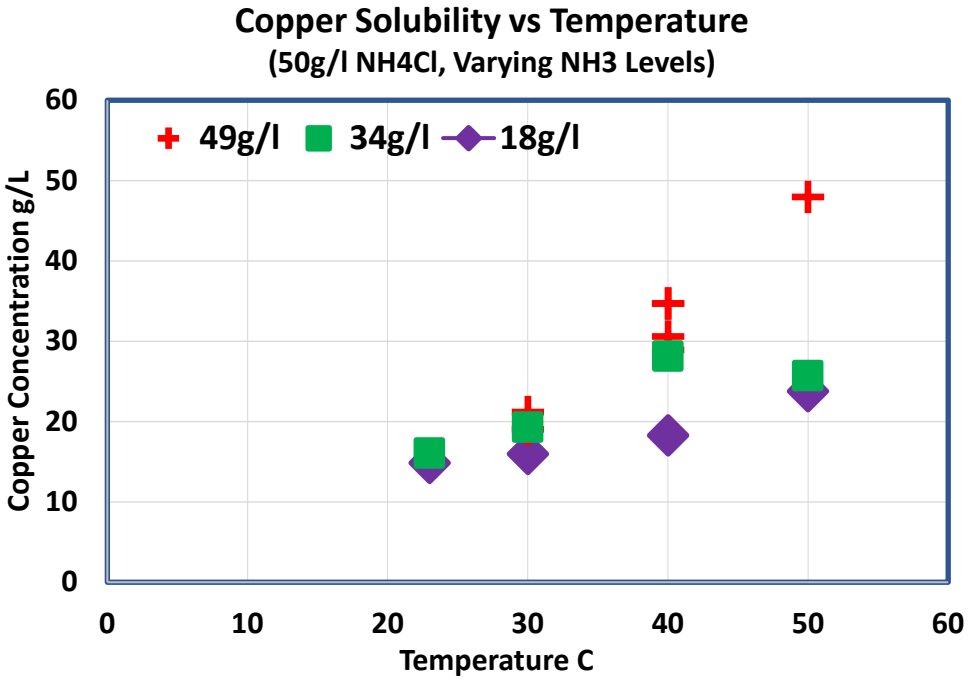

FIG 1 – Copper solubility at varying temperatures and liquor compositions.

The liquor dissolves oxidised copper minerals (Wei *et al,* 2010b; Yartasi and Copur, 1996; Ekmekyapar and Oya, 2003) but copper sulfides and copper metal do not dissolve without an oxidation step either prior to or during the leach (Dixon and Madigan, 1972).

Once dissolved the copper can be precipitated from the liquor by stripping off part of the ammonia and/or cooling to give copper containing crystals. These crystals are either cupric oxide or are suitable for conversion to cupric oxide which is readily reduced to copper metal at temperatures above 200°C (Bond and Clark, 1960).

Minetometal developed two conceptual flow sheets for the MTM Process to utilise the known chemistry for producing copper metal from sulfide concentrates. The two flow sheets shown in Figure 2 have a common crystallisation – reduction section but differ in their approach to oxidising the sulfides to enable their leaching.

A laboratory program has been carried out to confirm the chemistry behaves as reported by others to firm up the flow sheets and provide data for a first pass economic evaluation.

The two options for the sulfide oxidation are:

- Roasting at around 650–720°C in air to convert the copper sulfide to a copper sulfate – copper oxide mixture without the formation of refractory copper ferrites.
- Leaching the sulfide concentrates with oxygen injection such that the sulfides oxidise during the leach.

The choice between the two options depends on a mix of the concentrate composition, the availability and cost of energy and reagents and the target production tonnage.

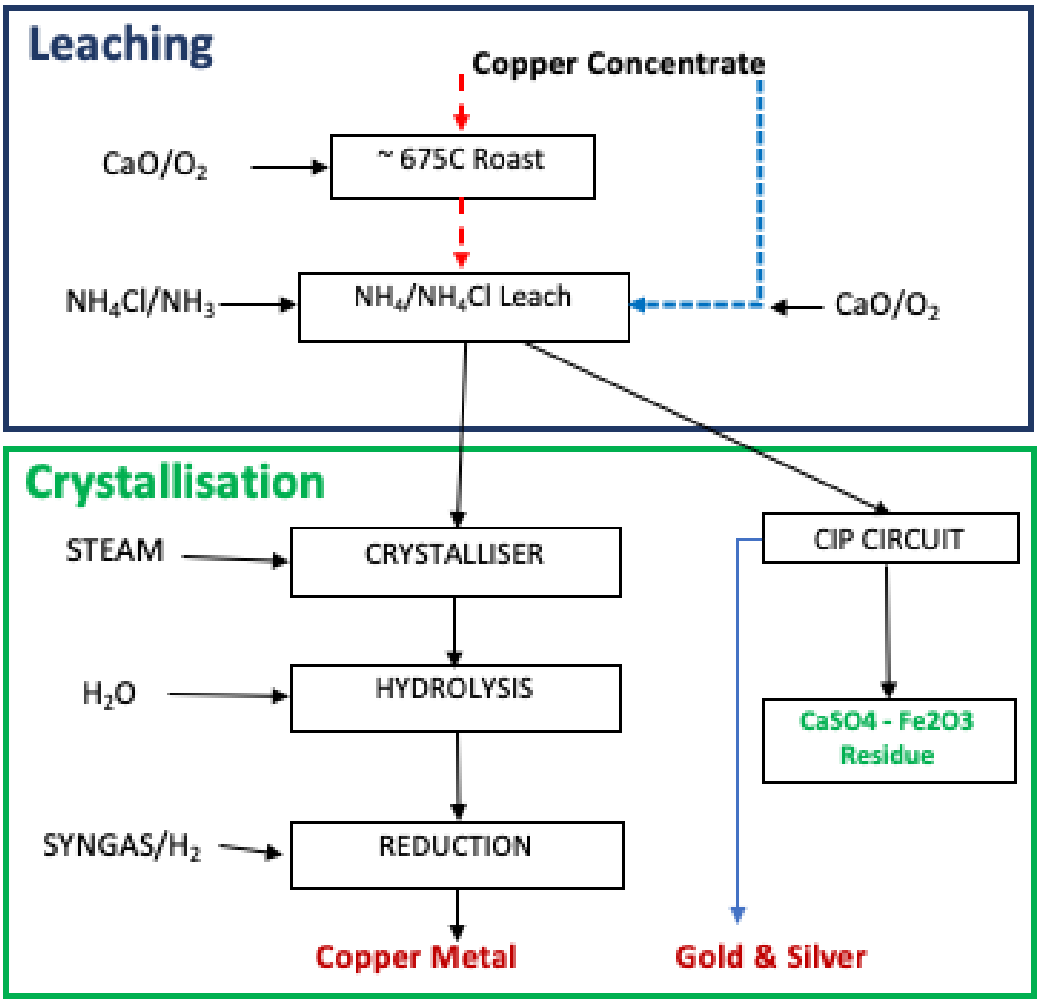

FIG 2 – The MTM process flow sheet.

DEVELOPMENT OF THE MTM COPPER PROCESS

Roasting

Thermodynamically copper sulfides are very difficult to dead roast to copper oxide without the formation of copper ferrites. Complete removal of the sulfur requires roasting at temperatures above 720°C where copper ferrite formation starts to occur. At temperatures below 720°C roasting gives calcine with a mix of copper sulfate and copper oxide. It is not possible to have all the copper report as copper sulfate (Guntner and Hammerschmidt, 2012).

Both copper oxide and copper sulfate are readily leached by the ammonia-ammonium chloride liquor so it is not critical to removal all the sulfur during roasting. The iron is not leached which avoids the problems of the acid systems working from calcine feed. The roasting can be carried out to either generate a high sulfur dioxide off-gas suitable for making acid or as a lime roast where a calcium source such as lime or limestone is added to the roaster to capture the sulfur as calcium sulfate (Bartlett and Haung, 1973).

The lime roast is preferred where the concentrate has a Cu:S ratio above 1 and/or where there is no suitable outlet for sulfuric acid. At Cu:S above 1 the sulfur dioxide of the off-gas is too low for sulfuric acid production with air roasting and even oxygen enrichment struggles to make it an economically attractive acid feed (Guntner and Hammerschmidt, 2012). Laboratory lime roasting at 650°C oxidised almost all the sulfides to sulfate as shown in the X-Ray Diffraction (XRD) analysis for the feed and calcine in Table 1.

TABLE 1

Mineralogy of Concentrate, Calcine and Leach Residue by XRD.

Mineral	Formula	Concentrate	Calcine	Leach residue
Chalcopyrite	$CuFeS_2$	33.5		
Bornite	Cu_5FeS_4	31.1	2.1	
Pyrite	FeS_2	10.5		0.9
Hematite	Fe_2O_3	16.8	27.2	22.5
Quartz	SiO_2	4.8	1.4	0.7
Covellite/Digenite	CuS/Cu_9S_5	3.4		
Chalcocyanite/Brochanite	$CuSO_4$		23.2	
Anhydrite/Gypsum	$CaSO_4$		38.8	73.1
Lime	CaO		2.7	
Tenorite	CuO		3.6	2.6

Leaching the calcine

The copper in the calcine as both copper oxide and copper sulfate leaches in less than two hours in the ammonia-ammonium chloride liquor. The conditions are chosen to give a target copper level rather than by the needs of the leach step. The preferred leach liquor has around 50 g/L ammonium chloride which gives 50 g/L copper in solution and a delta copper across the leach of ~30 g/L. The leach is quite selective for copper over iron and most other impurities such as arsenic.

The sulfate level in the liquor is controlled by dissolving some lime in the spent liquor which then precipitates the sulfate as gypsum as shown in Table 1. Having the calcium in solution prior to the leach avoids the difficulty of reacting solid lime particles with sulfate.

Direct oxidative leaching of concentrates

An alternative approach to obtaining the copper rich pregnant liquor is to leach the concentrate directly in the liquor under an oxygen atmosphere at moderate temperature and pressure. Warman filed a patent (Dixon and Madigan, 1972) outlining the leaching behaviour under a range of conditions and showed that all the sulfide minerals can react reasonably quickly. The sulfur can report as either the sulfate and/or a mix of elemental sulfur and sulfate depending mainly on the temperature, time and ammonia-ammonium chloride ratio (Dixon and Madigan, 1972; Filmer, 1978).

In the MTM Process we prefer to oxidise all the sulfur to sulfate and precipitate it as gypsum rather than leave elemental sulfur in the residue. Forming elemental sulfur requires less oxygen and lime but recovering a marketable sulfur product is difficult and the residue is not well suited to cyanide gold recovery. The elemental sulfur can form AMD (Litke, 2019) so dumping it has environmental issues and the inert gypsum residue is much more acceptable. The lime is soluble in the spent liquor and reacts with the sulfate as it forms avoiding the complex neutralisation circuits such as those in BIOX plants.

Crystallisation

The pregnant liquor from either the calcine leach or the direct oxidative leach typically contains around 50 g/L copper. As the solubility of the copper depends on the ammonia concentration for a set ammonium chloride concentration stripping off the ammonia causes copper containing crystals to precipitate. A process using this approach was patented (Bartlett, 1993) but it was never developed through to a commercial operation. Our work has also found the solubility to have significant temperature dependence such that cooling also causes precipitation.

The MTM Process removes part of the ammonia by steam stripping and then uses indirect cooling to drop the liquor temperature below 30°C. This enables around 60 per cent of the copper in the

liquor to be recovered into crystals while the remainder recycles in the spent liquor which typically contains ~20 g/L copper.

The copper concentration can be reduced further by stripping off more ammonia, but the energy needed per tonne of copper increases and the amount removed depends largely on the local energy cost for the steam generation. In the roasting based flow sheet heat recovery from the roaster supplies a substantial part of the energy required.

The composition of the crystals depends mainly on the ammonium chloride concentration and can be any one or a combination of diamine copper chloride, copper hydroxy chloride and cupric oxide. (Limpo, Luis and Cristina, 1995; Wei *et al,* 2010a, 2010b). Diamine copper chloride is difficult to convert to cupric oxide and/or copper metal and the liquor conditions are controlled such that this does not form. The crystals are usually ammonia free copper hydroxy chloride (atacamite) and/or cupric oxide (tenorite). These can both be reduced to copper metal in a hydrogen containing gas at temperatures above around 250°C.

Reduction

Two alternatives are still being considered for the reduction of the crystals to copper metal and further development work is underway. The choice will in part depend upon the presence of trace impurities in the crystals. The most likely option is to hydrolyse any chloride containing crystals by reacting them with a dilute ammonia solution to convert them to cupric oxide and leave the chloride in solution as ammonium chloride. Laboratory testing has shown this occurs readily with <10 g/L ammonium hydroxide liquor. Trace impurities present in the crystals also dissolve leaving high purity cupric oxides.

An alternative is to place the crystals in the furnace at 250°C without the hydrolysis step and decompose the copper hydroxy chloride to copper oxide (Sharkey and Lewin, 1972) and reduce this to copper metal while simultaneously volatilising the chloride present as hydrochloric acid vapour. This removes the need for the hydrolysis step but requires using materials that can withstand aqueous hydrochloric acid vapour. It also only removes impurities that form volatile chlorides and subsequent purification may be required when the copper powder is melted.

Water balance

All hydrometallurgical processes face issues of managing the water balance to both minimise losses of valuable metals in residues through insufficient washing and to avoid the need for complex bleed streams. The MTM Process makes extensive use of reverse osmosis to internally recycle water between the steps. This adds costs but is an essential part of the process. The liquor chemistry is controlled such that reverse osmosis can readily be applied. The process benefits from the major advantages in reverse osmosis over the past 20 years which have significantly reduced the CAPEX and OPEX of these systems.

DEVELOPMENT STATUS

The process has been developed at laboratory scale for all steps excepting the final copper reduction. This work has proven that the chemistry behaves as expected and has provided data to enable the basic design of a commercial plant. Much of the process is the same as the MTM Zinc technology for producing zinc oxide powder which has been extensively tested and developed through to a 50 t/a pilot scale. A prefeasibility study has been conducted for the zinc technology and the engineering design and cost data from that has been applied to the copper process.

CONCEPTUAL DESIGN OF A COMMERCIAL PLANT

To enable first pass costing and test the practicality of the process a conceptual design has been developed for a 50 000 t/a copper metal plant treating a high-grade concentrate with 33 per cent copper and 22 per cent sulfur. The design uses roasting with added lime for the oxidation step. A simplified Process Flow Diagram showing the main steps, but not internal recycles, is shown in Figure 3.

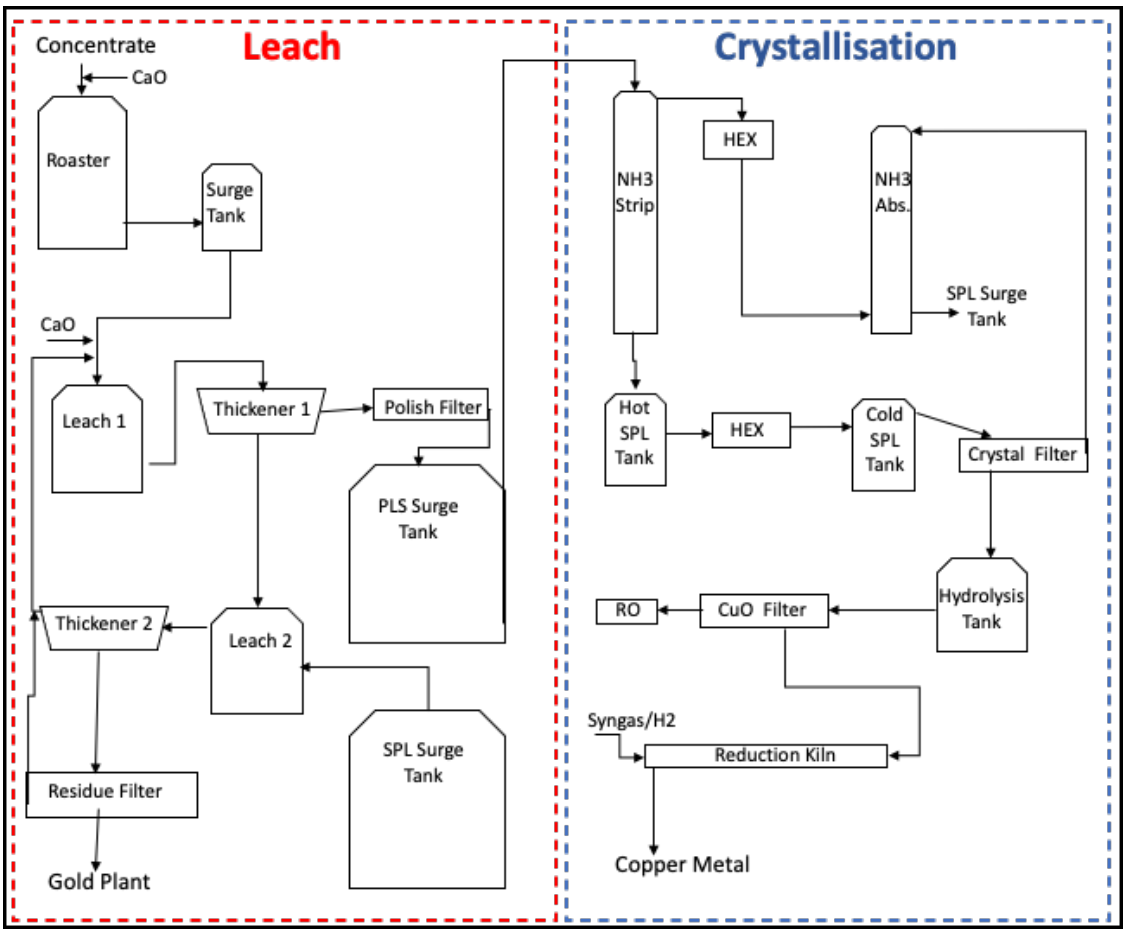

FIG 3 – Simplified process flow diagram for the MTM process.

The concentrate is mixed with lime and fed to a 7 m diameter circulating fluid bed and roasted at 680°C to convert all the sulfide to sulfate with >90 per cent of the sulfur remaining in the calcine as a mix of calcium sulfate and copper sulfate. The low sulfur dioxide off-gas is scrubbed with lime which is recycled to the roaster. The roast reactions are strongly exothermic and water additions are used to control the temperature and ensure there are no excursions leading to copper ferrite formation. The heat from the roaster off-gas is captured and used to provide steam for the ammonia stripping.

The calcine is leached in ammonia-ammonium chloride to dissolve the copper. The leach reaction is quite rapid, and a total residence time of two hours is sufficient. The current preference is to use a simple two stage counter current leach at 60°C to ensure complete leaching of the copper. Unreacted lime in the calcine is supplemented by lime added to the spent liquor to provide a small excess of calcium such that the sulfate present precipitates as gypsum. For 50 000 t/a copper two 300 m^3 leach tanks are sufficient for the leach stage.

The leach slurry is filtered and extensively washed to remove entrained copper and sent to a conventional gold plant. The residue at PH ~10 with minimal reactive copper or sulfur is suitable for the Carbon in Pulp (CIP) and Carbon-in-leach (CIL) processes.

The pregnant liquor from the first leach stage thickener overflow passes through a polishing filter to remove any solids and is then fed to the crystallisation circuit. Around 40–50 per cent of the ammonia is stripped off in a column which is of the order of 3.5 m diameter by 10 m high. Direct steam injection is used to heat the liquor to boiling point and drive off the ammonia. The steam is partly generated from heat recovered from the roaster and part from a conventional steam boiler fired by natural gas. The total energy requirement from the boiler is not large being of the order of 3–5 GJ/t of copper.

The ammonia depleted liquor is then cooled using indirect heat exchangers to below 30°C causing more crystals to precipitate. The liquor does not supersaturate, and the crystallisation rate is quite rapid so the residence time through the crystallisation circuit is quite low typically being <15 minutes

apart from time in the holding tank after cooling. The crystals are filtered off, washed on the filter and transferred to a stirred tank to undergo hydrolysis in dilute ammonium hydroxide liquor.

The cooled spent liquor is pumped to an ammonium absorption column to contact the stripped ammonia – water gas to recapture the ammonia. A cooling circuit is incorporated into the absorption column to maintain the capture liquor at around 30–35°C. The cooling is by indirect heat exchange with liquor circulating through a conventional cooling tower.

The crystals are held in a 100 m^3 hydrolysis tank for around 30 minutes at ~60°C to ensure any copper hydroxy chloride crystals are hydrolysed to cupric oxide and that trace amounts of impurities are leached out. After hydrolysis the crystals are filtered, washed and fed to a rotary kiln operating at 250°C with syngas being passed through to reduce the oxide to metal. The preferred gas is hydrogen but unless green hydrogen is available syngas produced from natural gas is used on both environmental and cost grounds. The copper metal powder can either be briquetted and sold in that form or more probably melted and cast into either ingot or directly into finished products such as wire or tubing.

Having to thoroughly wash the residue and product, and provide clean water for the steam boiler, requires considerable clean water which far exceeds the only outlets which are with the residue and from the reduction furnace. The water balance is maintained using reverse osmosis on selected streams and using the permeate from this for wash water and hydrolysis. The streams selected are those with little free ammonia present as reverse osmosis has quite limited selectivity for free ammonia.

ECONOMICS

The conceptual engineering design for a 50 000 t/a plant has been used to estimate CAPEX and OPEX. Where possible published data for related technologies has been used to supplement the cost data for a prefeasibility study on the related MTM Zinc technology.

CAPEX

A first pass estimate has been carried out for the plant outlined in Figure 3 treating the high-grade copper concentrate using a roaster to oxidise the sulfur and fixing the sulfur as gypsum. The residue is treated in a conventional CIP plant to recover the precious metals. The main costs centres are shown in Table 2. The CAPEX is estimated at US$4060 per installed annual tonne of copper which includes a 40 per cent contingency given the early stage of the development and the generic nature of the estimate.

TABLE 2

CAPEX and OPEX estimates for a 50 000 t/a MTM process plant.

CAPEX	US$	OPEX	US$/t Cu
Roaster	42	Natural Gas	45
Leach – Crystallisation	62	Electricity	35
Reduction Kiln	13	Lime	168
Melt and Cast	16	Reagents	44
Gold Plant	12	Labour	138
Total Installed Cost	145	Maintenance	87
Contingency (40%)	58	**Cost / tonne Copper**	**517**
Total	203		
Cost / t Copper Capacity	**4060**		

The process steps are all high intensity requiring much less equipment than processes such as those using bio-oxidation which require long residence time leaching, separate neutralisation and solvent extraction and electrowinning. The process uses conventional hydrometallurgical equipment all of

which is in operation albeit in different combinations in existing plants. There are no high pressure or temperature steps.

Ammonium chloride is corrosive to most common metals and so the plant is largely designed using plastics with titanium for heat exchangers and impellors. The inclusion of the roaster adds CAPEX, but it also provides significant usable energy for the crystallisation step. It also avoids the need for oxygen injection into the leach tanks. The process is quite suitable for smaller scale plants as the individual steps can readily operate at low tonnages.

OPEX

In common with other proposed hydrometallurgical processes for copper concentrates the operating costs are dominated by the cost of fixing the sulfur as gypsum, the energy cost for producing the metal and labour. The MTM Process avoid the high electricity cost for electrowinning but does require energy for ammonia stripping and gaseous reductant for the copper oxide reduction.

The roaster typically provides around 50–75 per cent of the steam needed for ammonia stripping and this must be supplemented by either solar thermal or fossil fuels. The preferred fossil fuel is natural gas rather than coal due to its lower carbon emissions and CAPEX cost. Solar thermal heating can also be used if the local conditions are suitable. The copper reduction step uses syngas from natural gas unless cost affective green hydrogen is available.

The direct operating costs of the process excluding any transportation or marketing expenses have been estimated for a generic plant using lime for the sulfur fixation and natural gas as the primary energy source for ammonia stripping and for generating the syngas needed for the reduction step. The costs are included in Table 2. With the limited number of processes steps the plant is well suited to automation and a labour force of ~80 operators should be sufficient to run the 50 000t/a plant.

The exact OPEX is location dependent but for a coastal site with direct access to natural gas the cost is likely to be around US$517/t of copper. The main location sensitivities are the availability and cost of labour and of natural gas. Lime is a globally traded commodity with the cost largely fixed by the world market. There may be scope to reduce the costs if there is a local source of highly active limestone that can replace the lime in the roasting step.

COMPARISON TO ALTERNATIVE TECHNOLOGIES

The process is potentially much lower CAPEX than alternative hydrometallurgical technologies through using high intensity simple steps. The leach stage is much simpler than Pressure Oxidation and much smaller than BIOX and there is no complex neutralisation stage. Replacing the high cost SX-EW stage which typically has CAPEX of over US$4000/t of Cu capacity (Stinn and Allanore, 2020; BioMore, 2018) by crystallisation and reduction more than offsets the inclusion of the roaster for the initial oxidation.

The OPEX costs are expected to be higher than current smelter costs but similar, or lower, than other hydrometallurgical processes. The higher cost of using lime rather than limestone for fixing the sulfur is offset by lower overall energy costs from not having electrowinning or the need for injecting oxygen and/or air into the leach for the sulfide oxidation.

The OPEX costs for the process are comparable to the historical Treatment and Refining charges (TC/RC) from smelters but well above those currently on offer. Even allowing for TC/RC increases, payment for more of the contained metal, and lower transportation costs the revenue margin for the MTM Process is insufficient to justify the CAPEX expenditure for a clean medium – high-grade concentrate which has ready access to the smelter market.

CONCLUSION AND FUTURE PLANS

The MTM Copper Process has the potential to be a low-cost hydrometallurgical process for treating sulfide concentrates. The process struggles to compete with smelting for high quality concentrates and Minetometal's target in developing the technology is to apply it to niche opportunities where the concentrate is not well suited to smelting. The primary focus is on concentrates which have difficult grade – recovery curves and/or have problem impurities especially arsenic and/or radionuclides.

Another opportunity is for concentrates that have valuable levels of other recoverable metals such as cobalt and/or rare earths.

Minetometal is continuing to develop the technology in parallel with our related work on zinc oxide technology. The next step in the development of the MTM Copper Process is further laboratory work addressing the purity of the metal and the recovery of other metals. In conjunction with that pilot plant testing is required to fully prove the process and provide data for more rigorous engineering and costing.

INTRODUCTION

Efficiently controlling foam/froth within mineral processing continues to pose a challenge to the mining sector. The foaming characteristics of aqueous solutions for two-phase systems of air/liquid are well-studied with theories and mechanisms proposed to describe and predict foam formation and stability. The types and structures of reagents that either promote or prevent foaming/froth formation and stability are well-defined in these studies and practiced across various applications. Three-phase systems of air/liquid/solid, such as froth from mineral slurries, however, pose a challenge with the presence of a large quantity of relatively fine mineral particles. Theories and mechanisms that rationalise the effects of chemical additives as a defoamer or foaming agent in aqueous can be applied as a general rule, but do not provide the most effective solution for mineral slurry systems.

Silicone-based defoamers, particularly their O/W emulsions, have been widely and successfully used at various stages of mineral processing to efficiently control the mineral slurry foaming properties. However, their foaming control ability could be significantly impacted by different processing aids used during the upstream process. In a zinc-rich mineral system, a silicone-based defoamer starts losing the properties necessary to effectively control foaming in the leaching circuit when throughput is increased. In this study, the synergistic defoaming/anti-foaming effects from surfactants and silicone-based defoamers are discussed to effectively control foaming/froth in the zinc leaching circuit, even with lower total defoamer dosage. Improvements during mineral processing can also lead to a cleaner mineral grade by reducing waste.

EXPERIMENTS

The zinc concentrate and associated leaching liquor are obtained from a zinc mine in Central America. The leaching liquor has a pH of less than 1.0 and over 1 per cent electrolytes by weight. A silicone/polydimethylsiloxane-based (polysiloxane) defoamer, is currently being used in the zinc leaching circuit at this mine. Nouryon provided Propomeen® T/12, Berol® 3100 and Ethylan® 1005 surfactant defoamers to compare with the product currently in use.

To simulate plant operation, lab-scale foaming and foam stability tests are done in a Denver D12 laboratory flotation machine with a 1.5 L plexiglass cell. Zinc concentrate and leaching liquor are conditioned in the cell to be uniform, then air is injected continuously and the height of the froth in the cell is measured to monitor froth stability at intervals of 1, 3 and 5 minutes. The froth height is observed to increase over time. About 800 mL of the slurry at ~13 per cent (solid per cent) is used in each test, and the tests are done at elevated temperatures of 40–45°C. By comparison, any observation of froth formation at more than 1.0 cm high in the cell is considered excessive foaming. Measurements of the static stability of the foam from the same slurry are also taken by vigorously shaking the slurry in a graduated test tube without external air injection.

RESULTS AND DISCUSSIONS

In the lab bench tests, without the addition of a defoamer, zinc slurry exhibits excessive foaming of more than 5 cm high foam in the cell within 1 minute (Table 1). When both the polysiloxane defoamer and the Propomeen® T/12 defoamer are used alone at a dosage up to 1.2 kg/ton, each shows a reduction in the amount of foam formed but the zinc slurry still yields excessive foaming. It is worthwhile to note the difference of physical appearance and particle accumulation of the froth when each defoamer product is used alone. The froth from the polysiloxane defoamer is dark in colour

with many fine mineral particles, while the froth from the Propomeen® T/12 defoamer is nearly colourless with almost no mineral particles present.

TABLE 1

Foam height and stability of zinc slurry with application of different defoamer systems.

Defoamer Used	Dosage (kg/ton)	Foam Height (cm)		
		1 min	3 min	5 min
Blank		> 5		
Reference polysiloxane defoamer	0.65	3.5	> 5	
	1.24	2.5	> 5	
Propomeen® T/12	0.63	5	> 5	
	1.30	4	> 5	
Defoamer 10 + Propomeen® T/12	0.21	1	1	2
	0.41	0	0.5	0.5
	0.61	0	0	0
Berol® 3100	0.25	0	0.5	0.5
Ethylan® 1005	0.28	0	0	0

From Table 1, when the Propomeen® T/12 surfactant defoamer and the polysiloxane-based defoamer are used together in this zinc slurry, significant defoaming synergism is observed. Not only is the height of the foam drastically reduced, but also the total dosage of defoamer is decreased to less than 50 per cent. It is suspected that when the Propomeen® T/12 defoamer and the polysiloxane defoamer are used together in this zinc slurry, the Propomeen® T/12 defoamer will modify the surface of zinc ore so it is less prone to entrainment. This results in a relatively clean froth and the polysiloxane defoamer effectively controls the froth height. Here, polysiloxane defoamer is believed to mainly function by reducing the local surface tension of the foam and causing bubbles to burst, while Propomeen® T/12 defoamer destroys the elasticity of the foam film, causing bubbles to burst and more importantly renders the mineral particles for fast drainage from foam films.

In addition to the Propomeen® T/12 defoamer, a propoxylated fatty amine surfactant, additional cationic surfactants with a similar chemical structure are tested in blends with the polysiloxane defoamer in the same zinc slurry system. Test results suggest that surfactant derivatives from propoxylation on fatty amines provide better foaming control than derivatives from ethoxylation on fatty amines. Further, both too high and too low hydrophobic lipophilic balance (HLB) of the surfactant derivatives tend to reduce the foaming control ability, whereas surfactant derivatives with a mid-range HLB value appear to provide the best foaming control. This seems to suggest that the blended defoamer system will show synergistic effects only when the polysiloxane defoamer is used together with cationic surfactants of necessary HLB range.

Blends of the polysiloxane defoamer with other types of low-foaming surfactants, namely branched alcohol ethoxylates such as the Berol® 3100 and Ethylan® 1005 defoamers, are also tested on this zinc slurry, observing no synergistic defoaming effects. In fact, the Berol® 3100 and Ethylan® 1005 defoamers work very well for foaming control when used alone in this zinc slurry, even at relatively lower dosages than the blends of the polysiloxane defoamer and the Propomeen® T/12 defoamer (Table 1).

Switching from ethoxylation to propoxylation on alcohols typically promotes the defoaming properties of chemicals within aqueous solutions, so alcohol propoxylates were incorporated in the foaming tests performed on this zinc slurry system. Contrary to initial expectations, the alcohol propoxylates alone result in worse foaming/froth control ability than the alcohol ethoxylates in the mineral system studied. Interestingly, when the alcohol propoxylates are used together with the polysiloxane-based defoamer, significant synergistic defoaming from the blend is observed. No synergistic defoaming is

observed from blending the polysiloxane defoamer with corresponding alcohol ethoxylates. Further studies will be needed to illustrate the mechanisms of how structural changes from surfactant defoamers affect their defoaming properties in mineral slurry systems.

Whether the Propomeen® T/12 surfactant defoamer is added to the polysiloxane defoamer or the Berol® 3100 and Ethylan® 1005 defoamers are used in zinc slurry, it seems that a lower dosage of chemicals is required to produce cleaner and more controlled froth. This is especially meaningful where operations are working to achieve environmental sustainability objectives.

ABSTRACT

Spiral concentrator is one of the most commonly used gravity concentration devices in mineral processing. The particles are classified based on their specific gravity and size. The present work analyses the experimental and numerical investigations of the water flow field, such as fluid depth and free surface primary velocity of two high gravity spiral concentrators at different flow rates. The measurement techniques use a flow depth gauge and flow visualisation technique adapting lycopodium powder as the tracer. Flow features in terms of liquid depth and primary velocity at the free surface of the flow are captured across the trough in two different high gravity spirals. A high-speed motion camera with an imaging frequency of 5400 frames per second and 768 × 768 pixel resolution is utilised to track the tracer particles in the liquid flow on the dark surface background. Further, the two-phase flow is studied numerically on high gravity spirals based on the volume of fluid (VOF) approach utilising the RNG k-ε model and Reynolds Stress Model (RSM) for predicting the fluid flow on trough surfaces such as water depth and free surface primary velocity. The CFD predictions of the flow field for the two spirals are attempted to validate against experimental data. The high gravity spiral concentrators show lower flow depths and free surface primary velocities but steep velocities on the outer trough zone compared to that of low gravity spiral concentrators (conventional coal spirals). Among the computationally tested high gravity spirals, higher pitch and higher secondary slope design shows greater flow characteristics.

INTRODUCTION

Spiral concentrators are widely used for processing beach sands, iron ore, rutile, gold, ilmenite, glass sands, high ash coal and chromite ore. A spiral concentrator consists of an open trough that extends vertically downwards in a helix configuration around a central axis (Napier-Munn and Wills, 2005). Complex mechanisms, including the combined effects of gravitational and centrifugal forces (among others), differential settling rates, interstitial trickling and Bagnold shear forces, affect the stratification of particles (Sivamohan and Forssberg, 1985). Large and dense particles migrate towards the near column zone of the spiral trough and are recovered as concentrates. Fine and lighter particles migrate towards the outer edge of the spiral trough and are collected as tailings. Spirals exhibit one of the most complex flow patterns among gravity separators. These flow patterns allow for dilation of the particle bed and provide an opportunity for separating mechanisms to operate. The primary flow is that of the slurry descending the inclined portion of the trough. The primary circulation is the result of primary slope (α), which varies from 0.2 to 0.5 and remains constant for a particular helix on the spiral. Because of the presence of mixed laminar, transitional, and turbulent flow regimes, particles on the spiral are subjected to a medley of randomly fluctuating, transient and steady force fields that act in a particular manner to generate a unique flow pattern called secondary circulation (Kapur and Meloy, 1998). The secondary water flows, which develop perpendicular to the primary flow and frictional drag effects, contribute to the mineral separation processes taking place on the spiral trough.

In the last few decades, researchers have attempted to examine the fluid flow patterns on spiral concentrators (Holtham, 1990; Holland-Batt and Holtham, 1991; Loveday and Cilliers, 1994; Ye *et al,* 2019; Meng *et al,* 2021). The spiral concentrator consists of primary and secondary circulation, which prevails in a lesser fluid depth in the inner zone and greater fluid depth in the outer zone (Holland-Batt, 1989). Holtham (1990) demonstrated the visualisation of secondary flow on the LD9 spiral by filming the dye streamline on the trough surface. Secondary circulation consists of an inward flow at the trough base and an outward flow at the free surface (Holtham, 1990). It is observed that secondary flow has a significant role in particle transport. The fluid flow can be considered fully developed only after the first two turns. The flow rate has no significant influence on fluid depths and primary velocities in the inner trough region but affects abruptly in the outer trough region (Doheim *et al*, 2008). The gauge measurements have shown that the flow depths normal to the spiral trough are in the order of 1–2 mm in the inner column region and can reach up to 12 mm on the outer edge region (Holtham, 1992). The mean primary velocities are less than 0.1 m/s in the inner zone and more than 2 m/s in the outer edge of the trough (Holtham, 1992). However, limited details are available on the water flow field in spiral concentrators.

Matthews *et al* (1998) developed and validated a computational fluid dynamics (CFD) model using Volume of Fluid (VOF) and formulations for predicting the fluid flow characteristics on the LD9 spiral. Doheim *et al* (2008) presented a computational model based on the volume of Fluid (VOF) approach, RANS turbulence models, namely k-ε, RNG k-ε, SST k-ω, and RSM models, were adopted and compared the predictions with the experimental measurements of LD9 spiral. Comparisons indicate that the Reynolds stress model (RSM) is the most accurate model for predicting the fluid flow on spirals. Ye *et al* (2019) demonstrated the influence of structural parameters such as pitch, flow rate, and transverse angle on the water flow field in LD9 spiral concentrator computationally. Meng *et al* (2021) computationally investigated the effects of cross-sectional geometry of laboratory spiral, which takes the trough profile of parabolic equation of the form $|x|=m|y|^n$.

From the literature, it is noted that most of the experimental and numerical investigations have been undertaken on conventional coal (LD9) spirals. Virtually no research is focused on the fluid and particle flow phenomenon of high gravity spirals. The aim of the present work is to measure the fluid film depth of high gravity spirals using a depth gauge and determine the primary free surface velocity of high gravity spirals experimentally using the tracer imaging technique. Once measurements are made, the flow field is simulated using the CFD model and validated against in-house experimental data on high gravity spirals. The measurement techniques use a flow depth gauge and high-speed camera for fluid flow measurements. The numerical approach incorporates the VOF method and RNG k-ε, RSM turbulence models for modelling the free surface transport on high gravity spiral concentrators.

EXPERIMENTAL METHODOLOGY

The study is performed on two vertically installed high gravity spiral concentrators with the same inlet feed provision, as shown in Figure 1. The geometrical parameters of the spirals are listed in Table 1. Both are single start wash waterless spirals. Compared to spiral 2, spiral 1 has a higher pitch and higher transverse slope. Both spirals have the same inner radii. The outer radius and trough width of spiral 2 is larger than spiral 1.

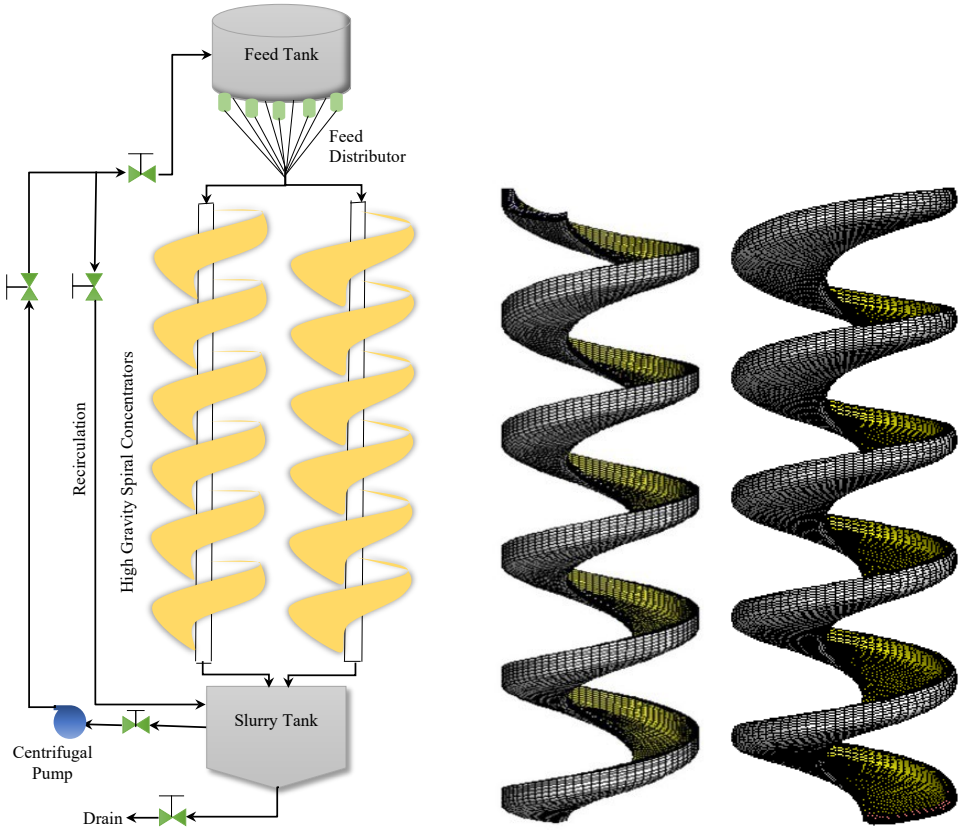

FIG 1 – Schematic of the experimental set-up and computational grids of high gravity spirals.

TABLE 1

Geometrical parameters of high gravity spiral concentrators.

Variable	Symbol	Spiral 1	Spiral 2
Inner radius (mm)	r_i	57	57
Outer radius (mm)	r_o	295	330
Trough width (mm)	W	238	273
Pitch (mm)	u	440	390
Primary slope (°)	α	7–32	10.65–42.81
Transverse slope (°)	β	3–26.5	1–25.46
Number of turns	n	7	6.5

The experimental rig comprises of two high gravity spiral concentrators, as shown in Figure 2. They are fed with clear water by a 5 HP centrifugal pump to the inlet feed tank at the top of the spiral rig. As the fluid flow is fully developed after the first two turns, the flow field measurements are taken at the fifth turn of the spirals for stabilised flow conditions. The depth gauge probe is mounted on a vertical stand at the top of the water-free surface perpendicular to the trough surface. It is submerged manually from the tip of the water-free surface at different radial locations to the trough base to measure the fluid depth. A high-speed motion camera (Photron FASTCAM SA 1.1) is used to measure the fluid free surface velocities by utilising lycopodium powder as the tracer particles. The utilised resolution is 1024 pixels × 512 pixels with a frame rate of 5400 frames per second (fps) and an exposure time of 10 µs. It is supported by a tripod stand and positioned normal to the spiral trough to reduce the distortion view of the trough. The experiments are carried out at the flow rates of 3, 4 and 5 m^3/hr.

(a) (b)

FIG 2 – Projection of (a) depth gauge and (b) high speed camera on trough surface.

Numerical model

The Reynolds average approach is typically suitable for solving the Navier-Stokes equation in most flow dynamics problems in fluid mechanics. The Volume of Fluid (VOF) method was used for modelling the free-surface flow on both spiral concentrators. The method is solved implicitly. In this study, the liquid phase is considered as the continuous phase using the RNG k-ε and Reynolds stress model (RSM). The semi-implicit method for pressure linked equations (SIMPLE) algorithm was applied for pressure-velocity coupling. The conservation equations are discretised using Quadratic Upwind Interpolation (QUICK) scheme for the momentum, turbulent kinetic energy equations, and turbulent dissipation rate.

Computational domain

The computational model has been applied to five turns of both high gravity spiral concentrators. The domain consists of multiple blocks with cells in 3D hexahedral control volumes. The grid for five turns of the spiral units is shown in Figure 1. The cells in a depth-wise direction are clustered towards the solid walls until the control volumes capture the thin films of the fluid medium. The analysis for grid independence is carried out with cells varying from 125 120 to 415 880 for spiral 1 and 243 200 to 420 600 for spiral 2, respectively. It is found that 314 240 cells for spiral 1 and 334 400 cells for spiral 2 are optimum to predict the flow field in spiral units.

Boundary conditions

At the inlet of the domain, the two-phase inflow velocity boundary condition. At the outlet plane, the pressure-out conditions were specified. The trough wall has a no-slip boundary condition, whereas the upper wall has a free-slip boundary condition.

RESULTS AND DISCUSSIONS

Comparisons are made based on the flow field characteristics such as water depth and free surface velocity on high gravity spiral concentrators. Figure 3 shows fluid depth and primary free surface velocity radial profiles (r/R = 0 represents the column centre and r/R = 1 represents the outer edge) obtained at 4 m^3/hr. The results show that fluid depths increase radially outward with shallow depths in the inner section and increase abruptly in the outer section. A similar trend is observed for primary free surface velocities. High centrifugal forces associated with the outer section cause the water surface elevation and create the circulation of secondary currents.

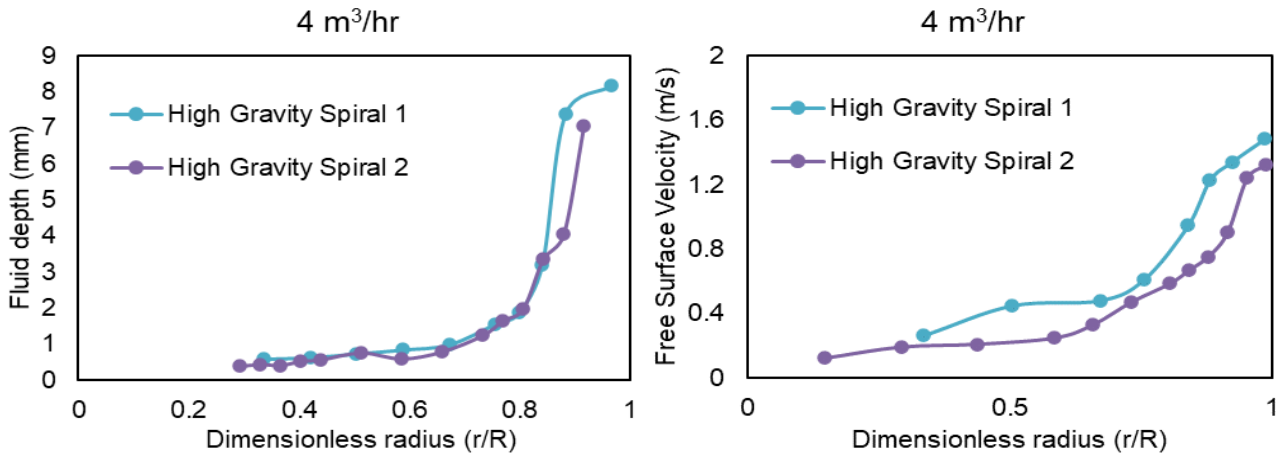

FIG 3 – Experimental measurements of fluid depth and primary free surface velocity profiles of high gravity spirals at 4 m^3/hr (fifth turn).

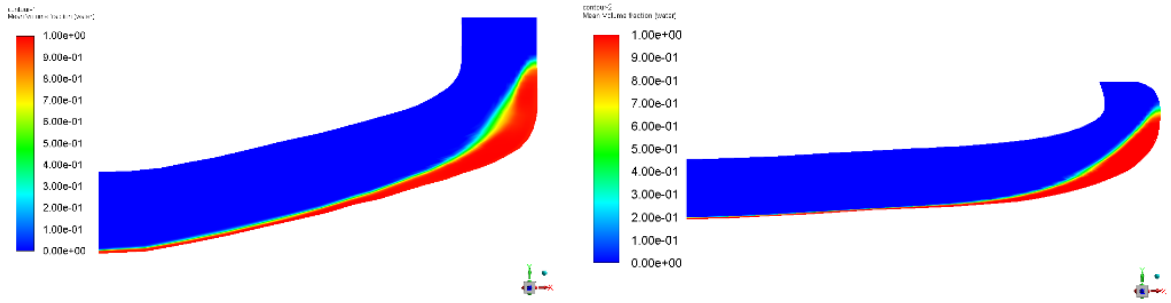
Figure 3 shows that the fluid depths and primary free surface velocities of spiral 1 are greater than spiral 2. High gravity spiral concentrators are designed with steep pitches and compound slopes. From the geometrical description in Table 1, spiral 1 has a higher pitch and higher transverse slope than spiral 2. The high pitch transforms the gravitational potential energy into kinetic energy and raises the elevation of the fluid level at the outer edge, 6. The steep pitch spirals were able to separate particles of specific gravity <~3 to the outer region. For low pitch spirals such as coal spirals, the differential specific gravity is ~2. The mineral ores having concentration criteria (CC) values greater than 2.5 are easily separable, and less than 1.5 are difficult to separate. Spiral 2 has a less acute slope (flat bottomed) at the inner trough and greater curvature at the outer trough than spiral 1. Flat profile (flat in the first section and low inclination in the second section) spirals with a lowered pitch should function effectively with very fine particles of similar densities because of the low velocities that exist. This design is beneficial in separating heavy mineral ores (<100 µm).

Fluid depth

The water flow on high gravity spirals will be directed outwards, causing an increment in depths radially along the trough can be seen in Figure 4. The flow down the spiral trough experiences very shallow depths (<1 mm) in the inner zones, and the depth of the fluid increases gradually towards the outer zone (15 mm and more). When the spirals were being monitored at 3, 4 and 5 m^3/hr, no significant increase in depths was observed at the inner zone, while the depth level at the outer zone increased abruptly with an increase inflow rate. With finite differences in primary slope, transverse slope, and pitch, the high gravity spirals exhibit different flow depth distributions in the radial direction. Spiral 1 experiences greater fluid depth at inner and outer sections than spiral 2 at all flow rates. The lowering of the pitch and the transverse angle decreases the fluid depth in the outer section as the trough profile makes it difficult for fluid to move outward. Figure 5 shows the comparisons of experimental and numerical predictions of fluid depths on respective spiral concentrators at 3, 4 and 5 m^3/hr. Both RNG k-ε and RSM turbulence models are qualified enough to capture the fluid depth in high gravity spiral concentrators. The outermost region of the spiral trough reflects the air entrainment caused by turbulent eddies, which is likely to increase the fluid depth by 15–20 per cent (Matthews, Holtham and Golab, 1998). The spiral 2 design creates intense turbulence flow at the outer edge region and causes air entrainment, for which the model prediction deviates from the actual parameter. Hence the numerical predictions show a significant deviation from the experimental results in the outer zone than the inner zone. The RSM model gives a more accurate prediction for the flow field in the outer and inner zones than the RNG k-ε model.



(a) (b)

FIG 4 – Fluid depth contours of the high gravity spirals at the end of the fifth turn at 4 m^3/hr; (a) Spiral 1; (b) Spiral 2.

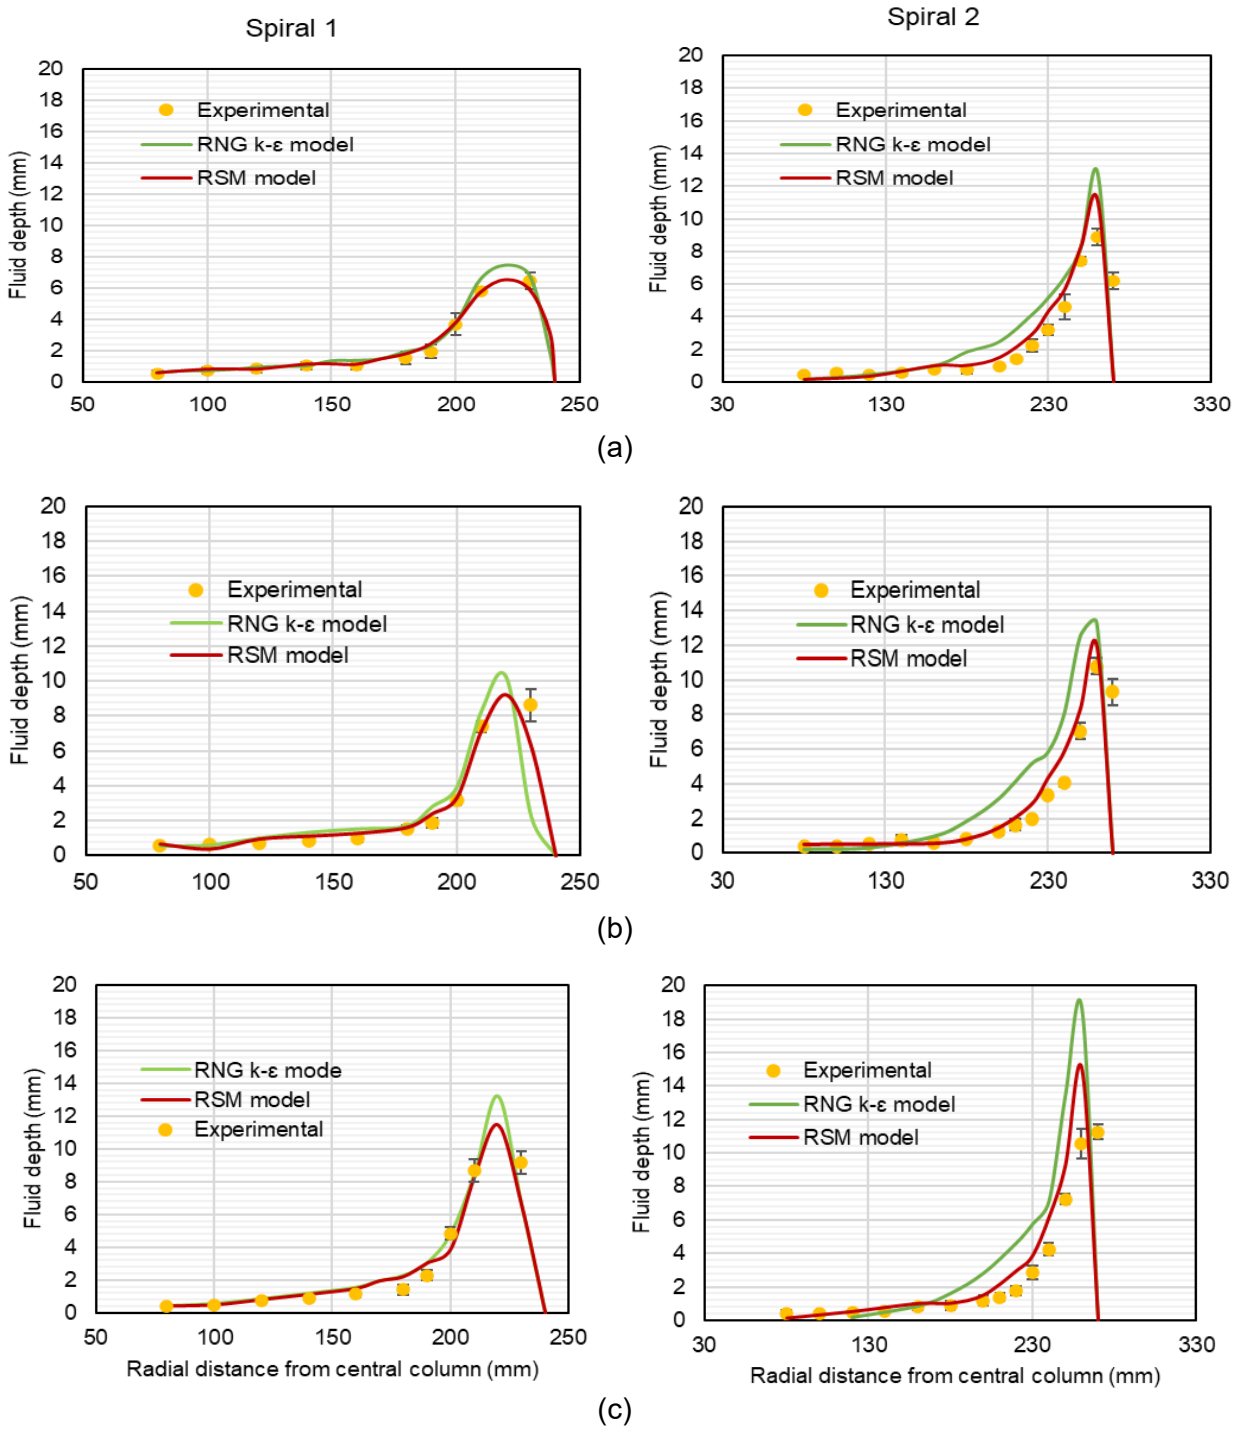


FIG 5 – Experimental and numerical predictions of fluid depth in spiral 1 and spiral 2 at: (a) 3 m^3/hr, (b) 4 m^3/hr and (c) 5 m^3/hr.

Free surface velocity

Free surface velocities also follow a similar trend with fluid depths across the trough. The free surface velocity increases evenly with radial distance at a given flow rate. With an increase inflow rate, there is an increment in free surface velocity as well. The pitch and flow rate have a more significant influence on the primary velocity in the outer zone (Holtham, 1992; Ye *et al,* 2019). At 3, 4 and 5 m^3/hr, the free surface velocities in spiral 1 are higher than in spiral 2 (Figure 6). The fluid velocity in a spiral concentrator with a higher pitch is greater than that of a lower pitch because the high pitch transforms the gravitational potential energy into kinetic energy. A comparison of velocity profiles among RNG k-ε and RSM turbulence models shows that the RSM model gives the best predictions at a free surface. It is noted that a maximum velocity of 1.75 m/s is observed for spiral 1 and 1.44 m/s for spiral 2.

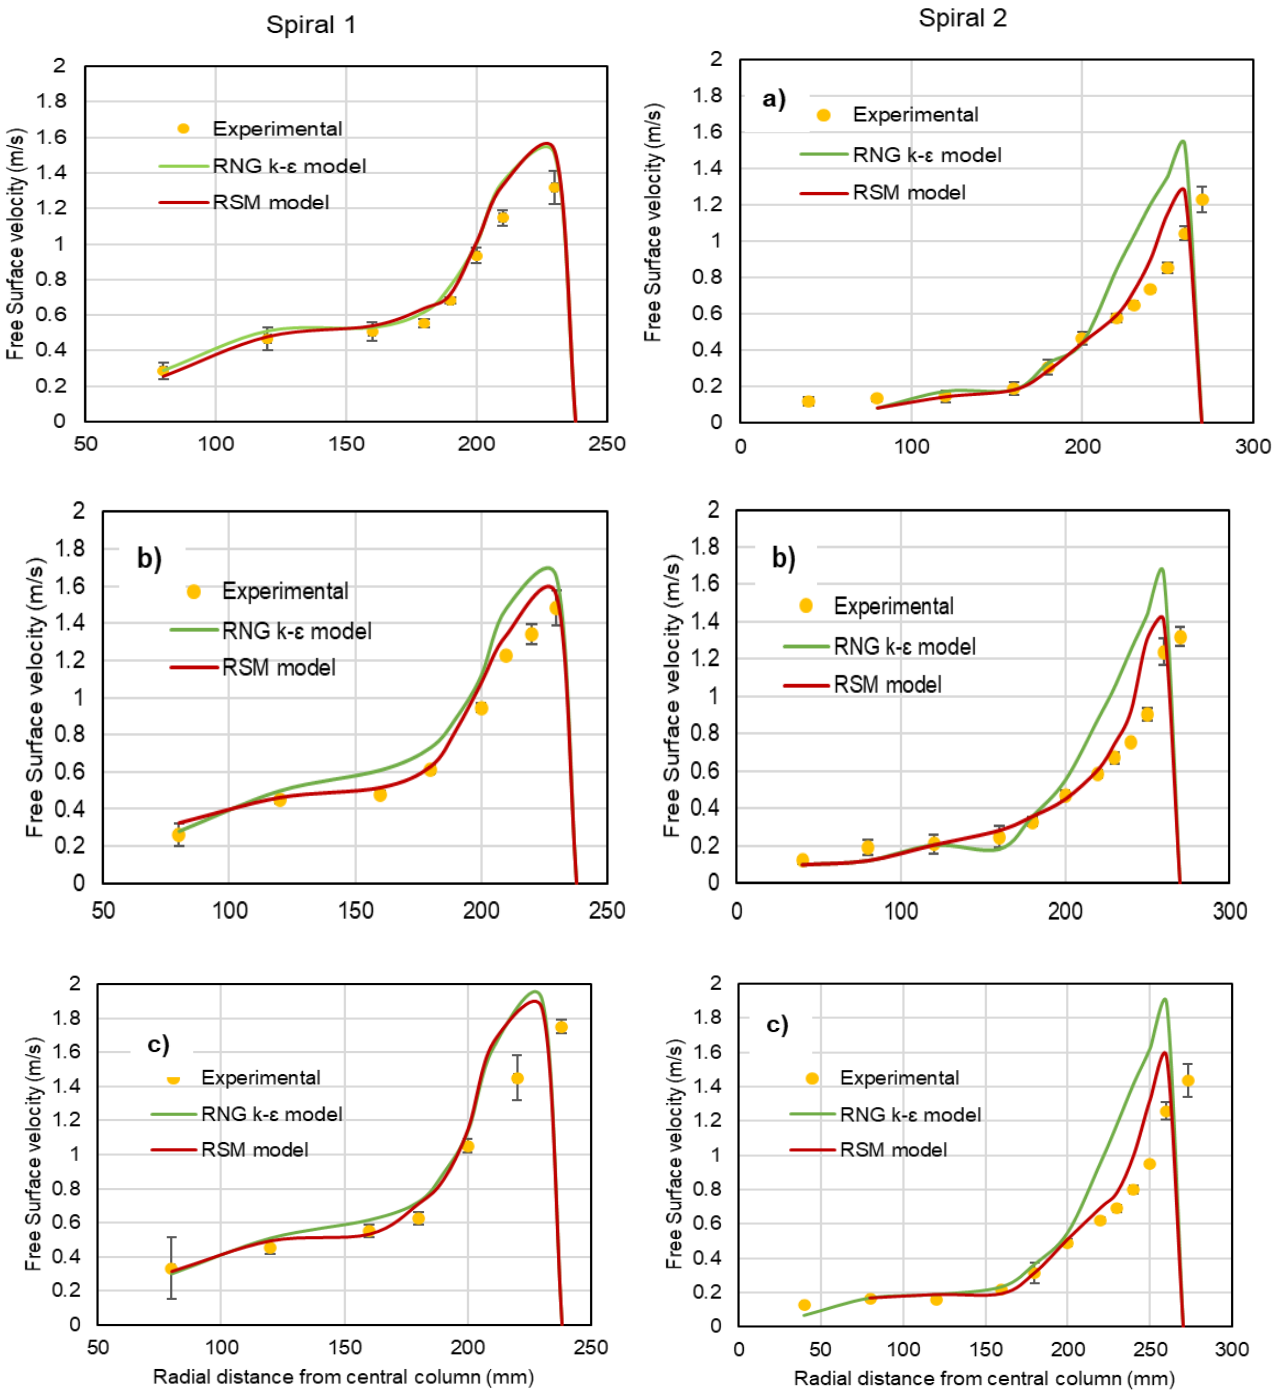

FIG 6 – Experimental and numerical predictions of Free surface velocity in spiral 1 and spiral 2 at: (a) 3 m^3/hr, (b) 4 m^3/hr, and (c) 5 m^3/hr.

CONCLUSIONS

The flow field measurements have been explored on the high gravity spiral concentrators, and the main conclusions can be drawn as follows:

- The flow field in LD9 coal spirals is greater compared to high gravity spirals because of finite differences in trough geometry, transverse slope, and pitch.
- The experimental and numerical studies with variations inflow rates are performed to understand the fluid flow phenomenon on high gravity spiral concentrators. An increase inflow rate leads to increased fluid depth and free surface velocity along the trough surface in the outer zone.
- The standard error for the measured fluid depths ranges from 0.01 to 0.08 and 0.004 to 0.03 for the free surface velocities at 3, 4 and 5 m^3/hr flow rates.
- The mean absolute percentage error between RSM and RNG k-ε models of fluid depth is 17.83 and 21.72 for spiral 1 and 23.32 and 35.95 for spiral 2, respectively.
- The mean absolute percentage error between RSM and RNG k-ε models of free surface velocity is 24.94 and 28.01 for spiral 1 and 16.34 and 35.75 for spiral 2, respectively.
- The error analysis shows that the RSM turbulence model gives a more accurate prediction for the flow field than the RNG k-ε turbulence model.

ABSTRACT

The study of air-core dynamics in hydrocyclone operation is essential for predicting separation efficiency in mineral processing. Electrical resistance tomography (ERT) allows non-invasive measurements of hydrocyclone internal flow dynamics. Existing regularisation methods such as Gauss-Newton and TV norms rely on optimisation techniques which have very high computational cost for very fine meshes. In contrast, the monotonicity method has much lower computational cost as it does not solve such minimisation problems. In this paper, results from the monotonicity method, Gauss-Newton (GN) (Tikhonov) and Total-Variation (TV) norm-based minimisation methods for estimating the air-core diameter in hydrocyclones are compared. We study these methods on the laboratory hydrocyclone experimental two-phase flow data. The results obtained are validated against High-speed video (HSV) imaging and Computational Fluid Dynamics (CFD) results. The results on different mesh sizes, in particular for very fine meshes with the number of cells ranging from 30 000 to above 100 000 are also investigated. The data used in this study is obtained from ITS Z8000 ERT system. This system does not measure the voltages on the current carrying electrodes. Since these voltage values are required for the monotonicity method, we implement an interpolation method to compute them. The results show that the monotonicity method provides a closer approximation of the interface between air and the water phases.

INTRODUCTION

The hydrocyclone, one of the fast-processing devices in the mineral processing industries, is used to separate particles from multiphase processing fluids. It works on the principle of centrifugal sedimentation in which particles separate according to size and density from processing fluid by centrifugal force (Rakesh *et al*, 2014). It consists of four main parts: the tangential feed inlet, cylindrical cone, spigot, and vortex finder. The tangential inlet of feed into the cyclone body creates an outer and inner vortex flows. The outer vortex moving in the downward direction carries the coarse size particles whereas the inner vortex moving in the upward direction carries the fine sized particles (Williams, 1995). Due to inner vortex formation, a low-pressure area prevails along the axis, responsible for forming air-core, which determines the separation efficiency. Careful control of the air-core in the process achieves the required efficiency in the separation. The initial ERT work in Hydrocyclone by (Ilyas *et al*, 1995) analysed air-core dynamics through a sensitivity density coefficient algorithm. Later literature (Dyakowski and Williams, 1996; Gutiérrez *et al*, 2000) reported air-core size estimation. Deoiling hydrocyclone operation with ERT analysis was provided in (Bennett and Williams, 2004). Recent studies of algorithm comparison in air-core dynamics have been analysed in (Rakesh *et al*, 2014) for Gauss-Newton (GN), Total Variation (TV) and Modified Sensitivity Back Projection (MSBP) for up to 6400 mesh elements. Later (Vakamalla *et al*, 2014) examined the air core variation with studies of inclined hydrocyclone through the linear back-projection algorithm.

To improve the sharpness of the interface, in this paper, we consider a relatively recent monotonicity-based method for reconstructing ‘binary’ conductivity profiles (Harrach, 2015). The monotonicity method relies on the full voltage data, ie voltages at the current carrying electrodes are also needed. Since these were not available for the experimental system ITS Z8000 for which the studies are conducted, we implement two interpolation schemes (geometric and linear) to estimate these missing values (Harrach, 2015). We compare the results of the monotonicity

method with that of the existing algorithms such as GN (Adler *et al*, 2007) and TV norm (Borsic *et al*, 2010) methods. The monotonicity method does not perform optimisation and hence is very fast compared to both GN, TV methods. Due to the small computational cost, the current work explores fine mesh elements ranging from thousands to one lakh for the monotonicity method.

The paper is organised into several sections. In section II, the ERT inverse problem is presented. This section also contains the discussion of optimisation-based techniques and the monotonicity method. In section III, reconstruction results of laboratory hydrocyclone experimental two-phase flow data. Concluding remarks are given in section IV.

ERT Inverse Problem

In ERT, a set of currents through adjacent electrodes are used as inputs whereas the outputs/solutions of the forward problem are u (the potential in the domain Ω) and U where $U^k = (U_1, U_2, \cdots, U_{L-1}, U_L)$ (the vector of voltages on the electrodes) for the kth current pattern. In experimentation, only U is measured L^2. These voltages can be rearranged into an $L \times L$ matrix for the L current patterns where each column vector is $U^k, k = 1,2, \cdots, L$. This matrix is denoted by V. For a numerical implementation, the domain is discretised into cells/pixels using a meshing algorithm. In this study, the meshing and the solution to the forward problem are implemented in MATLAB using the EIDORS toolbox. In the Sheffield measurement protocol, the potential differences between adjacent electrodes except at the current carrying ones are measured. The ITS Z8000 ERT system on which the current studies are done is based on this protocol and provides $L(L-3)/2$ independent voltage measurements. For $L = 16$ electrode set-up a total of $n = 16 * 13/2 = 104$ voltages are obtained.

Reconstruction of the conductivity profile from ERT data has been studied extensively in the literature (Borsic and Adler, 2012; Cheney *et al*, 1999; Tamburrino *et al*, 2000). The data obtained from the experiment is the difference of voltages $\Delta V = V - V_0$ where V, V_0 are respectively the true and the reference voltage matrices as defined above. The reference voltage matrix V_0 corresponds to the case where the domain Ω is filled with water. Let σ_0 be the reference conductivity and $F(\sigma)$ denote the solution of the forward problem. In other words, given a conductivity profile (σ) and some fixed current vector, $F(\sigma)$ equals the $L \times L$ matrix, V as discussed above. Then, by definition, we have $\Delta V = V - V_0 = F(\sigma) - F(\sigma_0) \approx F'(\sigma_0)(\sigma - \sigma_0)$ where $F'(\sigma_0)$ is the Frechet derivative $F'(\sigma_0)$.

Optimisation based algorithms

Most of the existing algorithms are based on the following minimisation problem:

$$\hat{\kappa} = argmin_{\kappa} \|Y - G\kappa\|^2_a + \|L\kappa\|^2_b \quad (1)$$

where the a, b refer to different choices of norms, Y is the difference voltage data (ΔV) for the various current patterns, G is the Jacobian/Sensitivity matrix, κ is the vector of conductivity differences and L is a fixed prior matrix. For example, $a = b = 2$ corresponds to the Tikhonov regularisation and with Laplacian prior, this is implemented in the Gauss-Newton One Step method of EIDORS. Another choice is $a = 2, b = TV$, ie when the TV norm is used for the regularisation term. The solution to the Tikhonov problem can be obtained analytically leading to a simpler and computationally efficient solution. In contrast, the TV norm results in a convex optimisation problem whose solution is relatively costlier to compute. It may be stressed that the goal of these methods is to obtain the conductivity difference κ_i at each mesh cell/pixel.

Monotonicity method

We now describe a recent method for inclusion detection in ERT, namely the monotonicity method. In contrast to the methods described before, the goal of this technique is to find the support of the conductivity change κ, ie to find the pixels where κ is non-zero. The monotonicity method assumes that the conductivity values of continuous phase (σ_0) and the air-core (σ_1) are known *a priori*. In the studies considered in this paper, the continuous phase is water with conductivity $\sigma_0 = 430\mu S$ and the conductivity of air is considered to be a very low value $\sigma_1 = 10^{-9} S$. Therefore, inside the air-core, the conductivity change is given by $\kappa = \sigma_1 - \sigma_0$ whereas outside the air-core $\kappa = \sigma_0 - \sigma_0 = 0$. Therefore, by finding the locations of the non-zero values of κ the approximate

diameter of the air-core can be computed. Assuming that the contact impedance vector z does not vary for the reference and the true measurements, the monotonicity relation can be written as (Harrach, 2015):

$$\int_{\Omega} \frac{\sigma_0}{\sigma}(\sigma_0 - \sigma)|\sum_{i=1}^{L} I_i \nabla u_0{}^i|^2 dx \geq I^T V I \geq \int_{\Omega}(\sigma_0 - \sigma)|\sum_{i=1}^{L} I_i \nabla u_0{}^i|^2 dx \text{ for any vector } I \in R^m \quad (2)$$

where $u_o{}^k$ is the solution to the current pattern I^k for the reference conductivity σ_0. The domain is discretised using a mesh generator and the cells (pixels) are represented as $P_i, i = 1,2,\cdots,N$, where N is the total number of cells in the mesh. Therefore, $\cup_{i=1}{}^{N} P_i \approx \Omega$, where the approximation is due to the curved parts of the boundary which may not be exactly covered by the triangular elements obtained from the mesh generator. From the discussion above, it is clear that if the cell P_i is inside the air-core, $\sigma_0 - \sigma = \sigma_0 - \sigma_1$, otherwise $\sigma_0 - \sigma = 0$.

In either case, $\sigma_0 - \sigma \geq 0$ in Ω. The monotonicity relation then provides the following. Let $\beta \geq 0$ and assume that $\beta \chi_{P_i} \leq \sigma_0 - \sigma$, then:

$I^T V I \geq \int_{\Omega}(\sigma_0 - \sigma)|\sum_{i=1}^{L} I_i \nabla u_0{}^i|^2 dx \geq \beta \int |\sum_{i=1}^{L} I_i \nabla u_0{}^i|^2 dx \geq -\beta I^T S_i I$ which shows that:

$V + \beta S \geq 0$, ie $V + \beta S$ is positive semi-definite. The monotonicity method computes,

$\beta_i = max\{\beta \geq 0; V + \beta S_i \geq 0\}$ and approximates the support of κ by the function $\sum_i \beta_i \chi_{P_i}$. Here χ_A represents the indicator function of the set A.

RESULTS AND DISCUSSION

The above section described the image reconstruction algorithms used in this study from a theoretical perspective. In this section, the spatial accuracy of these algorithms with respect to change in the mesh density has been studied on experimental data from a hydrocyclone. Two interpolation methods namely, geometric, and linear, are utilised to estimate the full voltage data in the monotonicity method. The ERT experiments were conducted using hydrocyclone with a diameter of 75 mm for gas and water phase studies. Sixteen equidistance and circular surfaced electrodes were placed to acquire the voltages. The electrodes were made of stainless steel. Air core is estimated for two phase flow experiments in the hydrocyclone with various operating pressures. The hydrocyclone was operated with 12.5 mm of spigot diameter and 25 mm of vortex finder diameter.

Figure 1 provides the tomograms and surface profiles for an operating pressure of 20 psi.

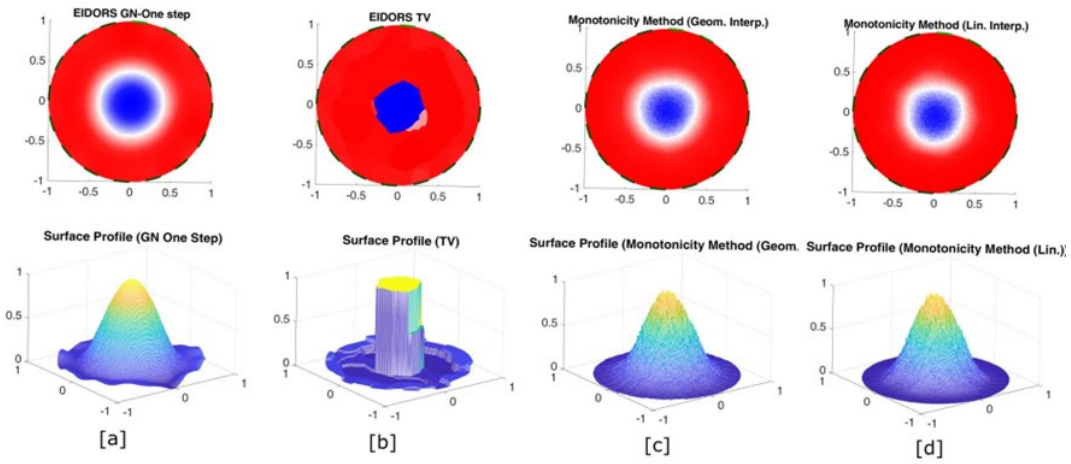

FIG 1 – Air core variation tomograms and profile shapes on 20 psi.

Compared with the other two algorithms, the TV norm method results in a sharper boundary separation between phases. However, we note that GN one-step and monotonicity methods do not provide a sharp interface. To obtain a good separation, we use a threshold on the tomogram values.

In this study, a variable threshold level in the range of 0.1 to 0.9 has been explored for each of the three methods. For each threshold level, the estimated diameter is compared with the diameter

obtained from image processing from a high-speed video (HSV) camera. Then, an optimal threshold for each of the methods is chosen. It may be noted that the threshold for each method is dependent on the operating pressure of the hydrocyclone.

Figure 2 shows the results after applying the optimal thresholds for different operating pressures. For the GN one-step method, the optimal threshold was found to be approximately 80 per cent whereas the TV norm method overestimated the air core diameter for all the thresholds in the above range. To get better comparisons with high-speed video camera (HSV) results a threshold of 98 per cent was calculated for the TV method. The Monotonicity method required a 75 per cent threshold to give estimates closest to the diameter estimated from HSV. Figure 2 also gives the predicted diameter from computational fluid dynamics simulations (CFD). GN one step exhibits a maximum error of 28 per cent with HSV data and 13 per cent with CFD predictions. The TV norm estimates resulted in a maximum error of 31 per cent with HSV and 16 per cent with CFD. Monotonicity with geometric interpolation has a maximum error of 26 per cent of error with HSV and 14 per cent with CFD predictions whereas with linear interpolation, the maximum error is 31 per cent with HSV and 15 per cent with CFD predictions. Therefore, overall, the monotonicity method with geometric interpolation showed a closer approximation with the CFD and HSV results than the GN and TV methods.

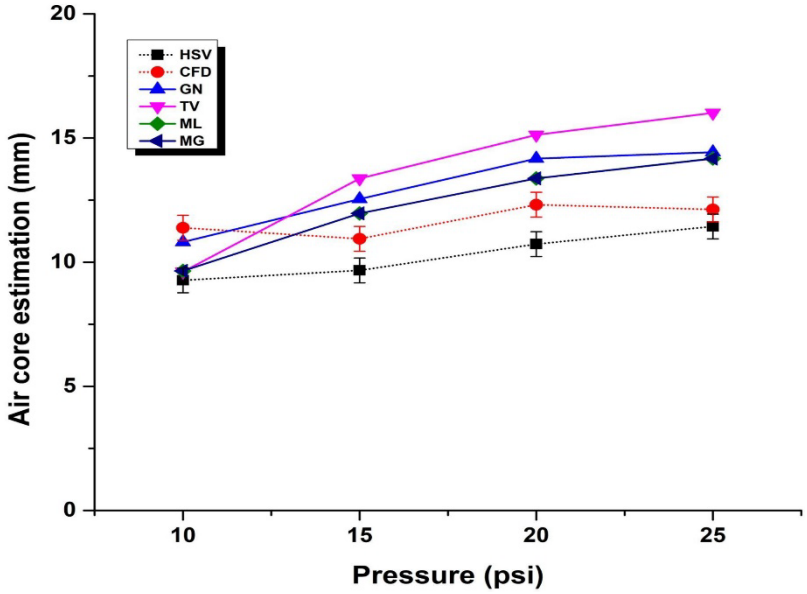

FIG 2 – Air-core diameter validation with HSV and CFD results.

We also evaluated the computational cost of each algorithm for mesh elements ranging from 4448 to 9091 elements. It can be seen that the monotonicity method is much faster. Figure 3 shows this comparison. Beyond these, we have also studied the computational time for each method individually for large meshes. The TV norm method proved to be the costliest algorithm in terms of computational time, about 36 minutes for 14 306 mesh elements. The GN-one step method took a maximum time of five minutes for 47 306 mesh elements. The evaluation time for the monotonicity method is 16 minutes for 127 191 mesh elements.

CONCLUSIONS

Comparison studies of image reconstruction algorithms have been performed to estimate the air core diameter for hydrocyclone operated with air-water flows. This work evaluated the monotonicity method and compared it to TV norm and GN one-step algorithms. The computational cost of GN one-step, TV, and monotonicity methods with varying number of mesh elements has also been studied. Monotonicity method gives the fastest reconstruction which is about 470 times faster than the TV norm and 26 times faster than the GN one-step for reconstructing 9091 mesh elements. Though TV performs well on shape and boundary sharpness, it is also the most computationally expensive, which could be impractical for finer meshes. The GN one-step and the monotonicity methods result in a diffusive tomogram; an appropriate threshold enables these methods to estimate the target with better accuracy and consume significantly less time compared to the TV norm method. To improve the accuracy, a thresholding method has been adopted. The overall percentage of error with HSV and CFD after thresholding is the smallest for the monotonicity method with geometric interpolation. Finally, we note that the threshold is dependent on the pressure. We are currently exploring other algorithms which can provide a radius independent threshold.

ACKNOWLEDGEMENTS

The authors would also like to thank the IITH for providing necessary facilities for the work and SERB project, DST (CRG/2018/004892) Govt.of India for funding the research work.

ABSTRACT

In the past 40 years substantial changes have occurred in flotation machines. This has included increases in mechanical cell size to 630 m^3, significant changes to flotation column aeration design and widespread use of the Jameson cell and other pneumatic flotation cells. Over the corresponding period there has been increased used of machine characterisation measurements to benchmark and optimise flotation circuit performance.

JKTech maintains a database of industrial flotation machine characterisation measurements. The database contains over 4000 entries and includes gas dispersion measurements, such as bubble size, gas hold-up and superficial gas velocity, cell dimensions and impeller tip speeds. Data comes from numerous operating sites and commodity groups, including gold, copper, molybdenum, nickel, palladium, lead-zinc, platinum, silica, phosphate, coal and iron ore. Flotation duties registered include flash flotation, preflotation, roughing, scavenging and cleaner circuits.

Measurements have been conducted on a wide range of flotation machines from different manufacturers. This includes forced air machines, such as Outotec and Dorr Oliver, and self-aerated machines, such as Denver and Wemco. The database also includes substantial flotation column entries, such as the Microcel, Eriez/CMT Slamjet and Jameson cell.

This paper describes the flotation machine characterisation database and discusses the variation between different types of industrial flotation machines, in operating production circuits.

INTRODUCTION

The study of flotation hydrodynamics that is commonly referred to as flotation machine gas characterisation dates back to research conducted in the 1980s, at McGill University and the University of Newcastle (Jameson and Allum, 1984; Dobby and Finch, 1986). This extended into the 1990s where research at the Julius Kruttschnitt Mineral Research Centre (JKMRC) by Barun Gorain provided a link between gas characterisation and flotation kinetics (Gorain, Franzidis and Manlapig, 1995a, 1995b, 1996, 1997, 1999; Gorain *et al,* 1998).

In the following 20 years flotation machine gas characterisation became a critical mainstay of flotation machine and circuit evaluation. There are numerous publications on its use in industrial flotation plants, including reviews by Deglon, Egyah-Mensah and Franzidis (2000), Nesset *et al* (2006), Power and Franzidis (2000), Gomez and Finch (2002, 2007), Fournier *et al* (2015), Lopez-Saucedo *et al* (2012), Gorain (2000) and Hernandez-Aguilar *et al* (2006).

Key gas dispersion measurements include bubble size (d_b), gas hold-up (ε) and superficial gas rise velocity (Jg), These measurements characterise the hydrodynamic conditions in the pulp phase of a particular flotation cell. Gas dispersion is defined as how well the air entering a flotation cell is dispersed throughout the volume of the cell and is heavily dependent on the air flow rate and impeller speed. Numerous sensors have been developed for gas characterisation measurements and continue to evolve. These sensors include devices by McGill University (Canada), the JKMRC (Australia), the University of Capetown (South Africa), the University of Santa Maria (Chile), the Helsinki University of Technology (Finland) and Anglo Platinum (South Africa). Reviews of gas dispersion devices have been published by Gomez and Finch (2002), Harbort and Schwarz (2010) and Grau and Heiskanen (2003).

This paper uses a similar format to that of the seminal presentation by Schwarz and Alexander (2006) at the Centenary of Flotation Conference. It makes uses of an extensive database of measurements from operating sites to determine typical operating conditions. The authors acknowledge that

flotation and gas charcterisation are complex processes, with multiple interacting factors (Harbort, Schwarz and Nguyen, 2018). Fundamental research measurements are excluded from the database and readers interested in these areas are referred to various other publications including Shabalala *et al* (2011), O'Connor, Randall and Goodall (1990), Finch, Gélinas and Moyo (2006), Grau, Laskowski and Heiskanen, (2005), Cappuccitti and Finch (2008), Cappuccitti and Nesset (2010).

DATABASE

Sources of information

Data included in the database was initially sourced from the AMIRA P9 project, utilising measurements taken by students from the JKMRC, McGill University and the University of Cape Town. With the introduction of JKTech, data sets collected from conducting plant optimisation studies were also incorporated. The last 15 years has seen multiple measurements taken by various groups including equipment manufacturers, research institutes, consultants and operating sites.

A requirement for inclusion in the database is that data can be independently verified. Some studies reported in literature have been excluded due to lack of sufficient verification information.

The database focuses on operating sites with solid-water-air systems. Measurements undertaken in laboratory flotation cells are generally not included, nor are measurements conducted in air-water systems.

As shown in Figure 1, most flotation cell entries were undertaken in the period 2006 to 2009. In recent years, a concerted effort has been untaken by the authors to collate measurements from operating sites and literature for database inclusion.

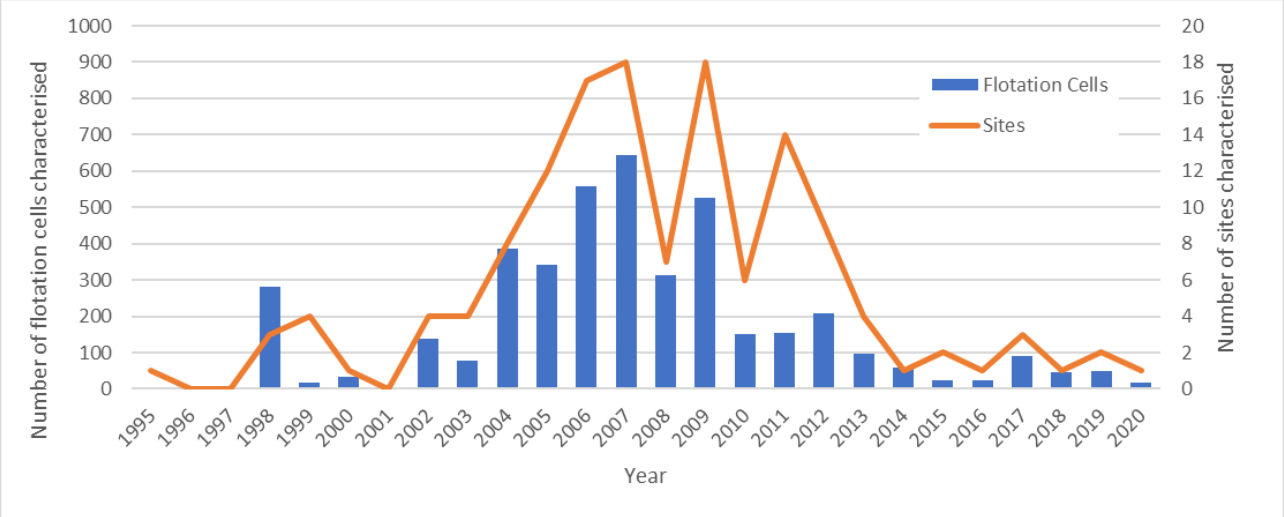

FIG 1 – Characterisation measurements per annum.

Measurements

The database currently contains hydrodynamic measurements from over 4200 flotation cells. The information included is dependent on the scope of gas characterisation surveys conducted, resulting in varying totals for different types of measurement. Measurements recorded include:

- Superficial gas rise velocity – 4092 entries.
- Air hold-up – 3264 entries.
- Bubble diameter – 3276 entries.

Calculations of bubble surface area flux (Sb) within the pulp zone are also included. The bubble surface area flux is a measure of the rate of bubble surface area rising through a flotation cell per unit cross-sectional area. This parameter combines the superficial gas velocity and bubble size into a single quantity, according to the following equation:

$$Sb = \frac{Jg \cdot 6}{d_b}$$

Sb is an important parameter as it links gas dispersion to flotation performance, being directly proportional to the kinetic rate.

An estimate of the bubble surface area flux can also be obtained using measurements of the superficial gas velocity, impeller speed (Ns), impeller design–characterised by the ratio of height to diameter (aspect ratio, As) and the particle size of the feed entering the cell (P_{80}). There are 1142 sets of data entry relating to these measurements.

Flotation cell geometry relating to froth area and lip length is also included. In instances where a gas characterisation survey is accompanied by a mass balancing survey this allows carrying rates per lip length or froth area to be conducted. In addition, residence times per cell calculations are also conducted.

In cases where a full flotation modelling survey is conducted the froth recovery can also be conducted. There are currently 743 froth recovery entries in the database.

Figures 2 to 4 give an indication of the variability in air hold up, superficial gas velocity and bubble size. Air hold-up measurements averaged 12.1 per cent across all cells measured. The majority of air hold-up measurements were between 7.0 per cent and 14.5 per cent. There were only a few measurements above 40 per cent, and the reasons behind these high values are likely due to ore viscosity properties at specific sites and ultrafine bubble sizes due to excessive frother addition. Superficial gas velocity averaged 1.3 cm/s. In operating cells with values less than 1 cm/s, it was recommended to investigate increasing the air flow rates to improve the pulp kinetics. However, values greater than 3 cm/s indicated possible flooding (pulp recovered in the concentrate) and it was recommended decreasing the air flow rates to improve the froth performance (increase stability and decrease entrainment). Bubble size measurements averaged 1.6 mm across all cells measured. The majority of bubble size measurements were between 1.1 mm and 1.9 mm.

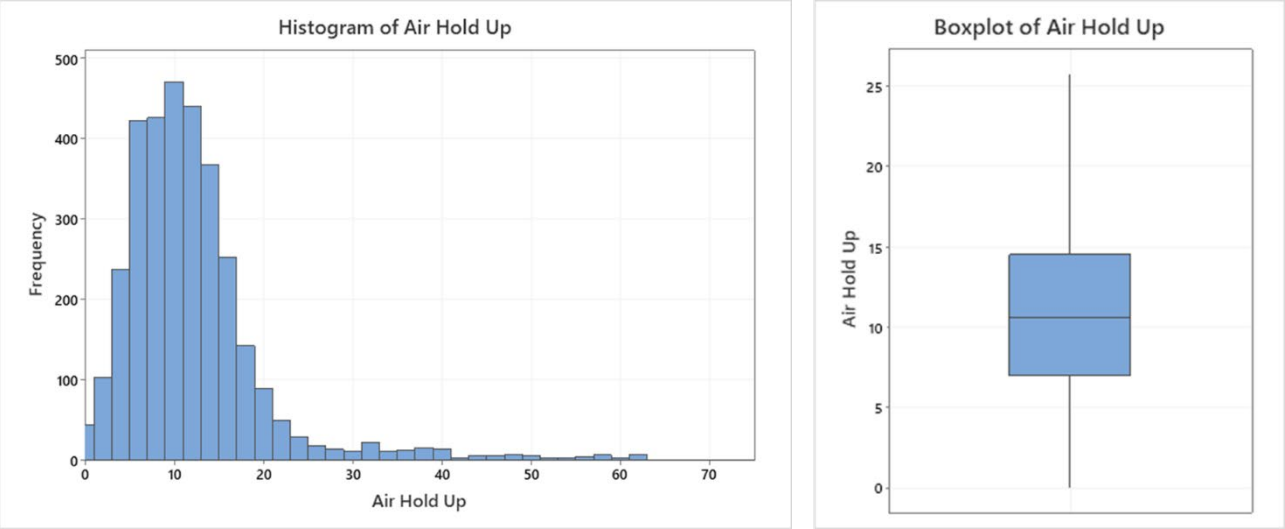

FIG 2 – Air hold up measurement histogram and box plot.

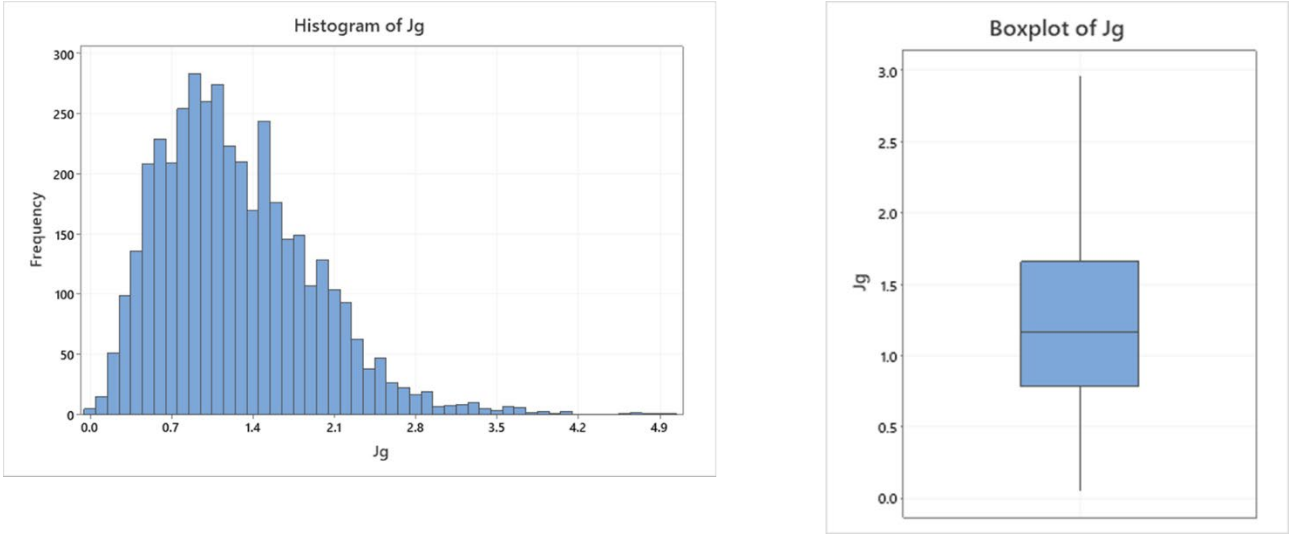

FIG 3 – Superficial gas velocity measurement histogram and box plot.

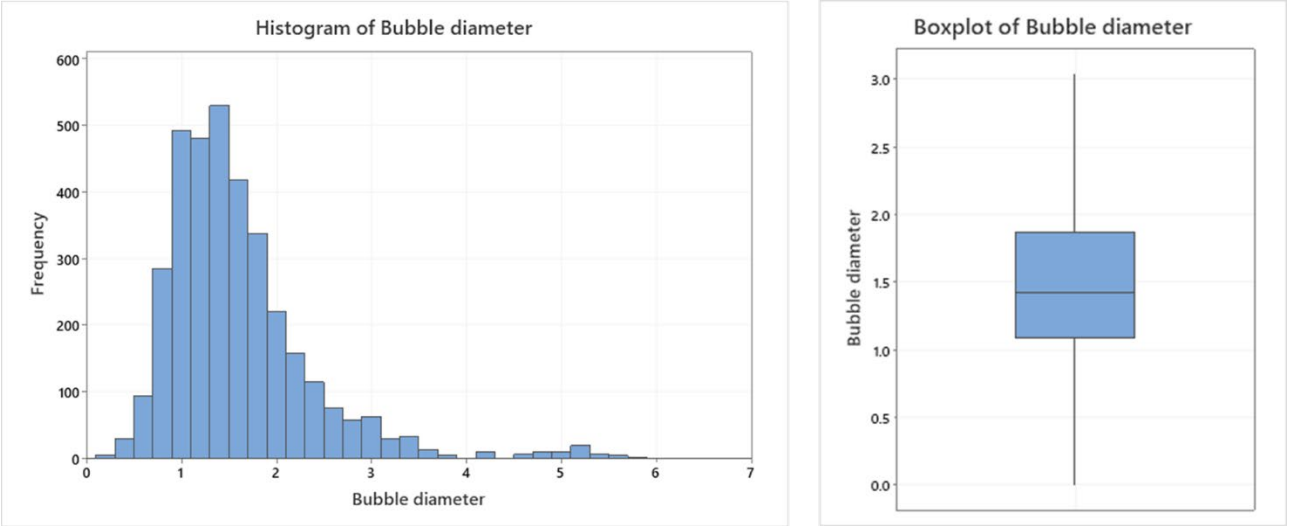

FIG 4 – Superficial gas velocity measurement histogram and box plot.

Flotation cell location and commodity

Gas characteristic measurements formed an integral part of the Australian Mineral Industries Research Association (AMIRA) P9 project, between 2000 and 2010. Measurements were conducted initially by researchers from the Julius Kruttschnitt Mineral Research Centre (JKMRC), McGill University and the University of Capetown (UCT), as well as JKTech, in the operating sites of P9 sponsor companies. This resulted in an emphasis on base metals (ie copper, lead and zinc) and precious metals (gold and platinum group metals). Table 1 shows this trend has continued, although in the last ten years there has been a number of characterisation measurements conducted in iron ore and phosphate operations. In 2005 the database geographic scope was limited, with 75 per cent of the total measurements from sites in. In the intervening years, gas characterisation measurements have become widespread, with 23 countries now represented.

TABLE 1

Database entry by commodity and cell location.

Commodity	Number of cells	Cell location	Number of cells
Copper	1492	Australia	1415
Platinum Group Metals	607	South Africa	594
Zinc	509	USA	414
Lead	412	Chile	283
Gold (pyrite)	366	Canada	259
Nickel	295	PNG	169
Molybdenum	214	Indonesia	151
Coal	127	Peru	143
Iron ore	90	Brazil	112
Other (including kaolin, palladium, phosphate, silica, talc)	157	Other (including Bolivia, China, Fiji, India, Iran, Ireland, Laos, Mexico, New Zealand, Portugal, Sweden, Tanzania, Zambia, Zimbabwe	712

Flotation cell duty

The database initially described flotation cell duty in terms of the operating site terminology. This resulted in multiple descriptions for cell duty, even when duties were similar. It has since been updated to summarise flotation duties as either flash flotation, prefloat, roughing, scavenging, cleaning, or cleaner scavenging. Although roughing-scavenging and cleaner flotation cells dominate Table 2, there are numerous entries for less common applications such prefloat and flash flotation.

TABLE 2

Database entry by flotation cell duty.

Flotation cell duty	Number of cells
Rougher	1868
Scavenger	678
Prefloat	32
Flash flotation	29
Cleaner	1509
Cleaner scavenger	149

Flotation cell size

The flotation capacity details for mechanical flotation cells are recorded in m^3. The cataloguing of flotation columns includes both short and tall columns, sparged columns, externally aerated columns and pneumatical flotation cells (Harbort, 2019; Harbort and Clarke, 2017).

A summary of data entry by flotation cell size is given in Table 3. Approximately 50 per cent of mechanical flotation cells entries are less than 20 m^3 in volume, with the remainder up to 300 m^3. There are a number of manufacturer data sets for 530 m^3 flotation cells they have not been independently verified and have not been included in the database. Flotation column entries are more evenly spread from 0.5 m diameter to greater than 5.0 m diameter.

TABLE 3

Database entry by flotation cell size.

Mechanical cell volume (m^3)	Number of cells	Flotation column diameter (m)	Number of cells
<20	1925	<0.5	90
20 to 50	824	0.5 to 1.0	55
50 to 100	185	1.0 to 2.0	29
100 to 150	417	2.0 to 3.0	63
150 to 300	289	3.0 to 4.0	77
>300	71	4.0 to 5.0	75
		>5.0	82

Flotation cell equipment type

The database currently catalogues 32 different flotation machine types. Entries commonly refer to the generally accepted industry name for a flotation machine, rather than the manufacturer name. A summary of the different equipment types is given in Table 4.

TABLE 4

Database entry by flotation cell equipment type.

Flotation cell	Number of cells
Outotec	1604
Wemco	1228
Dorr-Oliver	314
Agitair	280
Slamjet Column	113
Microcel	101
Denver	96
Bateman	84
Metso/Sala/Svedala	66
Other mechanical	99
Other column	168

Sufficient data exists to allow an evaluation of variation in flotation machine gas characterisation for Outotec, Wemco, Agitair, Dorr-Oliver, Jameson, Microcel and SlamJet column flotation machines. Miscellaneous columns were also grouped together for evaluation.

An effective way to increase flotation cell kinetic rate is to increase bubble surface area flux, either by increasing air addition (hence increasing superficial gas velocity) or decreasing bubble size. The most common method used in day-to-day operating is by variation in air addition.

Figure 5 provides a comparison of Jg with bubble size for the eight flotation machine types evaluated. Error bars represent one standard deviation. The data indicates that all the flotation machines have an increase in bubble size with Jg. Below a Jg of 1.5 cm/s bubble size variability, even in multiple plants with multiple duties and commodities is relatively small. Above a Jg of 1.5 cm/s bubble size variability increases.

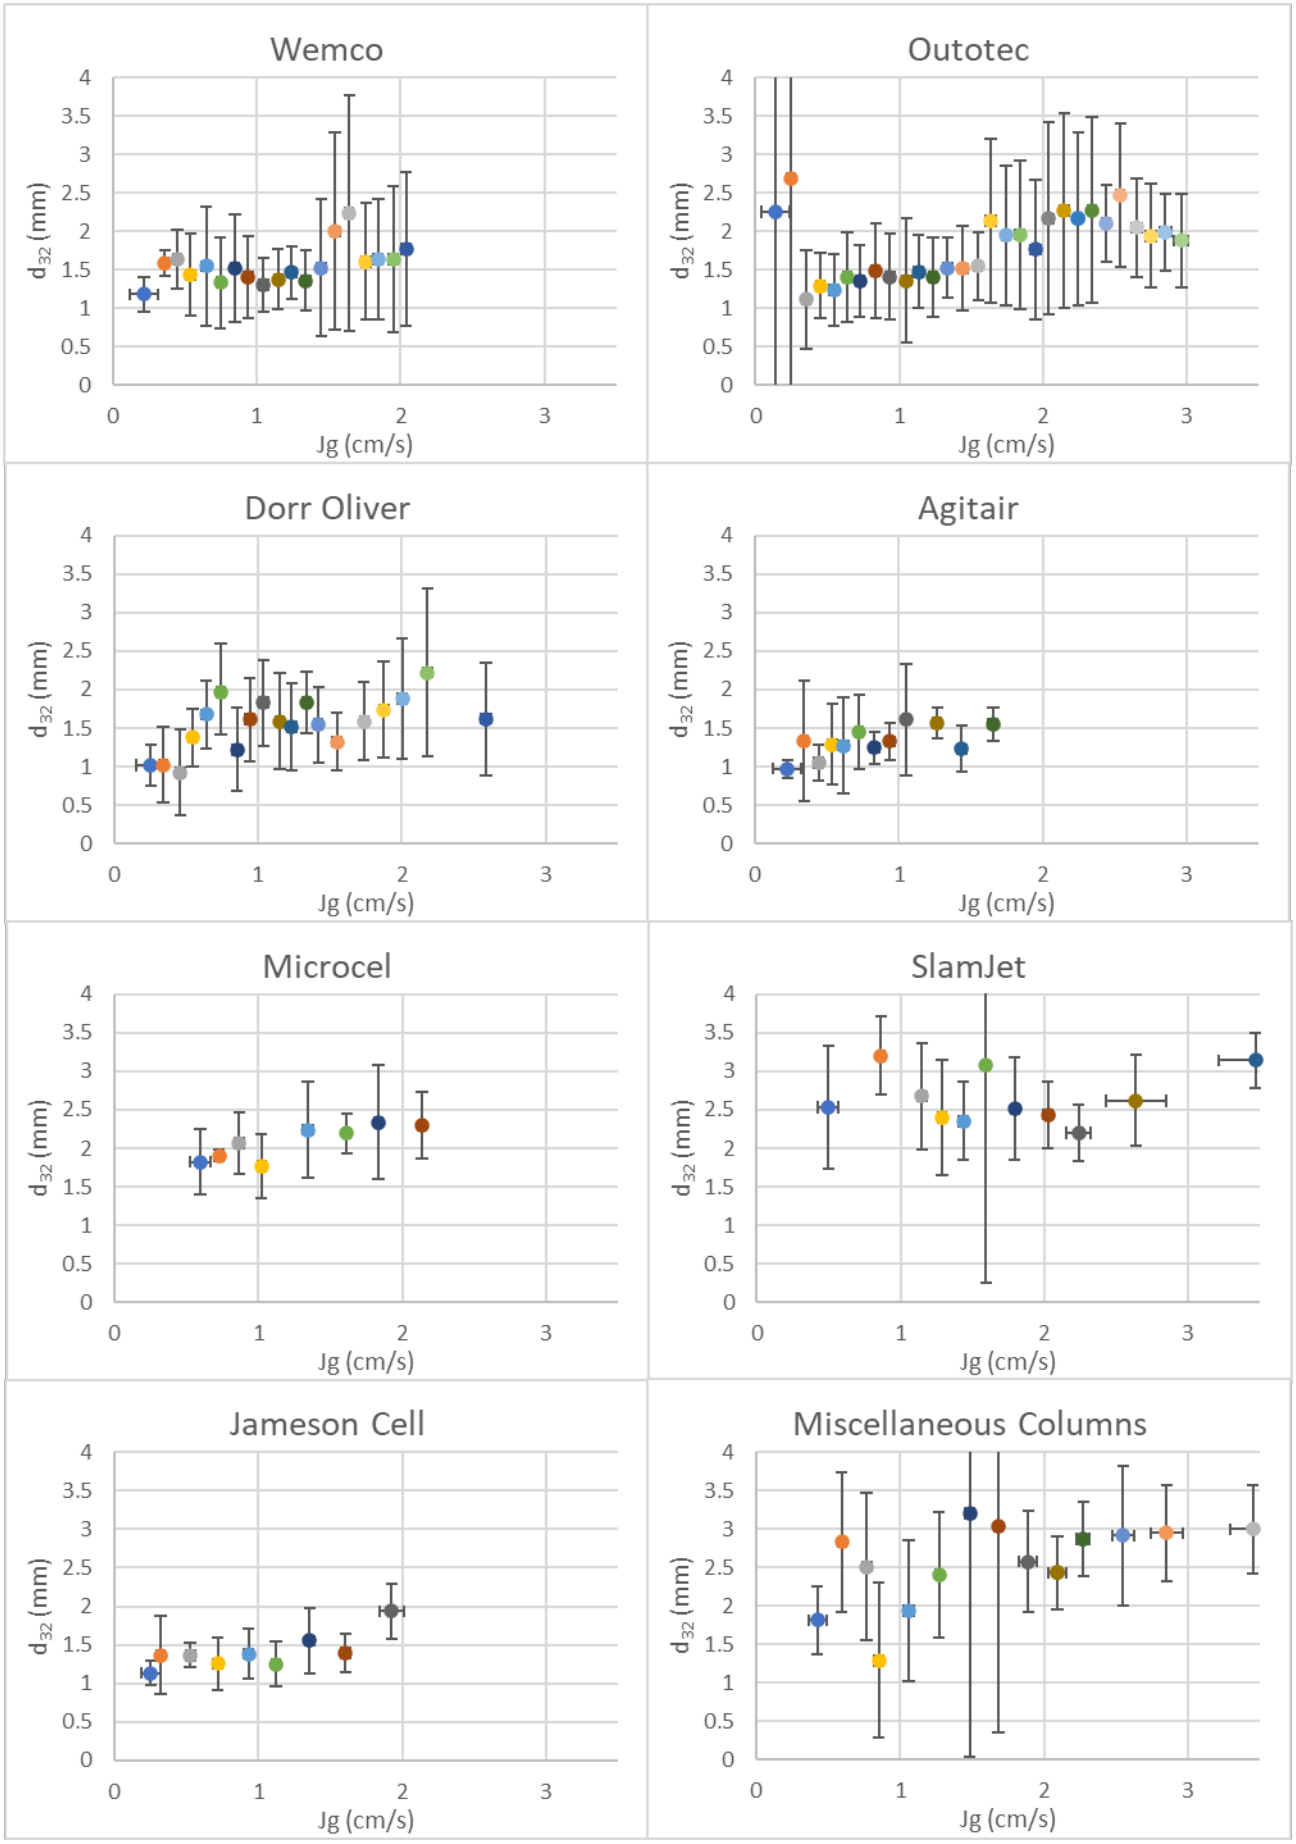

FIG 5 – Relationship between Jg and bubble sizes for various types of flotation machines.

The relationship between Jg and bubble size indicates that Jg and Sb do not form a linear relationship. This is evident in Figure 6 where each type of flotation machine has a maximum limiting Sb, or kinetic rate, based on gas characteristics.

The flotation machines can be catalogued into two groups base on the rate that Jg is converted into Sb, (ie the effectiveness of air addition to increase kinetic rate). The first group consists of Wemco, Outotec, Agitair, Dorr-Oliver and the Jameson Cell. These types of flotation machines could be considered more effective bubble surface are flux generators. The second group consists of the Microcel, SlamJet column and the miscellaneous column grouping. These types of flotation machines could be considered less effective bubble surface are flux generators.

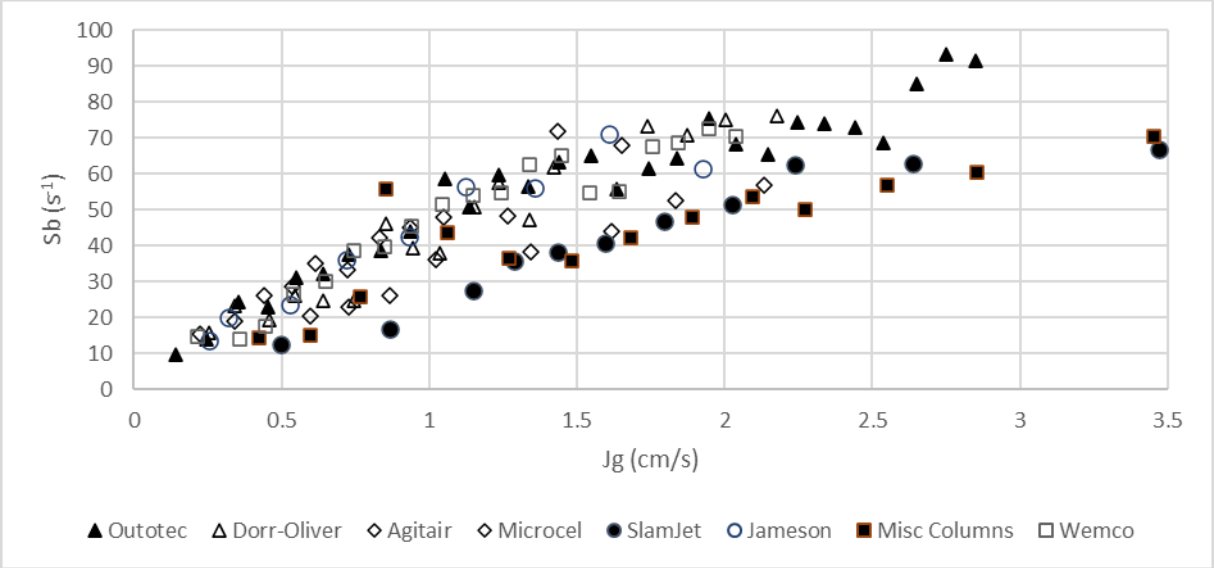

FIG 6 – Relationship between Jg and Sb for various types of flotation machines.

If the data is treated as a first order rate reaction, then k, the rate that Jg is converted into Sb, and $Sb_{max,}$ can be calculated. A summary of k and Sb_{max} values are given in Table 5. This indicates that the Jameson Cell and Agitair flotation cell are the most efficient bubble surface area flux generators, with k values of 1.64 and 1.61. They both achieved similar Sb_{max} values of ~72 m^{-1}. The Wemco, Outotec and Microcel had very similar Sb generation efficiency, with k values between 1.45 and 1.47. The Microcel however had a significantly lower Sb_{max} value of ~60 m^{-1}, compared to ~73 m^{-1} for the Wemco flotation cell an ~73 m^{-1} for the Outotec flotation cell. Of the mechanical flotation cells evaluated the Dorr-Oliver cell was the least efficient bubble surface are flux generator, with a k value of 1.31. It did however have the highest Sb_{max} value of ~80 m^{-1}. The SlamJet flotation column and miscellaneous columns group had the lowest bubble surface are flux generation efficiency, with k values of 0.84 and 1.61.

TABLE 5

k and Sb_{max} values for various types of flotation machine types.

Flotation machine type	k	Sb_{max}
Wemco	1.47	73
Outotec	1.47	75
Dorr-Oliver	1.31	80
Agitair	1.61	72
Microcel	1.45	60
SlamJet	0.85	72
Jameson	1.64	72
Misc Columns	0.80	74

Several observations can be drawn from this data, including:

- Wemco and Outotec flotation cells would require similar residence times to achieve the same performance.
- The Agitair flotation cell in a typical operating range would require less residence time to achieve the performance of Wemco and Outotec cells.
- The Dorr-Oliver flotation cell in a typical operating range would require more residence time to achieve the performance of Wemco and Outotec cells.
- The SlamJet column in a typical operating range would require notably more residence time to achieve the performance of Wemco and Outotec cells.
- At maximum stable Jg the Dorr-Oliver cell would require less residence time to achieve the performance of Wemco and Outotec cells.

CONCLUSIONS

A database has been generated using data collected from many types and sizes of industrial flotation cells over the past 27 years. The database currently contains gas dispersion measurements, such as bubble size, air hold-up and superficial gas velocity, for over 4200 cells and is continually growing with ongoing pulp phase investigations.

A review of data relating to different types of flotation machines indicates:

- the Jameson Cell and Agitair flotation cell are the most efficient bubble surface are flux generators.
- the Wemco, Outotec and Microcel had very similar Sb generation efficiency.
- of the mechanical flotation cells evaluated the Dorr-Oliver cell was the least efficient bubble surface are flux generator.
- the SlamJet flotation column and miscellaneous columns group had the lowest bubble surface are flux generation efficiency.

ABSTRACT

This work presents an experimental study of flow dynamics in a bubble column system (cross-section: 100 mm × 100 mm) using a non-intrusive optical technique with targeted application in a novel REFLUX™ Flotation Cell. The study had two aims – measurement of the bubble size distribution (BSD) and local energy dissipation rate in the system due to bubble motions over a low range of gas flux varied from 0.02 to 0.08 cm/s without impairing the visibility of the system. A central bubble plume was generated by injecting compressed air through a sintered glass distributor in quiescent liquid. Highspeed shadowgraphy imaging was performed to determine the BSD in the presence of surfactant (Sodium Dodecyl Sulfate (SDS) concentration ~ 10 ppm). The BSD exhibited a unimodal shape at different locations of the column for all gas flux cases. A non-intrusive particle image velocimetry (PIV) technique was used to quantify the flow field generated by the bubble motions, which was used to estimate the local energy dissipation rate. The local energy dissipation rate exhibited an increasing power-law dependency on the gas flux.

INTRODUCTION

The REFLUX™ flotation cell (RFC) is a novel flotation system that is capable of accommodating both fine and coarse particles and offers fast hydrodynamics and higher throughput than conventional mechanical flotation cells. The upper part of the cell is operated as an inverted fluidised bed of bubble-particle aggregates rising against the downflowing wash water in absence of any froth zone, and an array of parallel inclined channels in the bottom section for efficient segregation of bubbles from the tailings. Previous studies have analysed the operating principle of this system based on drift-flux analysis (Dickinson and Galvin, 2014); and demonstrated its superior desliming performance (Galvin and Dickinson, 2014; Galvin *et al* 2014).

The hydrodynamic characteristics, ie flow regimes, gas holdup, bubble size distribution, and local energy dissipation rate are some of the critical design parameters for evaluating the performance of the RFC system. However, these hydrodynamic parameters have not been extensively investigated for RFC system. Among the aforementioned parameters, bubble size plays a key role in governing gas holdup and bubble velocity. Ahmed and Jameson (1985) reported that a first-order rate equation could describe the removal of particles. They found that bubble size strongly influences the flotation rate constant (k), which is a complex function of the particle properties and the hydrodynamic conditions in the cell. However, bubble size has rarely been studied in lab-scale flotation cells, probably due to the fact that bubble size determination in aerated stirred vessels and particularly in three-phase systems (gas-liquid-solid) is complex. Tucker *et al* (1994) examined the influence of physical and chemical variables on bubble size in a modified 3 dm^3 Leeds flotation cell. Later, Laskowski *et al* (2003) extensively studied the influence of several commercial frothers on bubble

size in a 1 dm^3 open-top Leeds flotation cell using the University of Cape Town (UCT) bubble sizer technique.

Only a few studies have reported bubble size measurements in industrial cells which could be attributed to the complexities involved associated with such measurements and the lack of any standard methods. Jameson and Allum (1984) measured bubble size in operational cells using a photographic technique and reported that Sauter mean (d_{32}) bubble diameters in the range of 0.5–1.8 mm. Gorain *et al* (1997) reported values measured with the UCT (University of Cape Town) bubble sizer technique, in a 2.8 m^3 portable cell, in the range of 0.7–1.8 mm. While Deglon *et al* (2000), using the UCT method, found that d_{32} values varied over the range of 1.2–2.7 mm in industrial mechanical cells.

There are various intrusive and non-intrusive techniques are available for analysis the bubble size distribution (Adetunji and Rawatlal, 2017; Azizi *et al*, 2017; Guan and Yang, 2017; Hernandez-Alvarado *et al*, 2017; Lau *et al*, 2018a, 2018b; Möller *et al*, 2017; Murgan *et al*, 2017; Nedeltchevet al., 2017). The intrusive measurement technique tends to influence the fluid-structure, while the non-intrusive method does not affect the flow field in the system, which has attracted research attention in recent years (Wen *et al*, 2018).

The aims of the present study were two-fold – developing a non-intrusive technique to determine bubble size distribution that can be applied to RFC system and local energy dissipation rate in the system due to bubble motions. Experiments were performed in a rectangular bubble column of cross-section (100 × 100 mm^2) similar to a pilot plant scale RFC unit. High-speed imaging was performed, and an image processing algorithm was developed to quantify bubble size distribution. Additionally, local turbulence was characterised by energy dissipation rate at different bubble surface fluxes using the non-intrusive particle image velocimetry (PIV) technique.

EXPERIMENTAL DETAILS AND APPROACH

Apparatus

A schematic representation of the rectangular column is illustrated in Figure 1. The column is made of acrylic with dimension of 100 (L) × 100 (W) × 300 (H) mm^3. Compressed air and reverse osmosis (RO) water were used to generate the bubbly flow system. Gas was introduced into the column through a sintered disc type distributor located at the centre of the column. The pore size of the distributor varied in the range from 16 to 40 µm. The gas flow rate was varied between 0.1 to 0.5 L/min and monitored by measuring with a rotameter (Cole Parmer). The corresponding gas flux ranged from 0.02 to 0.08 cm/s. Before generating the bubbles, ~10 ppm Sodium Dodecyl Sulfate (SDS) was added to liquid to lower the surface tension and facilitate smaller size and spherical shape bubble generation. For all experimental conditions, the liquid level was kept at a height of 220 mm from the base of the column.

Experimental methodology

High-speed shadowgraphy imaging was performed to capture the motion of the bubbles in the presence of surfactant using a Phantom v311 camera (Figure 1a). The images (640 × 600 pixels) were captured at a frame rate of 2000 fps with an exposure time ~180 µs and stored in a computer. The experiments were carried out at two different locations in the column, (a) zone 1, located 80 mm above the gas distributor and (b) zone 2, located 20 mm below the free surface. An in-house image processing algorithm was developed and implemented in the open source tool *ImageJ* to determine the bubble size distribution.

In a separate set of experiments, high-speed particle image velocimetry (PIV) measurement (Figure 1b) was performed using a Nd:YLF laser system (Litron LDY303, wavelength: 527 nm, Dantec Dynamics, Denmark) involving 15 µm fluorescent seeding particles (Kanomax, Japan). Raw velocity data were processed using a combination of the adaptive PIV and average filtering algorithm to generate the velocity field. For the details of the PIV procedure readers are referred to Hoque *et al* (2018).

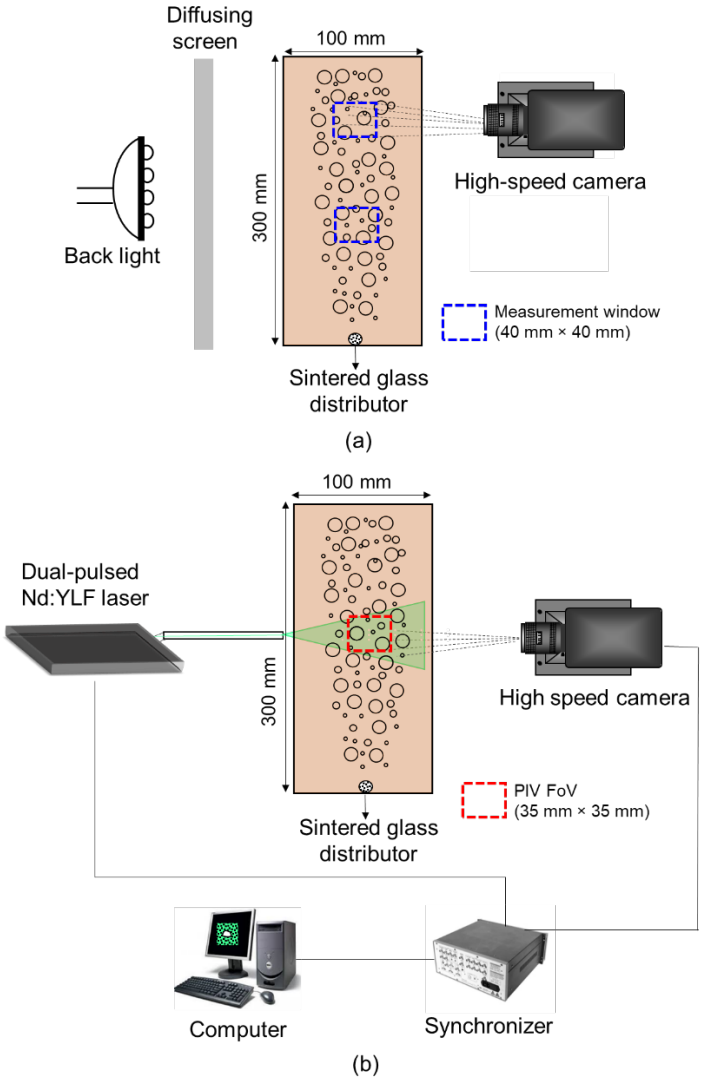

FIG 1 – Schematic arrangement of the experimental set-up with the measurement windows (a) bubble column with shadowgraphy technique and (b) PIV set-up for flow measurement inside the bubble column.

Image processing

The bubble properties that can be obtained from an image are the projected area and shape. Subsequently, from these quantities the centroids and equivalent diameter can be calculated. To acquire these values, a number of operations were performed using an in-house image processing algorithm in *ImageJ* (see overview in Figure 2). Starting with the raw image, the background was first removed using local area thresholding in conjunction with a median filter. Subsequently, a global threshold was applied to create a binary image, separating the bubbles from the background. After these filters have been applied, the detected objects were divided into individual bubbles and overlapping/clustering bubbles on the basis of the roundness.

The roundness is defined as:

$$Ro = \frac{S}{\sqrt{4pA}} \tag{1}$$

where S and A represent the surface perimeter and area of the bubble, respectively.

The criteria to distinguish isolated bubbles is $0.8 \leq Ro \leq 1.0$ pixels, was determined by applying the image processing algorithm to an initial set of image data. Finally, the area of each segregated bubble object was counted and converted from pixel to metric values using a predetermined

calibration factor (1 pixel ~ 61 μm). From the measured area, the equivalent bubble diameter was calculated as follows:

$$d_e = \sqrt{\frac{4A}{p}} \tag{2}$$

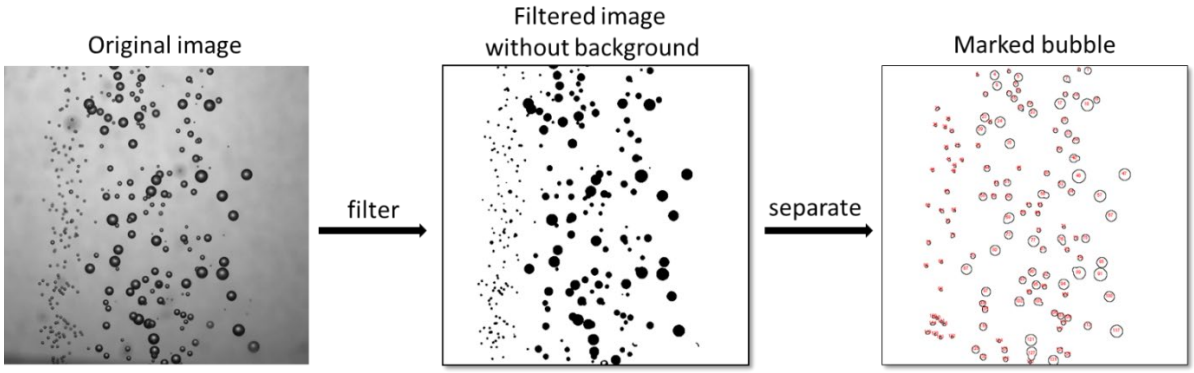

FIG 2 – Image processing sequences to determine the bubble size distribution.

Examples of the detected bubbles at different gas fluxes are shown in Figure 3. It can be observed that the algorithm marked different sizes of individual bubbles from the images leaving the aggregates of potential coalescence. The measured bubble size distributions (BSD) are expressed in the form of a number-based probability density function (PDF).

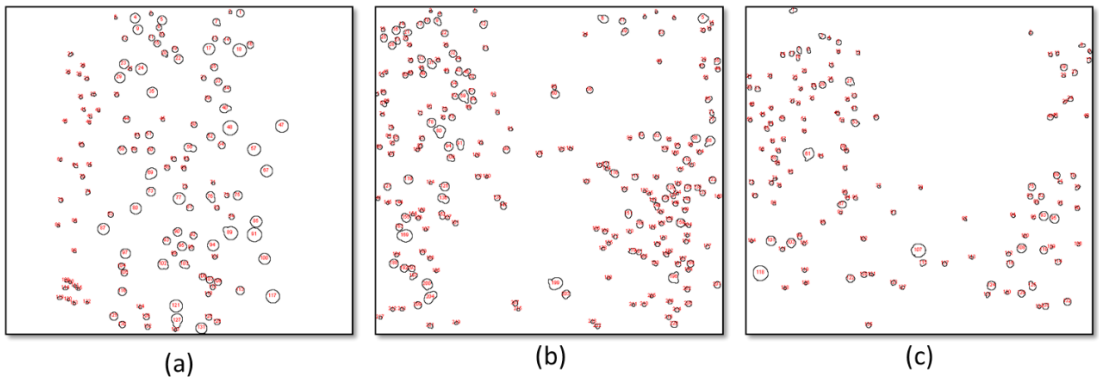

FIG 3 – Example images of detected bubbles at various gas flux (a) window 1: 0.02 cm/s (b) window 1: 0.05 cm/s and (c) window 1: 0.08 cm/s.

RESULTS AND DISCUSSIONS

Measurements were performed for initial liquid heights 220 mm with gas flux ranging from 0.02 to 0.085 cm/s for an air-water system. The measurement zones are shown in Figure 1. Samples of the obtained shadowgraphy images at zone 1 and zone 2 for different gas fluxes are demonstrated in Figures 4 and 5, respectively. At low gas flux of 0.02 cm/s (see Figure 4a), the bubbles appear to be similar in size at the different regions of the column (see Figure 5b). The bubbles rose upward in vertical chains in a homogeneous fashion without many interactions. When gas flux is increased to 0.03 cm/s (see Figures 4b and 5b), coalescence and breakup of bubbles start to play a role.

For a gas flux of 0.07 cm/s (see Figures 4c, and 5c), a bubble plume becomes more evident, which creates a strong liquid recirculation near the walls. A plume is a dynamic region within the bubble column, where the bubbles rise with a higher velocity. Bubble size in this dynamic region increases due to increased interactions among the bubbles, which lead to coalescence. The smaller bubbles accumulate close to the side walls and are dragged down by the down-flow of the liquid. Small vortical structures are also formed close to the side wall regions. At high gas flux of 0.08 cm/s (see Figures 4d and 5d), high bubble rise velocity is observed and the down-flow of smaller bubbles at the side walls is clearly visible. A large number of small bubbles were formed due to intense bubble breakup. The bubbly flow was very chaotic, which made visual observation very difficult.

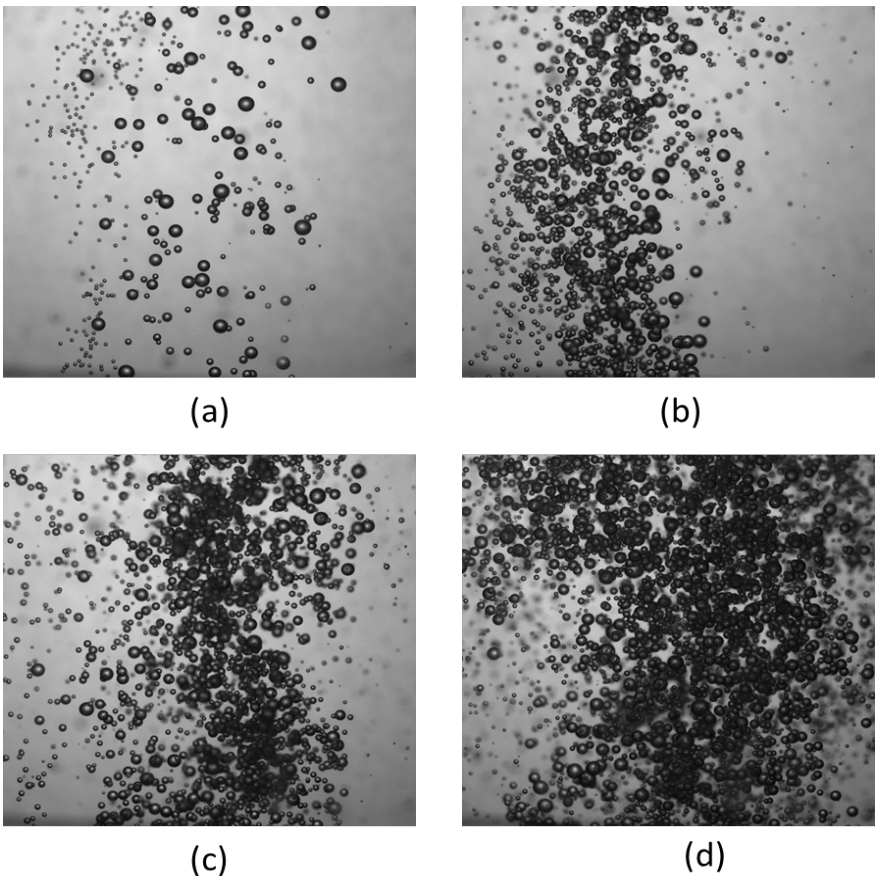

FIG 4 – Highspeed camera images of the bubbly flow at zone 1 for different gas flux: (a) 0.02 cm/s, (b) 0.03 cm/s, (c) 0.07 cm/s and (d) 0.08 cm/s.

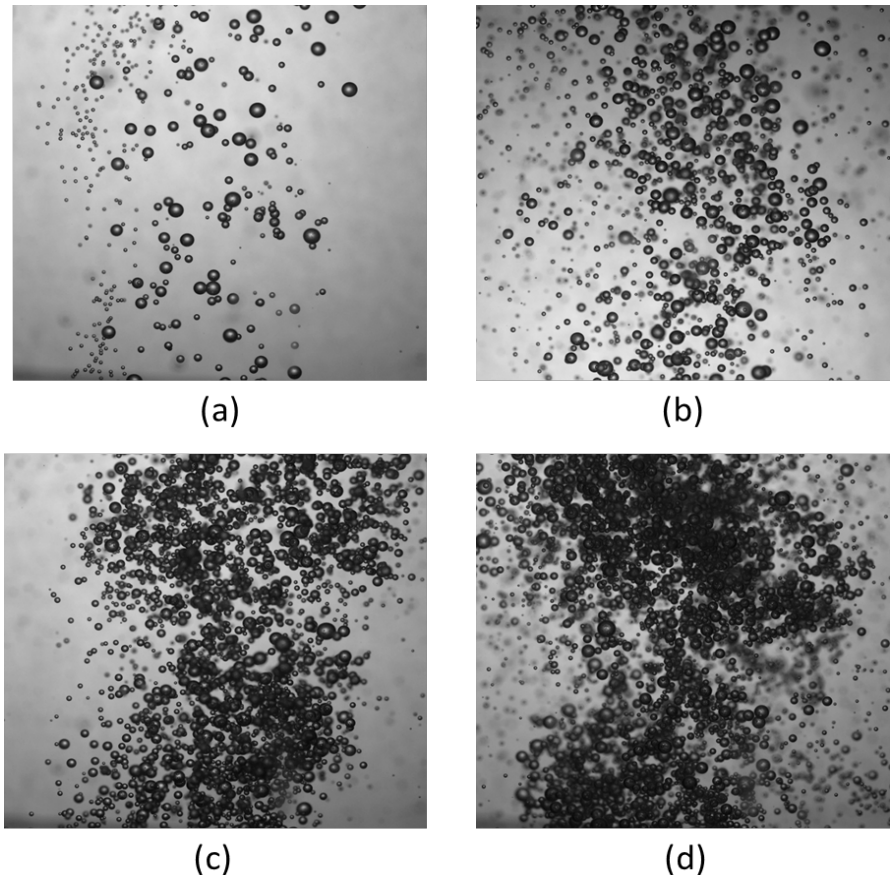

FIG 5 – Highspeed camera images of the bubbly flow at zone 2 for different gas flux: (a) 0.02 cm/s, (b) 0.03 cm/s, (c) 0.07 cm/s and (d) 0.08 cm/s.

The bubble size distributions for different flow rate at zones 1 and 2 are illustrated in Figures 6 and 7, respectively. A normal distribution curve was fitted to the experimental bubble size distribution to estimate the mean bubble diameter with standard deviation. For similar liquid heights, the trends (ie PDF has a unimodal shape) are the same and the bubble size distribution at zone 1 of the column prevails at the upper zone 2. There is an equilibrium between bubble coalescence and breakup along the height of the column, and the gas flux solely determines this equilibrium. To illustrate the effect of the gas flux on the BSD, the mean bubble diameter and corresponding standard deviation are listed in Table 1. It shows that the increase of gas flux decreases the mean bubble diameter with the corresponding standard deviation. The mean bubble diameter of zone 1 was approximately 8 per cent smaller than the bubble diameter of zone 2.

TABLE 1

The mean and standard deviation of the detected bubbles for different flow rate.

Gas flux (cm/s)	Zone 1		Zone 2	
	Mean bubble diameter d_b (mm)	Standard deviation	Mean bubble diameter d_b (mm)	Standard deviation
0.01	0.601	0.267	0.657	0.340
0.03	0.561	0.245	0.622	0.279
0.05	0.541	0.224	0.570	0.236
0.07	0.511	0.225	0.528	0.237
0.08	0.509	0.217	0.512	0.230

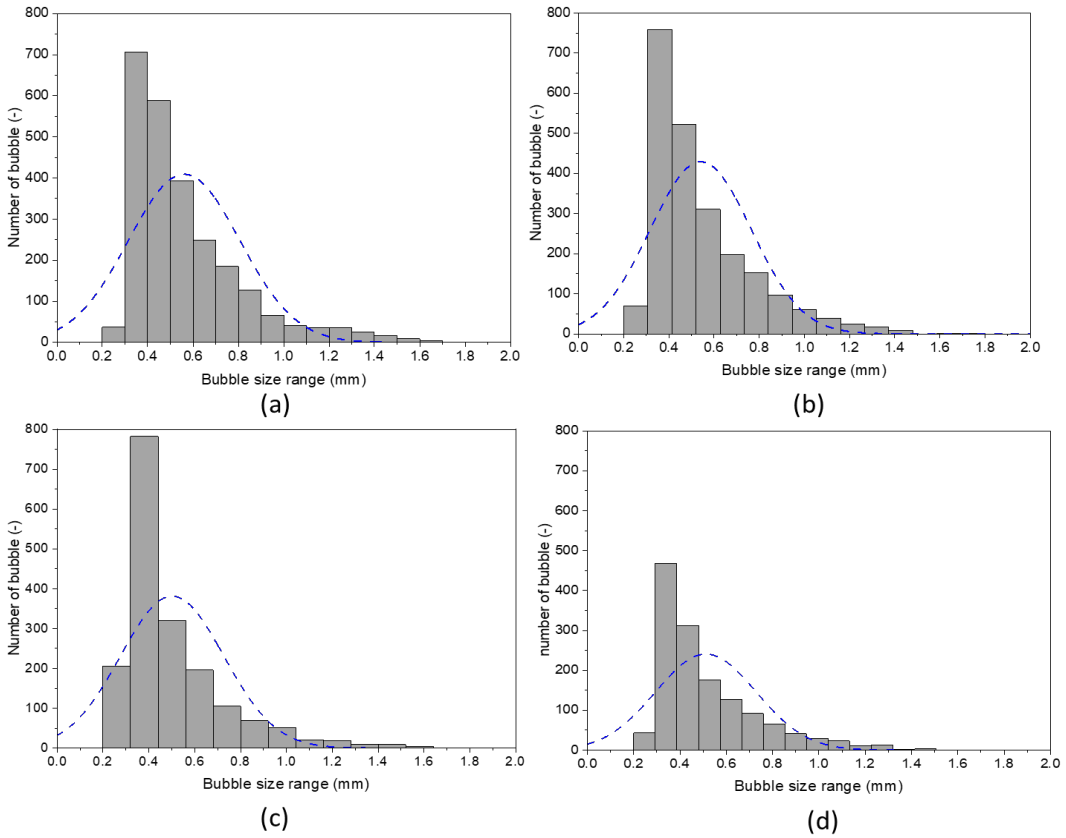

FIG 6 – Bubble size distribution at zone 1 for different gas flux: (a) 0.02 cm/s, (b) 0.05 cm/s, and (c) 0.07 cm/s and (d) 0.08 cm/s. The blue dotted curve represents the normal distribution.

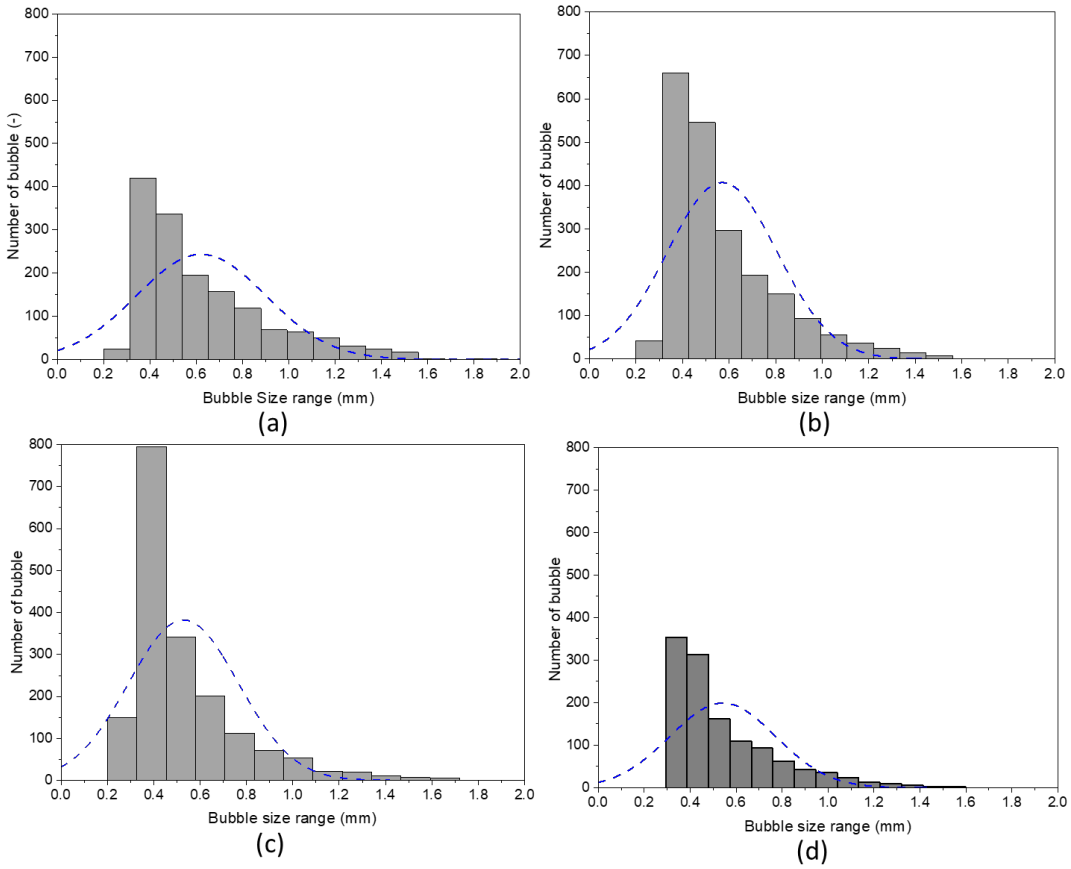

FIG 7 – Bubble size distribution at zone 2 for different gas flux: (a) 0.02 cm/s, (b) 0.05 cm/s, and (c) 0.07 cm/s and (d) 0.08 cm/s. The blue dotted curve represents the normal distribution.

It was interesting to carry out the PIV experiments in the bubble column to quantify the spatial distribution of the local energy dissipation rate. In the present study, the local turbulence energy dissipation rate was determined using the two-dimensional velocity gradient method and can be written as (Hoque *et al*, 2015):

$$\varepsilon = \nu\left(2\overline{\left(\frac{\partial u}{\partial x}\right)^2} + 3\overline{\left(\frac{\partial v}{\partial x}\right)^2} + 3\overline{\left(\frac{\partial u}{\partial y}\right)^2} + 2\overline{\left(\frac{\partial v}{\partial y}\right)^2} + 2\overline{\left(\frac{\partial u}{\partial y}\frac{\partial v}{\partial x}\right)}\right) \tag{3}$$

where u and v represent the fluctuating velocity components along the x and y directions, respectively.

Figure 8 compare the spatial distribution of energy dissipation rate for two different gas fluxes such as 0.02 and 0.08 cm/s, respectively. It can be observed that the local energy dissipation rate is high close to the bubble plume region. More specifically, the local energy dissipation rate could be seen concentrated near the bubble interface, the effect of which decreases further away from the interface. Serizawa and Kataoka (1990) mentioned two different effects of the bubble plume on the local energy dissipation rate: (a) an increase in the specific energy dissipation rate due to the higher velocity gradients near the bubble interface and (b) an energy dumping effect due to bubble deformation. The flow acceleration by bubbles and suppression of the coherent structures could also be responsible for a higher local energy dissipation rate (Zhang *et al*, 2015).

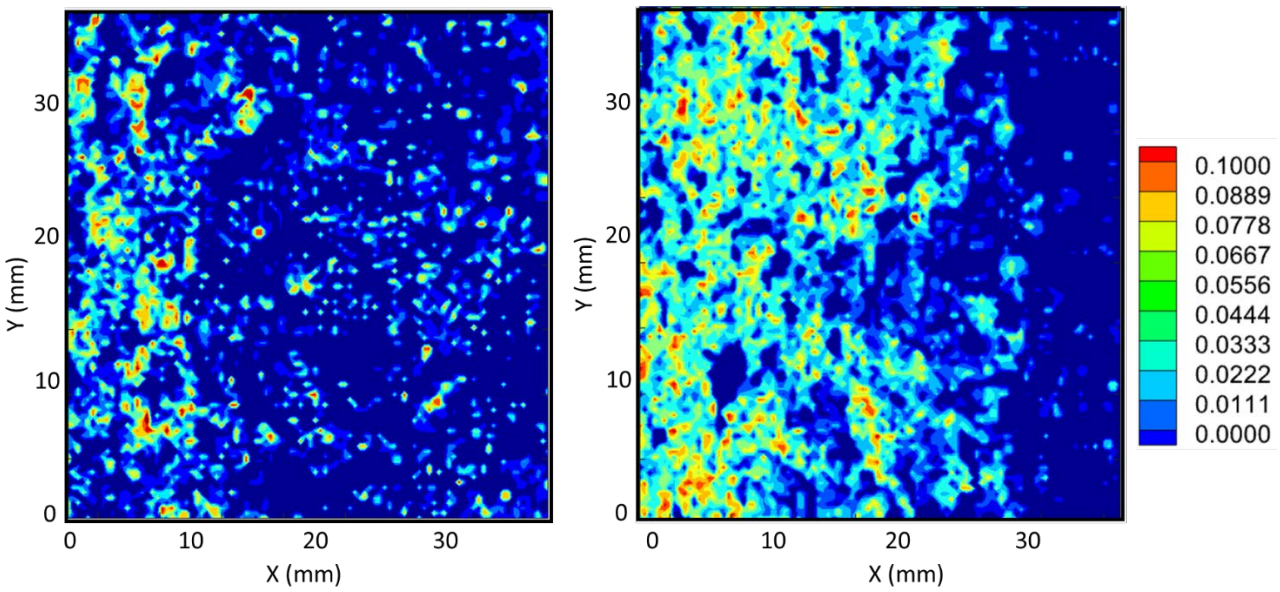

FIG 8 – Contours of local energy dissipation rate at different gas flux: (a) 0.02 cm/s and (b) 0.08 cm/s.

Figure 9 shows the time-averaged energy dissipation rate as a function of different gas flux. It can be observed that the value of ε increases with an increase in the gas flux, which can be attributed to more interfacial momentum exchange by the bubbles with the surrounding liquid leading to breakup and coalescence. The trend suggests a power-law dependency of local energy dissipation rate (R^2 ~ 0.99) and yields an exponent of 15.23 over the gas flux range studied.

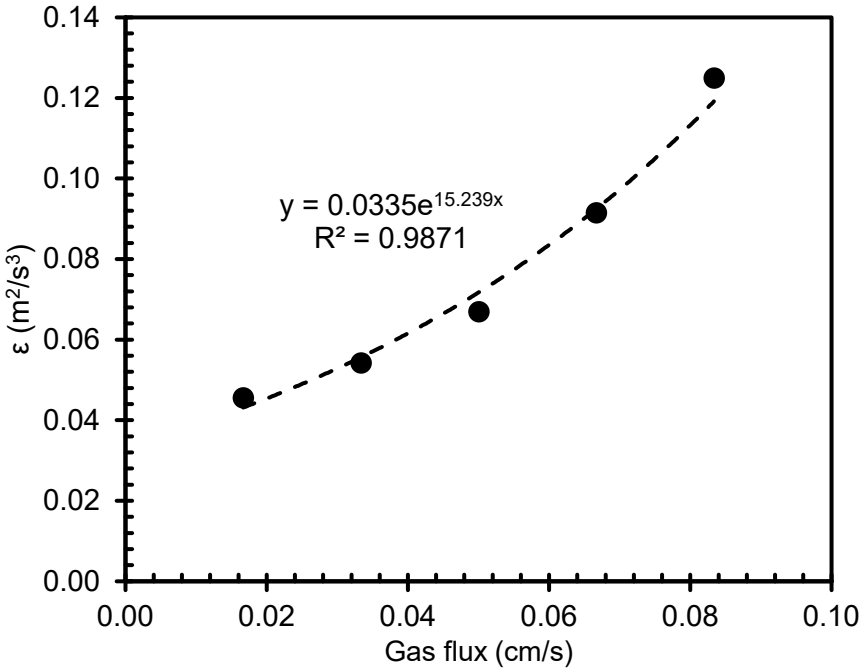

FIG 9 – Local energy dissipation rate as a function of gas flux.

CONCLUSIONS

In the present study, an image processing framework was proposed to optically measure bubble size distributions (BSD) in a bubble column system similar to the top section of a RFC system with potential application to a pilot plant scale RFC system soon. The algorithm was tested over the gas flux range from 0.02 to 0.08 cm/s to consistently isolate individual bubbles from the background interferences. The system showed increased heterogeneity with increased gas flux exhibiting bubble coalescence and breakups. Bubble size measured at the two locations (mid column and near the

free surface) showed similar distributions exhibiting reduction in mean bubble size at increasing gas flux. The local energy dissipation rate due to momentum transfer from bubbles to surrounding liquid was found to be positively correlated to the gas flux and showed a power-law dependency.

ABSTRACT

Platinum Group Metal (PGM) bearing ores from the Upper Group 2 (UG2) reef often contain significant concentrations of chromite which can potentially be upgraded to produce a saleable product. A common approach is to implement gravity separation on the PGM flotation circuit tailings. However, where the particle size range of interest is broad and the lower size limit ultra-fine, the challenge is how to maximise the recovery at a saleable product grade without compromising throughput. This study was concerned with the performance of a REFLUX™ Classifier for beneficiation of a PGM bearing chromite ore and the benefits of size classification. The sample had a nominal top size of 0.5 mm and was processed over the complete size range and in two discrete size classes following classification at 106 µm. The primary goal was to produce a concentrate exceeding 40 wt. per cent Cr_2O_3, ideally approaching 42 wt. per cent Cr_2O_3, with minimal PGM losses above 106 µm. A major challenge was to process at the required solids throughput in a single stage with the feed pulp density constrained to a nominal upper limit of 30 wt. per cent solids. It was found that varying the controller density set point of the REFLUX™ Classifier produced strong control of the product grade. Products as high as 41.1 wt. per cent Cr_2O_3 were produced at 78.6 per cent recovery for the +106 µm material, while in the −106 µm portion the product grade was as high as 41.4 wt. per cent Cr_2O_3 at 83.2 per cent recovery. Processing the feed in discrete size classes enabled the volumetric feed and fluidisation rates to be optimised for a given application; hence, superior performance was achieved at the finer sizes. This work has demonstrated the value in considering feed preparation as well as technology selection in developing a robust process solution.

INTRODUCTION

The world's largest deposits of Platinum Group Metals (PGM) exist within three South African orebodies: the Merensky reef, the Upper Group 2 (UG2) reef and the Platreef. The UG2 reef is unique in that the most abundant gangue is chromite ($FeO{\cdot}Cr_2O_3$) which can contribute to up to 75 per cent of the ore by mass (Hay and Roy, 2010). The concentration of chromite, as represented by a Cr_2O_3 assay, must be limited to 2.5–3.0 wt. per cent Cr_2O_3 in the final PGM flotation concentrate to avoid issues in smelting (Ross, 2018). However, additional value can be added to the operation by upgrading the PGM flotation tailings which can be sold as a separate concentrate exceeding 40 wt. per cent Cr_2O_3. The most common approach used within the industry has been gravity separation (Dawson, 2010; Engelbrecht, 2012).

There has been recent interest from the industry in the potential of a gravity separator known as the REFLUX™ Classifier for the recovery of chromite, primarily motivated by the need to process down to very fine sizes to extract maximum value. The REFLUX™ Classifier is the combination of a fluidised bed and a set of parallel inclined channels which is configured as shown in Figure 1. Feed material enters below the inclined channels and is fluidised by water delivered through the base to establish a suspension. The fluidisation rate is kept as close to the minimum as possible, promoting a high suspension density which provides a mechanism for an autogenous dense medium effect (Galvin *et al,* 2016). Here, low-density particles can be expelled from the bed and transported to the inclined channels where they readily report to the overflow. Conversely, high-density particles can settle onto the upwards facing inclined surface of the channel and slide back into the vertical section, eventually migrating to the underflow. Narrow channels provide enhanced settling area for retaining very fine high-density particles while simultaneously promoting stronger velocity gradients for re-suspending the relatively coarse gangue (Galvin *et al,* 2020).

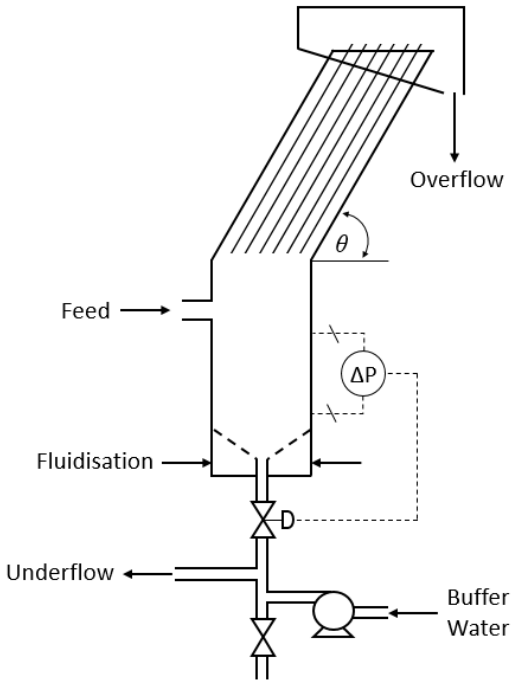

FIG 1 – Schematic of the laboratory-scale REFLUX™ Classifier.

The present study focuses on the beneficiation of a UG2 chromite sample of nominal top size 0.5 mm. The sample was processed over the complete −500 + 0 µm size range and in two discrete size classes following classification at 106 µm. In view of a proposed plant design, the −500 + 106 µm material needed to be processed at around 80 t/h in a full-scale system, while the finer fraction required only 20 t/h, with the feed pulp density constrained to a maximum of roughly 30 wt. per cent solids. These separations pose a significant challenge given the ultra-fine lower size limit and dilute nature of the feed which dictates high volumetric feed rates to achieve the desired solids throughput. In a conventional spirals plant the solution would likely be to increase the number of spiral starts and/or add additional processing stages. The approach outlined in this paper, however, is based on a single-stage of separation and therefore represents a significant simplification on current industry practice.

This paper outlines an investigation into maximising the product grade and recovery of dense minerals in a single-stage REFLUX™ Classifier, and the benefits of size classification in achieving this goal. A series of laboratory-scale experiments were conducted according to the above conditions and processing constraints, the objective being to produce a 40 wt. per cent Cr_2O_3 product grade at the highest recovery achievable. The data indicates that the performance of the separator is highest when the volumetric feed and fluidisation rates are optimised for a given size range.

MATERIALS AND METHOD

The feed was a UG2 chromite-bearing PGM ore of nominal top size 0.5 mm. The head grade of the −500 + 106 µm portion of the feed was around 32 wt. per cent Cr_2O_3 and 1.2 g/t 2E (Pt + Pd), for the −106 + 0 µm portion 30 wt. per cent Cr_2O_3 and 7 g/t 2E, and for the −500 + 0 µm sample 28 wt. per cent Cr_2O_3 and 7.9 g/t 2E. Note that the samples were received pre-classified. For each experiment, the feed solids were concentrated in a 300 L mixing tank and discharged into a series of buckets. The pulp density of the highly concentrated buckets was measured during preparation, allowing the concentrated feed slurry and a known volume of water to be added to the mixing tank to prepare the feed to the target pulp density, in this case nominally 30 wt. per cent.

As illustrated in Figure 1, the continuous separation experiments were conducted using the RC100, a laboratory-scale REFLUX™ Classifier with a horizontal cross-section of 100 mm × 100 mm. Both sections of the unit were 1000 mm long, though the upper section was positioned at an angle of 70° relative to the horizontal. The perpendicular inclined plate spacing was 3 mm. Fluidisation was supplied via mains tap water and delivered through an inverted square shaped pyramid chamber positioned below the vertical section. The underflow buffer system situated at the underflow discharge provided stability in the system control (Galvin *et al,* 2016).

Tables 1 and 2 summarise the process parameters for the experiments conducted on the −500 + 106 µm and −106 + 0 µm material, respectively, in order of increasing set point. Assuming a 3.1 m^2 RC2000 unit for full-scale implementation, the target solids throughput for the −500 + 106 µm experiments needed to be 26 t/(m^2 h), and for the −106 + 0 µm experiments roughly 7 t/(m^2 h). The final experiment, effectively Run 8, was for the −500 + 0 µm material and was processed using conditions equivalent to Run 1 in Table 1 to allow for comparison with a narrower size range at the same top size.

TABLE 1

Summary of the process parameters used for the −500 + 106 µm experiments in order of increasing set point.

Run	Feed pulp density	Feed rate	Solids throughput	Fluidisation rate	Set point	Channel spacing
(-)	(wt.%)	(L/min)	t/(m^2 h)	(L/min)	(kg/m^3)	(mm)
2	26.6	13.0	29.4	2.1	2650	3.0
3	31.6	13.0	34.5	2.1	2680	3.0
1	25.6	13.0	28.5	2.1	2750	3.0
4	30.9	13.0	31.0	2.1	2800	3.0

TABLE 2

Summary of the process parameters used for the −106 + 0 µm experiments in order of increasing set point.

Run	Feed pulp density	Feed rate	Solids throughput	Fluidisation rate	Set point	Channel spacing
(-)	(wt.%)	(L/min)	t/(m^2 h)	(L/min)	(kg/m^3)	(mm)
6	31.4	4.0	9.44	0.20	2500	3.0
7	30.6	4.0	9.20	0.20	2550	3.0
5	32.0	4.0	9.15	0.18	2600	3.0

The REFLUX™ Classifier control system was driven by a feedback PID control loop. The difference in pressure between two probes positioned 60 and 440 mm above the flange of the fluidisation chamber was used to infer the average suspension density. The position of the underflow valve was

regulated based on the measured value in comparison to the target suspension density, referred to as the set point. The set point is a major factor determining the mass yield for the separation.

The experiments were run for at least 60 min (often 180 min for the fine size range) to ensure steady-state had been reached before sampling the underflow and overflow streams simultaneously. Following this, a feed sample was taken. These run samples were then dried to determine the pulp density and solids rate of each stream before being combined and subdivided into smaller representative samples using a riffle splitter. The size distributions of each stream were then determined by de-sliming one subsample (chosen at random) at the low sieve size and sieving using a √2 series. The full set of sieves used were 500, 425, 300, 212, 150, 106, 75, 53 and 38 µm. The sized samples were then sent to an external laboratory for assay analysis to determine the concentration of Cr_2O_3 using XRF and Pt + Pd using fire assay with ICP-MS finish. A mass-balance reconciliation was then performed to provide a consistent basis for calculating the yield and recovery using the two-product formula (Wills and Finch, 2016).

RESULTS AND DISCUSSION

−500 + 106 µm experiments

The approach was taken to vary the controller density set point of the REFLUX™ Classifier to examine the relationship between the product grade and recovery achievable. Table 3 summarises the results from the experiments while Figure 2 plots the product grade as a function of recovery.

TABLE 3

Summary of the results for the −500 + 106 µm experiments in terms of Cr_2O_3 (mass-balanced data).

Run	Feed grade	Underflow-grade	Overflow-grade	Mass yield	Upgrade ratio	Cr_2O_3 recovery
(-)	(wt.% Cr_2O_3)	(wt.% Cr_2O_3)	(wt.% Cr_2O_3)	(wt.%)	(-)	(%)
2	30.8	39.2	2.6	76.9	1.3	98.1
3	32.6	40.2	4.4	78.9	1.2	97.2
1	32.6	41.1	18.5	62.3	1.3	78.6
4	31.9	41.4	28.6	25.9	1.3	33.6

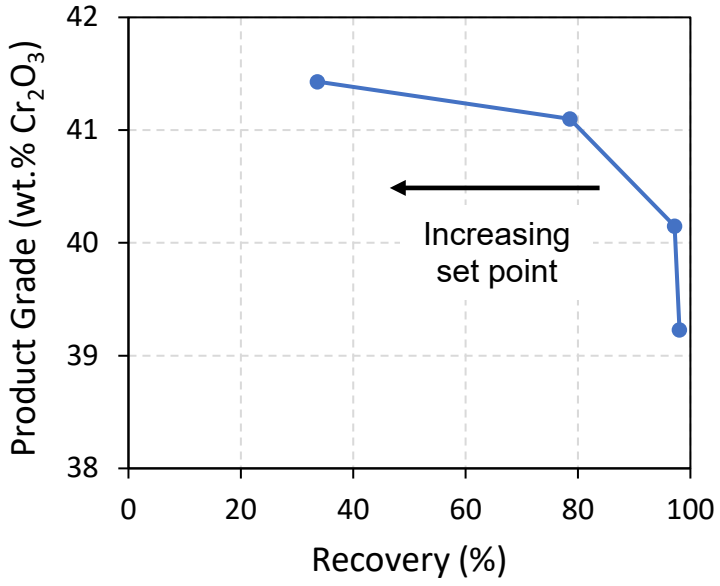

FIG 2 – Cr_2O_3 product grade as a function of recovery for the −500 + 106 µm experiments. The set point values of the experiments range from 2800 kg/m^3 (left) to 2650 kg/m^3 (right).

In Run 3, an underflow product just exceeding the minimum for metallurgical grade chromite (40 wt. per cent Cr_2O_3) was produced with a remarkably high recovery of 97.2 per cent. By increasing the set point, the product grade has increased to as high as 41.4 wt. per cent Cr_2O_3, though Run 1 is considered a better result given the product grade was only marginally lower at 41.1 wt. per cent Cr_2O_3 with a significantly higher recovery of 78.6 per cent. This sharp drop in recovery for a very similar product grade reflects the liberation characteristics of the material where it becomes difficult to build very high suspension densities without incurring some losses. Clearly, however, the density set point provides a robust method for controlling the product grade to achieve the maximum recovery possible.

High PGM recovery in this size class could be considered problematic given the PGM's are unlikely to be liberated such that the overflow could be re-ground once stripped of chromite. However, as shown in Table 4, the PGM recovery was 23.4 per cent in Run 1, reaching as high as 25.6 per cent in Run 3. This is not considered an issue given this means that effectively 75 per cent of the PGMs reported to the overflow. In fact, there has been an effective upgrade of PGM into the overflow stream by a factor of roughly 3 in Runs 2 and 3 which may help justify the option of regrinding.

TABLE 4

Summary of the results for the −500 + 106 µm experiments in terms of PGM (mass-balanced data). Note that the 2E Recovery refers to the percentage of the PGM in the feed which reported to the underflow stream.

Run	Feed grade	Underflow-grade	Overflow-grade	Mass yield	2E recovery
(-)	(g/t 2E)	(g/t 2E)	(g/t 2E)	(wt.%)	(%)
2	1.12	0.25	3.92	76.3	17.0
3	0.80	0.26	2.75	78.4	25.6
1	0.72	0.27	1.47	62.5	23.4
4	1.06	0.26	1.34	25.9	6.4

−106 + 0 µm experiments

The second size class provided was much finer but only needed to be processed at the equivalent of 20 t/h in a full-scale unit, equivalent to ~7 t/(m^2 h). Again, the approach was taken to vary the controller density set point. Table 5 summarises the key results from this program of experiments.

TABLE 5

Summary of the results for the −106 + 0 µm experiments in terms of Cr_2O_3 (mass-balanced data).

Run	Feed grade	Underflow-grade	Overflow-grade	Mass yield	Upgrade ratio	Cr_2O_3 recovery
(-)	(wt.% Cr_2O_3)	(wt.% Cr_2O_3)	(wt.% Cr_2O_3)	(wt.%)	(-)	(%)
6	30.8	41.0	5.9	70.8	1.3	94.4
7	30.8	41.1	14.0	62.0	1.3	82.8
5	29.4	41.4	12.1	59.1	1.4	83.2

The performance for the finer separations was once again strong, with product grades exceeding 41 wt. per cent Cr_2O_3 produced at recoveries as high as 94.4 per cent. The recovery at the highest set point was 83.2 per cent so there may still be scope to push the product grade even higher at a loss in recovery by increasing the set point above 2600 kg/m^3.

Figure 3 shows the recovery and product grade as a function of the geometric mean particle size for Runs 5–7. Note that the +106 µm and −38 µm size fractions were assigned geometric mean sizes of 106 and 38 µm, respectively. It is evident from Figure 3a that very high recoveries have been

achieved for all sizes greater than 38 µm. For the −38 µm size fraction, the recovery in Run 6 is still reasonable at roughly 60 per cent, particularly considering this includes particles below 10 µm.

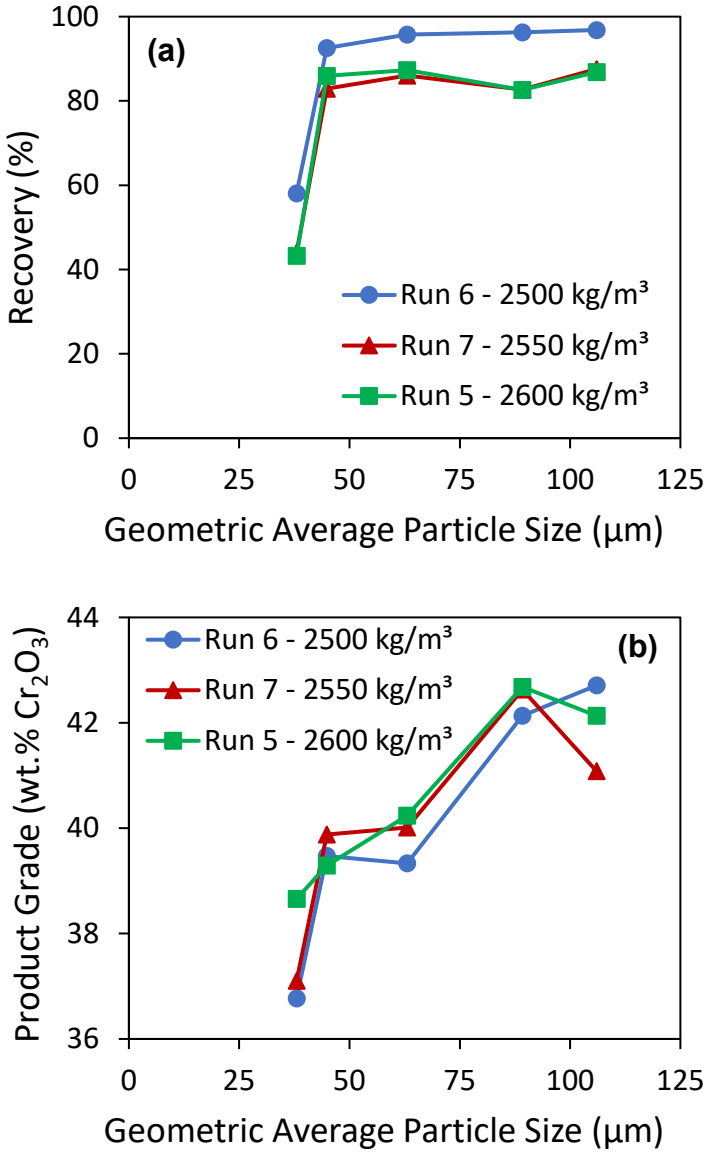

FIG 3 – (a) recovery and (b) product grade as a function of geometric mean particle size for the −106 µm experiments based on Cr_2O_3 (mass-balanced data).

−500 + 0 µm experiments

The target parameters for the −500 + 0 µm experiment were the same as Run 1 where the set point was 2750 kg/m^3 and the fluidisation rate 2.1 L/min. The feed pulp density was 21 wt. per cent solids which was slightly lower than expected, delivering a solids throughput of 20.3 t/(m^2 h). The volumetric feed rate was roughly three-fold higher than that used in the −106 µm work. Table 6 shows the mass-balanced mass percent and Cr_2O_3 assay data as a function of particle size for the feed, underflow and overflow.

TABLE 6

Mass percent and Cr_2O_3 assay data as a function of particle size for the −500 + 0 µm experiment (mass-balanced data). Note that data in red font was assumed in the mass-balance reconciliation because there was insufficient mass for an assay.

Size Range (µm)	Feed		Underflow		Overflow		Yield (wt.%)	Recovery (%)
	Mass (wt.%)	Assay (wt.% Cr_2O_3)	Mass (wt.%)	Assay (wt.% Cr_2O_3)	Mass (wt.%)	Assay (wt.% Cr_2O_3)		
+500	1.25	27.0	5.79	32.1	0.26	2.32	82.9	98.5
−500 + 425	2.35	31.9	10.8	38.2	0.51	3.17	82.2	98.2
−425 + 300	7.85	31.0	30.4	41.5	2.93	7.26	69.4	92.8
−300 + 212	11.5	29.6	30.6	44.9	7.32	15.6	47.7	72.4
−212 + 150	16.6	28.3	18.1	42.3	16.2	24.9	19.6	29.3
−150 + 106	16.9	28.2	4.09	43.7	19.7	27.4	4.36	6.77
−106 + 75	12.7	27.6	0.26	44.1	15.4	27.6	0.36	0.58
−75 + 53	10.8	26.3	0.0	48.1	13.1	26.3	0.05	0.08
−53 + 38	2.91	25.1	0.0	43.3	3.54	25.0	0.05	0.09
−38	17.3	22.5	0.0	44.2	21.0	22.5	0.09	0.18
Head Grade		27.3		41.9		24.1	17.9	27.5

Table 6 shows that a 41.9 wt. per cent Cr_2O_3 product was produced. The recovery by size data indicated that reasonable recovery was obtained as fine as 212 µm, with some recovery down to 106 µm, though the overall mass yield was only 17.9 wt. per cent. Given the mass yields in the earlier experiments were at least 60 wt. per cent when high recovery was achieved, the set point for this composite separation was clearly far too high.

It is noted that 56.3 per cent of the feed was coarser than 106 µm. In Run 1, which used the same set point to process the +106 µm feed, the recovery was 78.6 per cent. Thus, based on the entire −500 µm feed, the Run 1 recovery was effectively 0.563 × 78.6 ~ 44 per cent which is significantly higher than the recovery value of 27.5 per cent achieved here on the overall feed. While a modest shift in set point would likely match the Run 1 result, this work does suggest advantages in operating in parallel instead of series by classifying the feed prior to the gravity separation.

The recovery effectively drops to zero below 106 µm. This behaviour is a result of the high fluidisation velocity required to facilitate fluidisation of the 500 µm top size, roughly an order of magnitude higher than that required in the −106 µm work. The net result is that it becomes increasingly difficult to recover fines as the particle size range broadens. Therefore, the best approach is to classify the feed upfront so that a lower fluidisation rate can be used for the fine separation.

CONCLUSIONS

A series of REFLUX™ Classifier experiments have been conducted on size classes of −500 + 106 µm, −106 + 0 µm, and −500 + 0 µm. A product grade as high as 41.1 wt. per cent Cr_2O_3 was produced at 78.6 per cent recovery for the −500 + 106 µm material, while in the −106 + 0 µm portion the product grade was as high as 41.4 wt. per cent Cr_2O_3 at 83.2 per cent recovery. Varying the controller density set point provided strong control of the product grade and recovery, with recoveries exceeding 94 per cent produced at saleable grade for both discrete size classes. For the −500 + 0 µm experiment, the recovery declined significantly below 106 µm, largely due to the high fluidisation and volumetric feed rates required. The improved performance for the discrete particle size ranges demonstrates the benefits of classifying the feed so that the volumetric feed and fluidisation rates can be optimised for the application.

ABSTRACT

Mineral processing plants require a storage buffer to bridge differences in production rates between mining and processing. Where coarse ores are processed, such as coal or hard rock, this buffer may be an ore stockpile or silo.

For wet-mining processes, eg dredging or hydraulic mining, or where fine ores are slurried close to the mining face, a surge-bin is used to contain the plant feed and smooth out the variations in mining rates. These bins have gradually evolved from simple storage vessels to units that are now frequently part of the mineral separation process itself, such as providing a desliming function to remove deleterious ultrafine gangue. This feed conditioning is often essential to achieve the levels of plant performance required in times of declining ore grades and or where inherent ore characteristics make separations harder to achieve.

To achieve these dual roles requires careful consideration of bin design factors such as geometry and lining selection and increased use of instrumentation and advanced, or remotely supervised, control systems. All this ensures they provide capacity to smooth out variations in mining rates and guarantees that when conditioning ores or adjusting slurry densities ahead of the plant it is achieved without loss of valuable minerals.

This paper examines the evolution of the modern surge-bin from a simple, so called, constant density tank with its inherent mass-flow compromises, limited feed preparation and beneficiation abilities, and footprint penalty, to a current state-of-the-art surge-bin, the LFCU, with a control system which provides demonstrable steady outputs, while conditioning and in some cases beneficiating the ROM material and all from a highly compact unit.

It further discusses their use in other applications around the world, for example providing the necessary security for long distant high-density pumping systems; constant high density, low water usage, tailings disposal pipelines and high capacity ultrafine iron ore beneficiation.

INTRODUCTION

In the mineral processing industry, even the simplest of processing units requires a method of introducing material into the process which bridges the different production rates between mining and processing. For coarse ores, typically greater than say 5 to 10 mm the required buffer can be a stockpile or silo which are invariably dry or low moisture storage units. The stockpile or silo discharge can then be regulated to the desired feed rate and with water added to the required density provide the process plant with the optimum feed conditions.

For fine ores where wet mining is utilised, eg dredging or hydraulic mining, or where the ROM material is slurried close to the mining face and pumped to the processing plant, a surge bin is utilised to smooth out the mining rate fluctuations and provide a steady feed rate, in terms of solids rate and slurry density, to the process by varying its contained solids volume according to the balance between the input and output. That is the solids level in the bin will rise should the mining rate exceed the bin output rate and vice versa when the mining rate is less than the discharge rate. This type of surge bin is the subject of this paper.

PROCESS REQUIREMENTS

In the traditional sense the surge bin is designed to carry out two functions:

1. To smooth out variations in input flows so that stable output flows can be maintained which, in turn, allows downstream equipment to be adjusted to operate at optimum conditions.
2. To provide a storage of material so that output flows can be maintained during short interruptions to input flows.

In the first instance, so long as input flows do not exceed the maximum design input flows to the extent, or for sufficient time, such that the amount of material added to the bin would exceed its capacity and overflow the surge bin, the surge bin can operate effectively providing steady output flows in perpetuity. The target range of the surge bin capacity or level in operation is therefore set by the degree of 'safety margin' the operator wishes to maintain to avoid bin overflows in the event of occasional severe and short-term spikes.

Where long-term input and outflows are reasonably matched and input flow spikes are reasonably infrequent, short-lived and/or not extreme, the bin level can be set at almost any level. In this scenario, residence or retention time is largely immaterial.

The more frequent, extreme and/or sustained are any input flow spikes, the more defensively the notional operational bin level may need to be set.

To fulfill its second duty then, the surge bin target operating level should be set close to the maximum design capacity so that, in the event of an unforeseen loss or reduction of input flow, downstream operation is maintained for as long as required before the input flow recommences and presumably catches up over time. If a known input flow downtime is approaching, the surge bin can be run to full design capacity just prior to the input flow interruption to maximise the volume retained in the bin and hence maintain downstream operation for as long as possible.

Clearly, maximum benefit from the surge bin is achieved when the input supply and output demands are reasonably matched over the medium or longer term and input spikes are not the result of very extreme flows or sustained operation above output flow rate.

Should the surge bin be set-up with a continuous overflow it will provide additional de-sliming of the ROM feed material.

CONSTANT DENSITY TANK TO SURGE BIN

Perhaps the original slurry surge bin concept followed the dry storage silo principle where a volume of slurry was held at or marginally higher density than the discharge density required. This type of surge bin acted somewhat like a large transfer hopper and generally were typified by operating without an overflow. Without an overflow no additional de-sliming of the feed occurs.

In addition, the CD tank without overflow does not take advantage of the natural consolidation property of the material to optimise the solids surge volume that consequently limited the available capacity to smooth out input variations. For example (Table 1), at 800 t/h bin discharge rate, a CD tank with some 250 m^3 bin surge volume a CD tank would provide 10 minutes of surge capacity. Compared to the modern surge bin, taking advantage of the consolidation properties of the feed material, would provide some 50 per cent more surge time (15 minutes) for the same volume and although the modern surge bin has a conical bottom section and the CD tank is cylindrical, they would be similar in overall dimensions (~7 m Ø × ~7 m tall).

TABLE 1

CD tank versus surge bin**.**

Parameter	Unit	CD Tank	Surge Bin
Discharge Rate	t/h	800	800
Surge Capacity	minutes	10	15
Surge Mass	t	135	203
Surge Material Density	% solids (w/w)	40	80
Surge Material Density	% solids (v/v)	20	30
Surge Material Slurry Volume	m^3	253	203
Surge Material Water Volume	m^3	253	51

As the material consolidates in the modern surge bin, an up-current of liquid occurs that reports to the bin overflow which carries with it slimes (ultra-fine material) in a process Mineral Technologies refers to as ‘autogenous’ classification. This has the benefit of providing additional desliming of the feed to the downstream process and in some cases can replace a second stage of desliming hydrocyclones.

It is noted that as the surge volume contained in the CD tank is very sensitive to all but relatively minor feed fluctuations, particularly in regard to feed density, its application in most mining operations and certainly for dredging operations is not recommended nor appropriate.

MAXIMISING CONSOLIDATION IN THE MODERN SURGE BIN

Conventional surge bins were design as large tanks, under the assumption that simply storing a large volume of feed would even out fluctuations in feed rate and feed density to downstream equipment (Lyons *et al,* 2009). Typically, these conventional surge bin had sidewall angles of around 45 degrees above the horizontal and designed without consideration of the flow properties of the material.

In the past, surge bins were not designed to promote mass flow and instead operated with funnel flow (Figure 1) with a rat-hole in the centre of the bin allowing the incoming feed to pass straight through the bin. Interruptions in feed caused the consolidated material hanging up on the bin sides to slough off, sending high density slugs forward to the processing plant (Lyons *et al*, 2009).

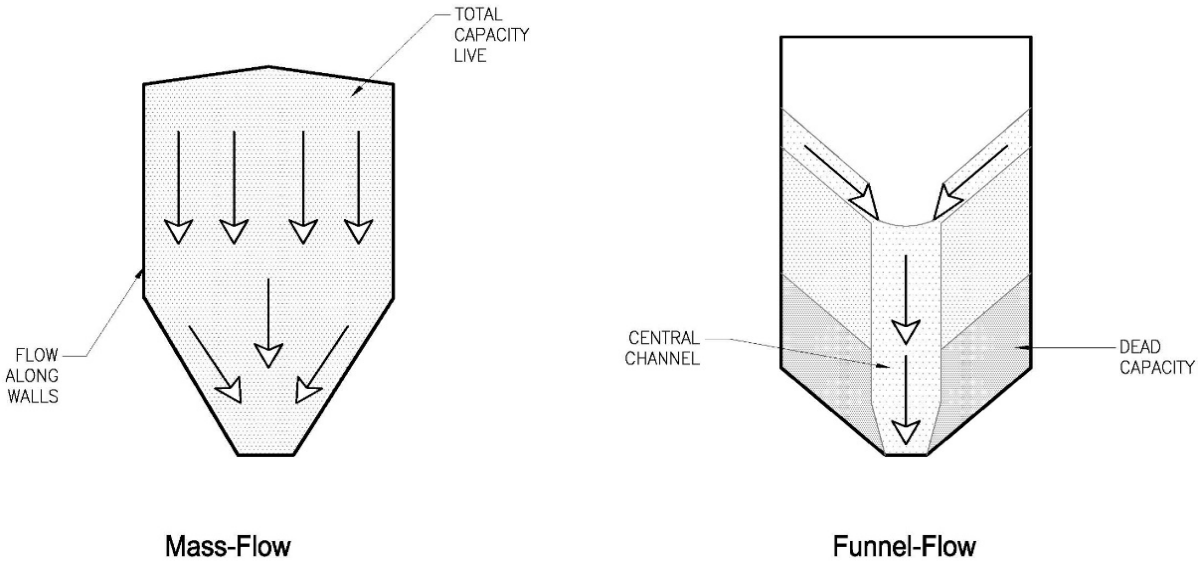

FIG 1 – Mass flow versus funnel flow.

To overcome some of these material flow problems, surge bins were designed with 60° sidewall and agitation water was injected near the pump suction point to fluidise the material. In some later surge bins, system was added to draw water from the top of the bin and inject into the underflow pump suction point. Underflow density could be controlled by throttling the waterflow through this bypass using valves. These surge bins operated reasonably well within a narrow range of solids levels inside the bin, but outside this range the pressure differential between the slurry suction and the bypass suction made density control difficult (Lyons *et al*, 2009).

A change of thinking started slightly more than 10 years ago: the slurry in the surge bin is considered as a consolidated bulk solid in saturated conditions instead of a viscous liquid. The surge bin is then designed more like a silo than a slurry tank.

It has been shown (Lecreps and Wiche, 2013) that Jenike's (1964) design principles can be applied to the design of modern surge bins handling slurries if the test work is conducted in a submerged condition. In other words, when designing bins to treat water and mineral ore slurry mixtures, the mixture is should be considered a bulk solid under saturated conditions, rather than as a viscous liquid.

One major benefit of the modern surge bin design is the capability to handle very high density material (>80 per cent w/w) by achieving mass flow-through adherence to Jenike's (1964) design principles. Storing the surge bin feed at higher density increases the solids storage capacity of the tank. Furthermore, the process of consolidating the feed displaces a large volume of liquid in a rising current that can be used to achieve a separation, or desliming step. In some cases, a beneficiation process can be achieved (Hasan *et al,* 2021).

MODERN SURGE BIN OPERATING STRATEGY

By way of an extreme example demonstrating how the modern surge bin coupled with an optimised production strategy manages a highly variable mining operation (by a floating dredge) and provides a very stable and consistent feed to the wet plant, a simulation of an African mineral sands operation is presented below. The operation has a name plate design capacity of 500 t/h and consists of a floating dredge supplying a floating wet concentrator spiral plant.

Dredge operation

The dredge in this operation would be considered somewhat oversized for optimum synchronisation between the dredge output rate and the WCP feed rate, which tends to make the output in terms of the solids rate extremely variable and difficult to regulate. This factor tests the surge bin operation and clearly demonstrates its effectiveness. It is noted that the dredge volume output is well regulated.

The dredge output for the simulation has been based on actual data gathered from the operation data logging system and is tabulated (Table 2).

TABLE 2

Dredge output.

Parameter	Unit	Value
Upper Push Rate	t/h	1200
Upper Reduced Rate	t/h	1000
Minimum Rate	t/h	10
Maximum Volume Rate	m^3/h	1600
Minimum Volume Rate	m^3/h	1400
Bin Level Reduced Rate Trigger	t	100
Bin Level Push Rate Trigger	t	50

The 'Upper Push Rate' is the maximum instantaneous production rate derived from the plant SCADA system and is triggered when the surge bin reaches the minimum operational level, while the 'Upper

Reduced Rate' is a notional reduction or easing off in the maximum production rate which is triggered when the surge bin reaches the maximum operational level.

Surge bin

The surge bin in this operation is primarily provided to stabilise the dredge output rate as feed to the WCP. The relevant surge bin design data and simulation parameters are tabulated in Table 3.

TABLE 3

Surge bin design parameters.

Parameter	Unit	Value
Total Maximum Live Capacity	t	125
Maximum Rougher Spiral Feed Rate	t/h	520
Minimum Rougher Spiral Feed Rate	t/h	480
Maximum RSF Volume Rate	m^3/h	880
Minimum RSF Volume Rate	m^3/h	860

Simulation

The simulation output is depicted in Figure 2.

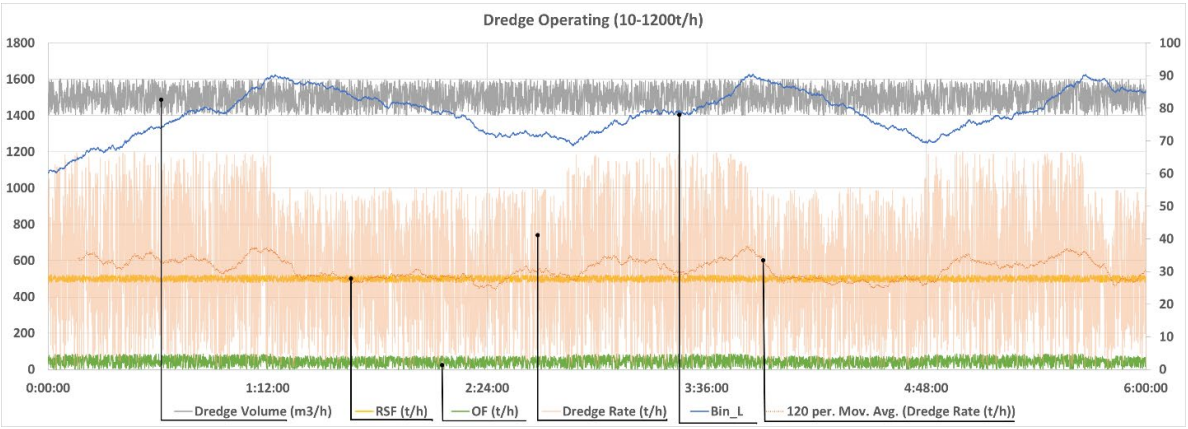

FIG 2 – Simulation output.

Figure 2 clearly indicates that incorporating a push and reduced maximum dredge output rates (t/h) that are triggered by the minimum and maximum bin levels stable rougher spiral feed can be sustained.

Although this strategy has not been adopted it is useful to note that as depicted in Figure 3 similar stability of the rougher spiral feed is being achieved.

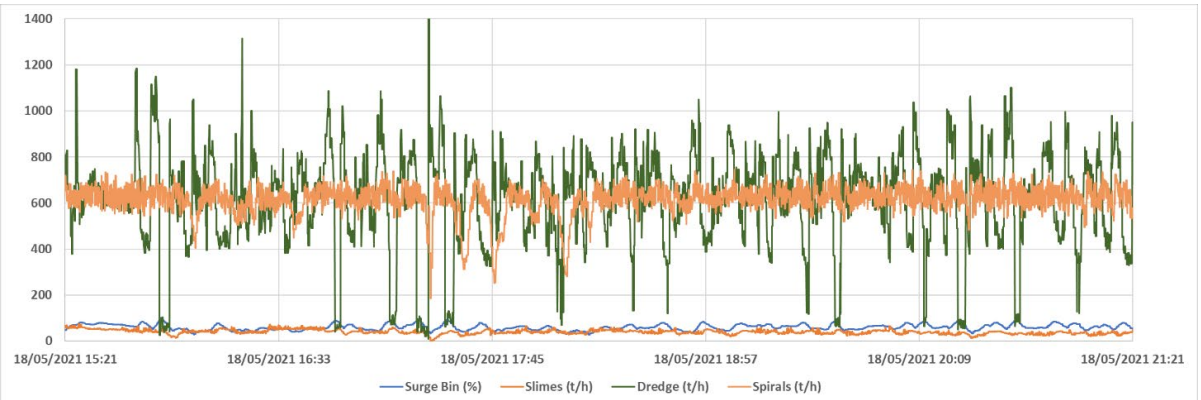

FIG 3 – Actual plant trend data.

BENEFICIATION IN A MODERN SURGE BIN

Mineral Technologies (MT) worked with a prominent Australian iron ore producer over five years (starting in 2017) to implement gravity separation technology based on the modern surge-bin design for the beneficiation of ultrafine magnetite.

Extensive laboratory and pilot-scale test work has shown that, when well liberated, the magnetite can be efficiently separated from the gangue material using a modern surge-bin design referred to as Lyons Technology. Four Lyons Units, with a combined throughput capacity of 4500 t/h solids, reduce the SiO_2 content by a factor of approximately 2.2 (from 19.7 per cent to 9.0 per cent) whilst upgrading the magnetite Fe content by a factor of approximately 1.2 (from 53.7 per cent to 63.6 per cent Fe) (Hasan *et al*, 2021).

Figures 4 and 5 show these results graphically, whilst Figure 6 provides a qualitative visual illustration of the upgrade.

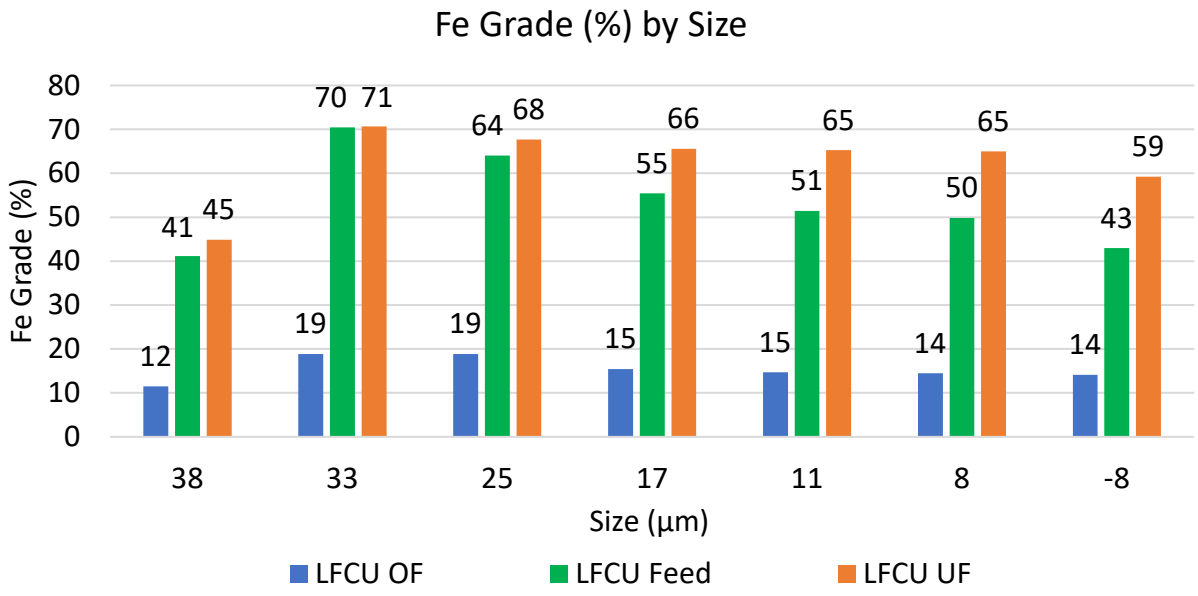

FIG 4 – magnetite beneficiation results using modern surge-bin technology, Fe grade by size.

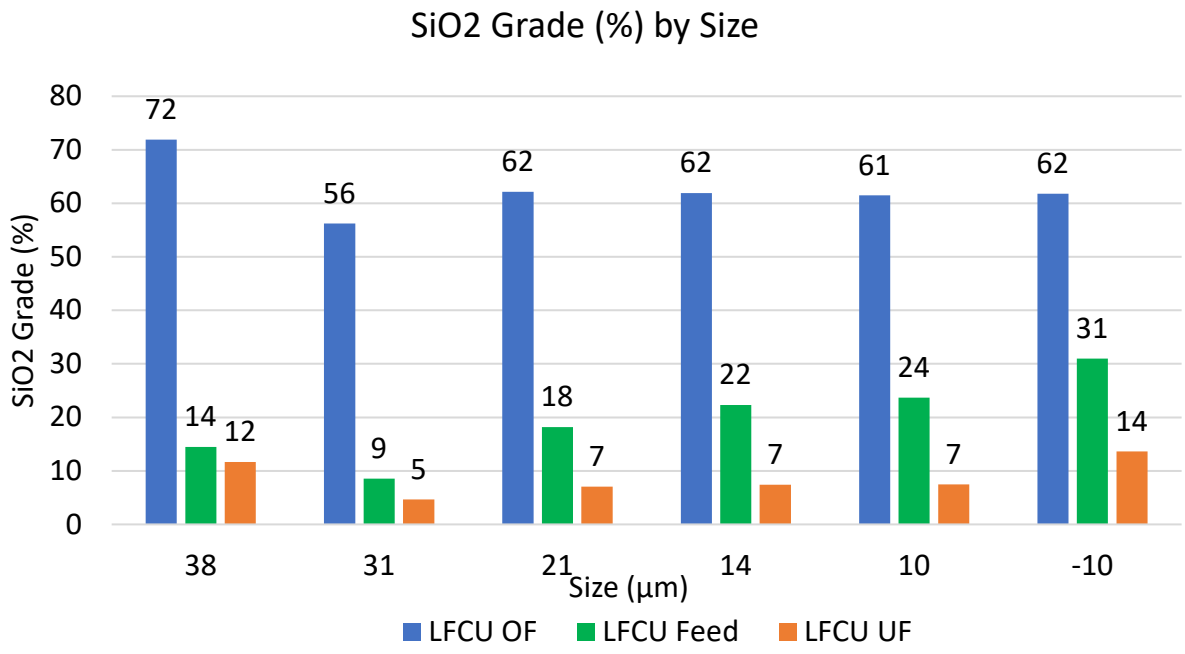

FIG 5 – Magnetite beneficiation results using modern surge-bin technology, SiO_2 grade by size.

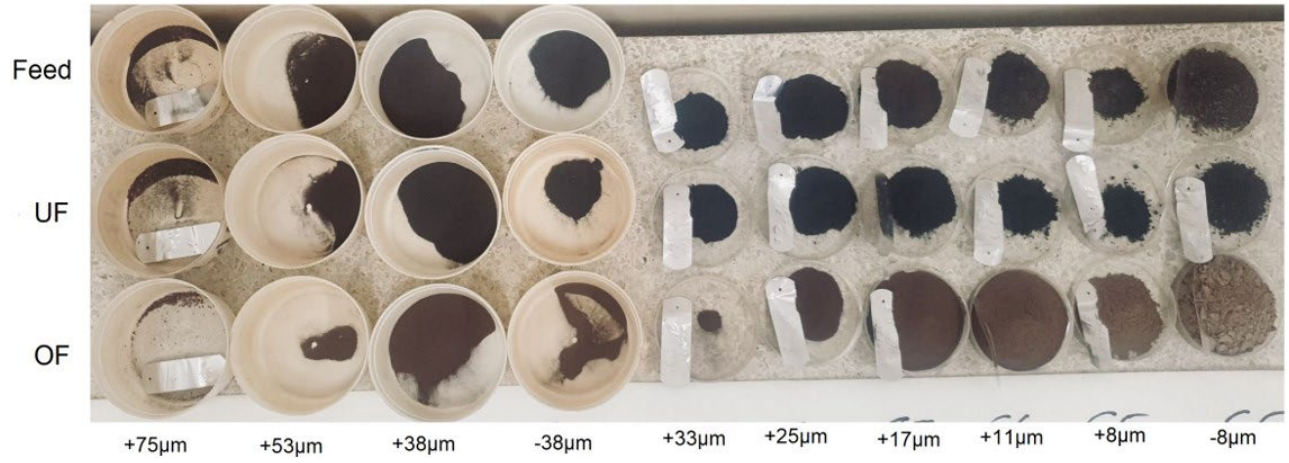

FIG 6 – Magnetite beneficiation results using modern surge-bin technology.

CONCLUSIONS

The modern surge bin:

- copes with extreme variations in mining rates
- provides the necessary stability of feed (rate and density) to downstream process stages to ensure they can operate optimally
- ensures continuity of feed to downstream processes during mining disruptions
- will provide additional de-sliming function
- can provide beneficiation of heavy values to the bin discharge.

ACKNOWLEDGEMENTS

The management of Mineral Technologies is thanked for their support in publishing this paper.

ABSTRACT

Spiral concentrators are one of the flowing film gravity concentration devices used to beneficiate coal and mineral ores. The aim of the current study is to understand the particulate flow and separation performance of an LD9 spiral concentrator using a multi-phase Computational Fluid Dynamics (CFD) model. The CFD model utilises the Algebraic slip mixture model to simulate particulate flows. The model employs the Renormalisation group (RNG) k-ε turbulence models to resolve the fluid turbulence. Initially, the volume of fluid method was adopted to track the water-air interface. Simulations were then carried out at low (0.3 and 3 wt.%) and moderate (15 wt.%) solids concentrations. Multiple particle-phase representing particles of poly sizes (75–1400 μm) and multi-densities (1450–2650 kg/m^3) were simulated to study the particle segregation on the spiral trough surface. The numerical predictions are compared with the literature performance data at a diluted pulp flow rate of 6 m^3/hr. The results were found in close agreement. Further, the same CFD model is used to study the change in pulp velocity, streamflow rates, and separation performance at increasing solids concentration. For the same density particles, Fine particles mostly show higher volume concentration in the middle and outer trough regions, whereas coarse particles show higher volume concentration in the interior and central trough regions. It implies that the fine particles mostly segregate towards the outer region, and dense particles segregate towards the axial column.

INTRODUCTION

The usage of gravity separation as a mineral concentration technique has increased significantly in the past few decades. The separation of minerals using the gravity concentration method has widely been considered a cost-effective, eco-friendly process, absence of reagents usage and less operating costs due to lower power consumption. Spiral concentrators are flowing film gravity separation devices that can efficiently separate minerals in size range of 75 μm to 3 mm. However, for coal beneficiation, the size of particles in the feed is 200 μm to 850 μm is recommended (Fuerstenau and Han, 1979). The spiral concentrator is simple in structure, and it has a helical sluice of an altered semi-circular cross-section wrapped around a central supporting cylindrical column (Matthews, Fletcher and Partridge, 1998). Since their widespread commercial introduction over 80 years ago, spiral concentrators have been simple, metallurgically efficient, low-cost, and less energy-consuming devices. Each spiral concentrator has a distinctive trough profile with constant or variable pitch and features. Spirals have gone through continuous improvement over the last couple of decades for specialist applications and the availability of high-capacity spirals. Each spiral concentrator is used for specific and sometimes diverse processing requirements to ensure efficient separation. Spirals are used to process fine coal, silica sands, heavy mineral sands, sulfide minerals, tungsten, chromite ore, and gold ores.

As the prepared feed slurry mixture flows into the spiral trough surface through the feed box, gravitational and centrifugal forces act on the flowing slurry to radially segregate the particles on the trough surface based on density and size. Segregation of particles occurs, where fine

suspended minerals move to the outer trough region, and dense particles settle and travel to the inner trough region under the influence of secondary circulations. Medium-sized particles are segregated across the trough in close ratios (Wills and Napier-Munn, 2005; Bazin *et al,* 2014). The higher the concentration criterion needed, the easier separation of two minerals is.

Researchers (Holland-Batt, 1989, 1995; Holland-Batt, 1994; Tripathy *et al,* 2012; Sadeghi, Bazin and Renaud, 2014, 2016) have investigated separation theory and conducted experiments to understand the particle segregation in the spiral trough. Boucher used the PEPT technique to understand the mineral particles motion in a fluid flow (Boucher *et al,* 2014, 2016). Fluid flow in a spiral has primary and secondary flow components, where secondary flow superimposes the primary flow (Holland-Batt, 1989).

The water depth increases in a radial direction. Researchers (Holtham, 1990, 1992; Jain and Rayasam, 2017) have captured the generation of secondary circulations using colour dye on the trough surface and revealed that the secondary flow plays a crucial role in particle separation across the spiral trough. However, limited details were measured using experiments. Wang and Andrews (1994) initiated the development of a fluid flow mechanistic model of the spiral operation. His model was used to predict the flow fields for simplified rectangular spiral sections (Wang and Andrews, 1994). Ye *et al* (2019) simulated the interaction between the design variables and the water flow field distribution for the LD9 coal spiral concentrator using the VOF method (Ye *et al,* 2019). Four turbulence models are used to find the best suitable model for simulation studies. Much of simulation studies (Matthews *et al,* 1999; Doheim *et al,* 2008; Ye *et al,* 2019) are carried out CFD modelling of the two-phase (water and air) flow in an LD9 spiral concentrator. Matthews, Fletcher and Partridge (1998) simulated the dilute particulate (coal and quartz) flow in a spiral by the Lagrangian method, VOF approach and Renormalisation group k-ε turbulence modelling (Matthews, Fletcher and Partridge, 1998). Doheim *et al* (2013) initiated the simulation of a dilute particle flow in a spiral based on the Eulerian approach and turbulence modelling (Doheim *et al,* 2013).

The key drawbacks of previous particulate flow studies are that the dynamics of particulate flow in a spiral concentrator at industrial solid concentration have not been studied. Fluid flowing on a spiral trough surface consists of various phases, including water and particles of different densities and sizes. As a result, a suitable multi-phase model is essential for accurate modelling. Very limited studies on particulate flow have been carried out using the discrete phase model (DPM) and eulerian model (Matthews, Fletcher and Partridge, 1998; Matthews, Holtham and Golab, 1998; Doheim *et al,* 2013). DPM is not appropriate for feed solids concentrations over 10 wt.% because of the absence of particle concentration effect on the fluid medium and the inability to consider the interaction between particles (Ansys Fluent, 2013). A full Eulerian-Eulerian model is more accurate but computationally expensive due to solving more number of transport equations (Ansys Fluent, 2013). To overcome the above limitation, a simplified Eulerian approach, ie the Algebraic slip mixture model, is employed in various mineral processing applications to numerically simulate the multi-phase flows. The ASM model solves fewer transport equations compared with the full EE approach and is computationally efficient. Multi-phase simulation studies using a standard ASM model can predict the experimental data at dilute feed solids concentration. No studies on particulate flow dynamics have been carried out using the algebraic slip mixture (ASM) model. The present study uses the standard ASM model to study the particulate flow dynamics such as particle radial segregation, pulp velocity and stream flow rate at a low and medium concentration of solids. The predicted results are validated against experimental results (Holtham, 1997).

METHODOLOGY

Identification of a better CFD model for spiral concentrators is helpful for designers and operators. It helps design the various spiral concentrators and reduces the expense of real experimental models. These are also beneficial for operators to decrease time usage and the expense of trials to get better operating conditions. The current study predicts flow field characteristics of an LD9 spiral concentrator using ANSYS Fluent 19.2 software by solving the continuity and Navier-stokes equations in 3D cartesian coordinates by the finite volume method. The initial step in the multi-phase modelling is to identify the water profile on the spiral trough. Following that, the second step in the spiral concentrator simulation is to model particulate flow. The Renormalisation group (RNG)

k-ε turbulence model has been employed to resolve the laminar to turbulence transition across the spiral trough surface. The VOF model, coupled with the RNG k-ε turbulence model, is used for the initial tracking of the interface between the water and air. The coal, quartz and glass beads particles are modelled using the Algebraic slip mixture model (Manninen and Taivassalo, 1996). In industrial practice, spiral concentrators can operate from 10 to 40 wt.% of solids. An increase in feed solids concentration leads to an extra generation of stresses because of particle to fluid and particle to particle interactions and also increases the slurry viscosity. The present work aims at evaluating a standard ASM model by incorporating these extra formulations.

Algebraic slip mixture (ASM) model

Before introducing distinct size range particles to the converged two-phase CFD simulations as secondary phases, the multi-phase model was changed from the VOF scheme to the ASM model. The ASM model enables the interpretation and movement of the phases at different velocities. It solves the continuity, the Navier-stokes equations for the mixture, and the volume fraction equation for the dispersive phases (Manninen and Taivassalo, 1996). The solid particle phases are introduced in the ASM model by enabling the granular option in ANSYS's Fluent (Ding and Gidaspow, 1990).

The continuity equation:

$$\frac{\partial}{\partial t}(\rho_m) + \nabla.(\rho_m \vec{v}_m) = 0$$

Here ρ_m is the mixture density and $\vec{v}_m$ is the mass averaged velocity.

$$\vec{v}_m = \frac{\sum_{k=1}^{n} \alpha_k \rho_k \vec{v}_k}{\rho_m}$$

Here n indicates the number of phases.

$$\sum_{k=1}^{n} \alpha_k = 1$$

$$\rho_m = \sum_{k=1}^{n} \alpha_k \rho_k$$

The momentum conversation equation is

$$\frac{\partial}{\partial t}(\rho_m \vec{v}_{m,i}) + \frac{\partial}{\partial x_j}(\rho_m \vec{v}_{m,i} \vec{v}_{m,j}) = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\mu_m\left(\frac{\partial \vec{v}_{m,i}}{\partial x_j} + \frac{\partial \vec{v}_{m,j}}{\partial x_i}\right)\right) + \rho \vec{g}_i + \frac{\partial}{\partial x_j}\left(\sum_{k=1}^{n} \alpha_k \rho_k \vec{v}_{dr,ki} \vec{v}_{dr,kj}\right)$$

where $\vec{v}_{dr,k}$ the secondary phase drift velocity, μ_m is the mixture viscosity and expressed as

$$\mu_m = \sum_{k=1}^{n} \alpha_k \mu_k$$

$$\vec{v}_{dr,k} = \vec{v}_k - \vec{v}_m$$

The secondary phase volume fraction is

$$\frac{\partial}{\partial t}(\alpha_p \rho_p) + \nabla.(\alpha_p \rho_p \vec{v}_m) = -\nabla.(\alpha_p \rho_p \vec{v}_{dr,p})$$

where p is the secondary phase.

$$\vec{v}_{pq} = \vec{v}_p - \vec{v}_q$$

where $\vec{v}_{pq}$ is the slip or relative velocity. It is defined as the secondary phase (p) velocity relative to the primary phase (q) velocity. This is modelled by the Manninen and Taivassalo model (1996).

The air slip velocity is disabled and set to zero (Schiller and Naumann, 1935). The present multi-phase model is applicable at dilute feed solids concentration.

Boundary conditions and numerical treatment

The LD9 spiral concentrator is used in the current study to conduct the multi-phase CFD simulations. The details of the spiral are shown in Figure 1a. The LD9 spiral concentrator geometry and mesh are generated by ANSYS's ICEM tool. For CFD simulations, a 3D unstructured grid of the LD9 spiral concentrator is utilised (Figures 1b and 1c). The grid independence study is performed using six different sizes and is tested and presented elsewhere (Sudikondala *et al*, 2022). The optimum grid size utilised for better flow field predictions in the CFD simulations is 404 k. The given domain has an inlet, outlet, and solid walls as the boundaries. In the inlet section, the desired velocity and volume fraction of solids are assigned for the slurry. At the outlet boundary, pressure out conditions is chosen. No-slip and no penetration conditions are recommended for water in the trough wall boundary. The trough wall roughness coefficient was fixed to 0.5. The top wall was considered to be the free slip condition. The details of the primary and secondary phases, together with their properties, are shown in Table 1. All the phases considered in the simulation studies have constant physical properties. The SIMPLE scheme was used for pressure velocity coupling. The momentum, turbulent kinetic energy and turbulent dissipation rate equations were discretised using a QUICK scheme. Body Force Weighted opted for a pressure interpolation scheme. Compressive was chosen for the discretisation of the volume fraction equation. The model of particulate flow uses a time-dependent formulation, and equations were solved using an unsteady solver. Residuals of all variables were fixed to 0.00001 to attain the convergence criterion. The complete details about the RNG k-ε turbulence model and the Volume of Fluid model are presented elsewhere (Sudikondala *et al,* 2022). The reason for choosing the RNG k-ε model is that it is most suitable for experimental velocity profiles at low swirls (Escue and Cui, 2010). The current spiral concentrator simulations are performed using ANSYS Fluent 19.2 software (Ansys Fluent, 2013).

3	Coal	1450	0.004	75, 530
4	Glass beads	2440	0.004	75, 530
5	Quartz	2650	0.004	75, 530, 1400

RESULTS AND DISCUSSIONS

Numerical predictions of particulate flow at 0.3 wt.% solids

The current CFD simulations of particle flow in the LD9 spiral concentrator are conducted at 0.3 per cent feed solids and a flow rate of 6 m^3/hr. The predicted numerical results are validated against the experimental measurements (Holtham, 1997). All simulation studies use a highly accurate turbulence model for spirals, ie the RNG group k-ε model (Doheim *et al,* 2013; Mahran *et al,* 2015). At 0.3 wt.% feed solids, the model uses glass beads (75, 530 μm) and quartz (1400 μm) particles having densities of 2440 kg/m^3 and 2650 kg/m^3, respectively, and the ratio of a mix among the three sizes is 1:1:1. The particulate flow parameters, such as particle distribution, pulp velocity, and flow rate, are discussed below. The converged multi-phase flow simulations are used to analyse the particulate flow parameters.

Radial segregation of particles

Predicting the distribution of particles with varying sizes across the trough surface helps in fixing the splitter location on the spiral trough. Figure 2 shows the cumulative weight percentage of particle distribution across the trough surface at 0.3 wt.% of solids. For a better understanding of the CFD model predictions across the trough surface, the spiral trough surface has been divided into three regions, namely the inner region (0–116 mm), middle (116–195 mm) and outer region (195–280 mm). The present model predictions reveal that the 75 μm glass beads particles show the 41.78, 25.45 and 32.77 wt.% distribution in the inner, middle, and outer trough regions. Glass beads particles of size 530 μm are majorly reported in the inner radii, and it shows 97.20 wt.% distribution in the inner region. Finally, 1400 μm quartz particles are distributed across the trough surface, and it shows 46.84, 23.89 and 29.27 wt.% distribution in the inner, middle, and outer trough regions. Numerical predictions show satisfactory agreement with the experimental data. The present model underpredicts the results near the inner radii.

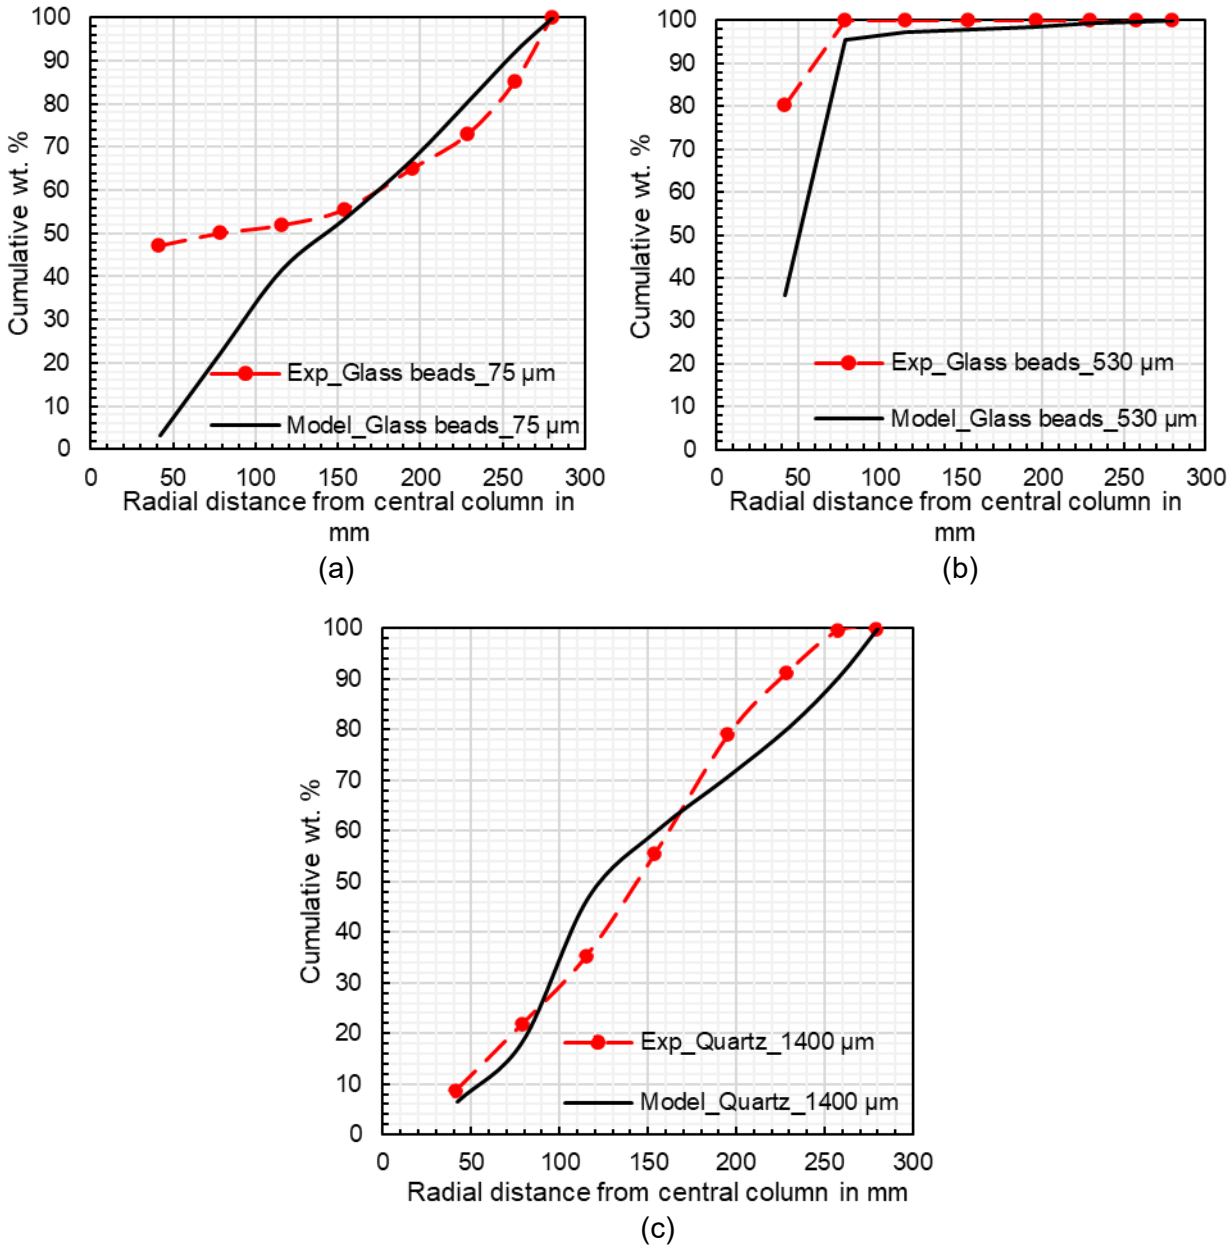

FIG 2 – Numerical prediction of (a) glass beads, 75 µm (b) glass beads, 530 µm and (c) quartz, 1400 µm particles radial distribution on the trough surface at 0.3 per cent of solids (Holtham, 1997).

Pulp velocity and streamflow rate

The experimental measurements of pulp velocity on the trough surface are presented as mean stream velocity, which implies that the spiral concentrator trough surface is separated into eight streams by employing seven splitters (Holland-Batt and Holtham, 1991) (Figure 3a). Figure 3b shows the contour map of pulp velocity across the spiral trough. It increases continuously in the outward direction from the centre of the cylinder column due to an increase in centrifugal force dominance over the gravitational force (see Figure 4a). Figure 4b shows the numerically predicted results of the stream flow rate. The flow rate in different streams varies with the cross-section area and the velocity of the flowing pulp in individual streams.

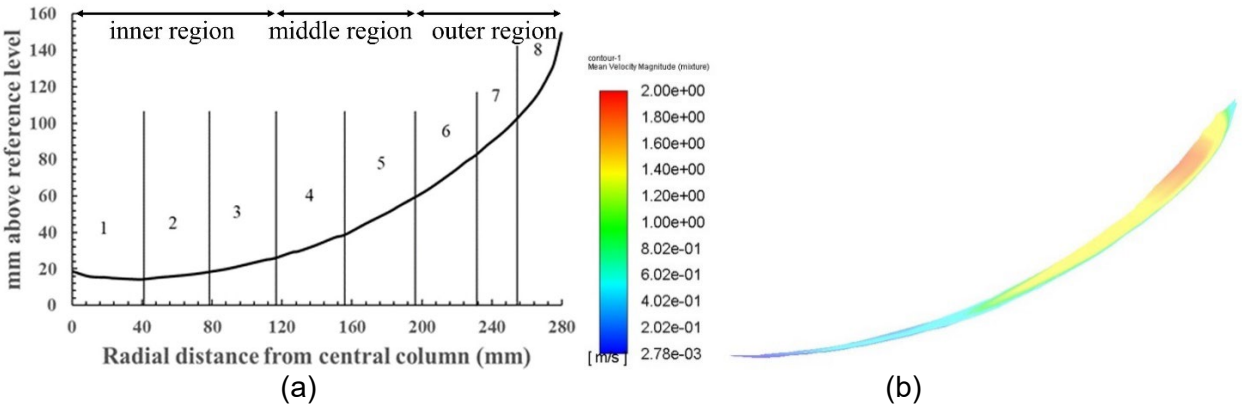

FIG 3 – (a) Sampling streams employed on the LD9 spiral concentrator (b) The pulp velocity contour map at 0.3 wt.% of solids.

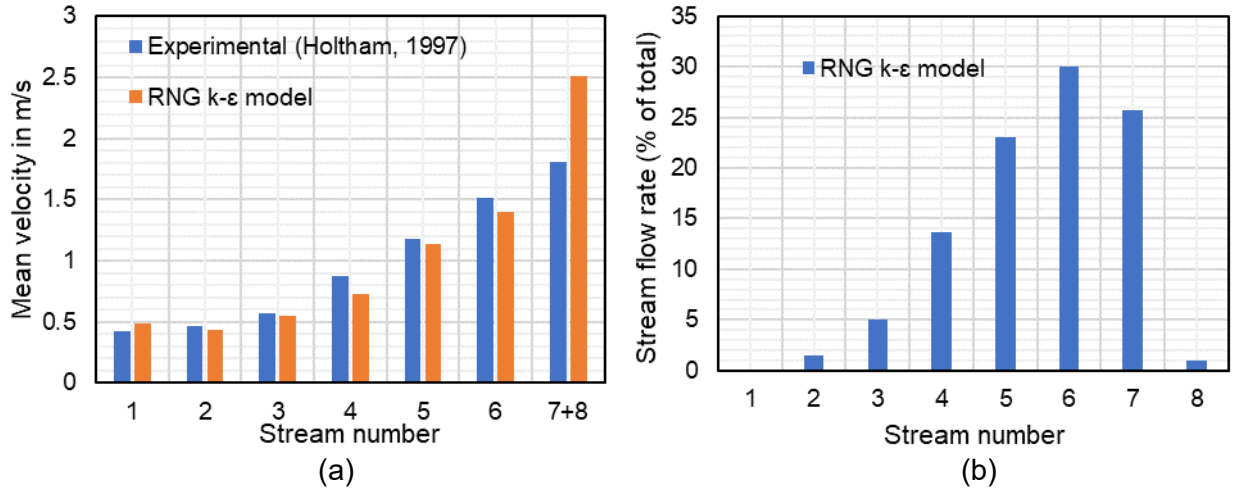

FIG 4 – Predicted values of (a) mean pulp velocity and (b) flow rate in different streams at 0.3 per cent solids.

Numerical predictions of particulate flow at 3 and 15 wt.% feed solids

The current study of particulate flow was extended from dilute feed solids content (0.3 wt.%) to medium feed solids content (3 and 15 wt.%) at a flow rate of 6 m^3/hr. In the case of 3 wt.% of feed solids content, the current model uses glass beads particles (2440 kg/m^3) of sizes 75 and 530 µm at an equal mix ratio. The details of the particles at 15 per cent by weight are shown in Table 2. Figure 5 shows the cumulative volume percentage distribution of particles of various sizes across the spiral trough at 3 and 15 wt.% of solids, respectively. Table 3 shows the predicted results of various particle volume per cent distribution in three regions at 3 and 15 wt.% of solids. In the case of 3 wt.% of solids, 75 µm glass beads particles are mostly distributed in the middle and outer trough regions, whereas 530 µm glass beads particles are majorly distributed in the inner and middle trough regions (see Table 3). In the case of 15 wt.% of feed solids content, 75 µm coal particles are mostly distributed in the middle and outer trough regions, whereas the 75 µm quartz particles are majorly distributed in the middle region. Both coal and quartz particles of 530 µm size are distributed in all three regions (Table 3). In both cases, fine particles move to the outer radii, and coarse particles move to the inner radii. Pulp velocity increases towards the outer radii of the LD9 spiral trough due to an increase in centrifugal force dominance over the gravitational force (Figure 6).

TABLE 2

Particles used at 15 wt.% of solids.

S. No	Particle type	Density in kg/m^3	Size in µm	Mix ratio
1	coal	2440	75	2
2	coal	2440	530	2
3	quartz	2650	75	1
4	quartz	2650	530	1

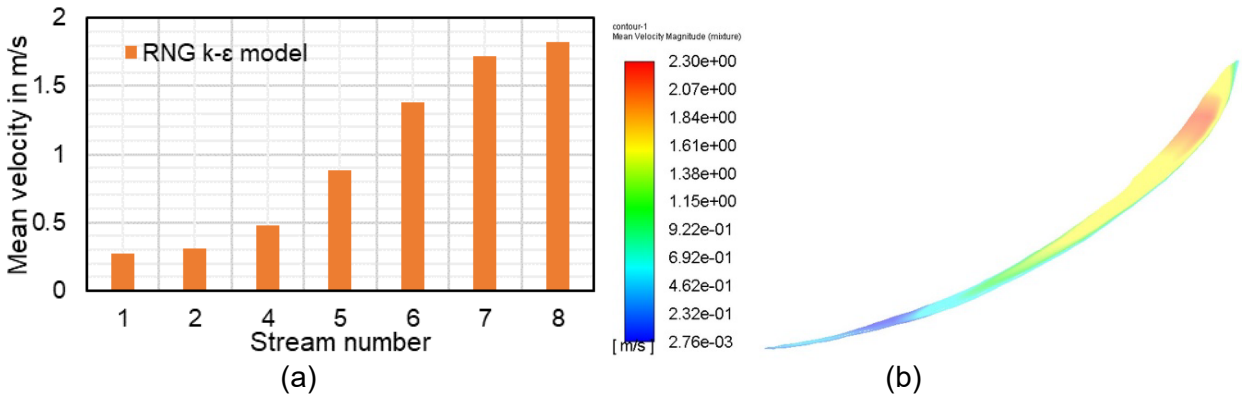

FIG 6 – Predicted values of (a) mean stream pulp velocity and (b) contour map at 3 wt.% solids.

CONCLUSIONS

Numerical prediction of particle flow in an LD9 spiral concentrator has been studied using the ASM model at low (0.3 and 3 wt.%) and medium (15 wt.%) solids concentrations. The numerical predictions of particulate flow at 0.3 wt.% of solids showed better validation with experimental results using the RNG k-ε turbulence model. The maximum pulp velocity of 2.5 m/s was observed in streams numbers 7 and 8 together. In the particulate flow model predictions at 3 per cent of feed solids, the 75 µm glass beads particles distribute in the middle and outer regions, and it shows the 20.27, 42.68 and 37.05 vol. per cent distribution in the inner, middle, and outer trough regions. Glass beads particles of 530 µm size distribute in the inner and middle regions and show the 40.22, 58.07 and 1.71 vol. per cent distribution in the inner, middle, and outer trough areas. The final implemented CFD model aids in designing the various spiral concentrators operating at moderate feed solids with different components. Future work will model the particulate flow in spiral concentrators at a high solids concentration using various turbulence models.

ABSTRACT

Online monitoring of particles cumulative percent passing (PCPP) for a target size at hydrocyclone overflow, compared with traditional offline methods, provides PCPP feedback in real time, and is advantageous in enabling energy-efficient comminution, increasing downstream flotation efficiency, and improving upstream resource knowledge. However, existing online approaches are generally costly and bespoke, and some are sensitive to operational changes. Therefore, this study proposes a new low-cost alternative based on accelerometer measurement for online PCPP monitoring in the overflow of hydrocyclones and provides a preliminary experimental investigation under dry condition. The proposed method uses a sensing probe inserted into the overflow pipe of a hydrocyclone to receive particle impact from the incoming slurry, with accelerometers attached to the probe and mounting frame outside the pipe for particle-probe impact detection. As a preliminary investigation before studying particle-probe impact events in slurry, tests under dry condition without fluids were conducted using dry sand particles in free fall from a fixed height. Accelerometer measurements are analysed in both time and frequency domains through root-mean-square (RMS) and fast Fourier transform (FFT). Results show that accelerometer measurements are useful in estimating mass flow rates, which are correlated to the accelerometer output amplitude RMS values in time domain, in a non-linear mapping. Different particle size classes can be identified by examining the accelerometer output amplitude at a known mass flow rate. Different particle size classes feature their distinct signature frequencies (SFs) that can be examined via FFT and the SF is found to be independent of the mass flow rate. The results imply that any PCPP changes can be detected by the change in the accelerometer output amplitude as well as a shift in SF, which demonstrates the effectiveness of using accelerometers to gauge changes in PCPP. Based on the current findings in dry condition, future work will investigate particle-probe impact events in slurry.

INTRODUCTION

Hydrocyclones play an important role in classification process within a grinding circuit, where fine or light particles are directed to the overflow and sent to flotation while coarse or dense particles are classified to the underflow and fed back for regrinding. Oversized particles reduce flotation efficiency while over-grinding wastes energy (Wills, 2006; Maron, O'Keefe and Sepulveda, 2018). Therefore, online monitoring of particles cumulative percent passing (PCPP) for a target size at hydrocyclone overflow is crucial to maintaining effective and energy-efficient grinding and flotation (Blasco and Kongas, 2011). A majority PCPP monitoring procedures are performed offline via methods such as sieving analysis (International Organization for Standardization, 1988), sedimentation and elutriation (Heywood, 1958), microscopic sizing and image analysis (Allen, 1997), electrical impedance (Hogg and Coulter, 1967) and laser imaging (Napier-Munn *et al,* 1996), resulting in additional labour cost as well as hours of delay (Wills, 2006). A conservative measure to maintain acceptable PCPP otherwise leads to increased margin, either between the actual percent passing size (eg P80) and a target dimension, or between the actual PCPP and the desired PCPP of a target size. This means extended grinding task and higher energy consumption as a result (Maron, O'Keefe and Sepulveda, 2018).

Camera-based online imaging technique has been proposed for monitoring PCPP for the underflow of hydrocyclones (Aldrich, Uahengo and Kistner, 2015), which however, is inapplicable to the overflow due to considerably smaller sizes of overflow particles. It has been shown that particle size analysis via laser diffraction can also be used online (Norris and Kongas, 2011) and further improvements to measurement accuracy have been made in the work of Tabuchi *et al* (2019). A most common disadvantage of laser-based methods is that slurry needs to be diluted prior to analysis. Instead of using laser, solid concentration and PCPP can also be estimated via measuring the ultrasonic velocity and the attenuation spectrum in slurry (Hathaway and Guthnals, 1976). Variants among ultrasonic approaches have arisen in recent decades to deliver more accurate measurement results (Coghill, Millen and Sowerby, 2002; Xue *et al,* 2009; Coghill and Millen, 2012; Greenwood, 2012). However, an additional sampler is inevitable for slurry treatment prior to PCPP analysis. Another interesting direction towards online PCPP estimation is based on analysing acoustic emissions from particles impacting a sensing probe (Pecorari, 2013; Sun *et al,* 2014; Wang *et al,* 2019a; Nsugbe *et al,* 2019; Zhang *et al,* 2019). The size detection range by acoustic emission sensing is nevertheless limited towards the finer side, compared to laser and ultrasonic methods. It is also worth noting that the aforementioned online PCPP monitoring methods can all incur high cost for application on hydrocyclone overflow given that every individual overflow pipe needs to be monitored (Maron, O'Keefe and Sepulveda, 2018) and normally there are dozens of or more hydrocyclone units at a mineral processing plant.

A relatively low-cost alternative for online PCPP estimation can be based on particle impact force measurement (Gao *et al,* 2013; Sun *et al,* 2014; Wang *et al,* 2019a*,* 2019b), where piezoelectric sensors are used to detect vibrations resulted from particle impact on a sensing medium. These methods were tested in airflow with particles of sizes down to 400 μm at low concentrations, allowing every single particle-probe impact event to be individually identified and counted. However, it remains unclear whether force sensing can be applied to the overflow of hydrocyclones where the majority of particles are smaller than 400 μm and the solid concentration is significantly higher.

Particle-probe impact forces normally present themselves in the form of vibration, which could be better captured via accelerometers which are also potentially cost-effective. Vibration sensing via accelerometers has been used in combination with acoustic emission methods for measurement of bubble solids mass loading at Jameson cell (Spencer *et al,* 2012). The application of accelerometers on hydrocyclones can be seen in the work of Nayak *et al* (2019) where vibration signals are found useful in online choking detection. A comprehensive review on online vibration sensing for monitoring hydrocyclone performance is given by Mishra and Majumder (2022), and corresponding applications are found limited to roping and choking detection. In general, there has been no work related to the use of accelerometers for PCPP measurements at hydrocyclone overflow.

Therefore, this paper explores the feasibility of utilising accelerometers for capturing particle size dependent vibrations to perform online PCPP estimation at the overflow of hydrocyclones and provides a preliminary experimental investigation in dry condition without fluids.

METHOD

Proposed prototype

The proposed vibration measurement unit (VMU) prototype is shown in Figure 1, which consists of a probe and two miniature single-axis accelerometers. The probe is inserted into the overflow pipe to capture particle-probe impact events on the probe head that is interchangeable and can vary in shapes. In this paper, a triangular prism is used for the probe head. The vibration movements on the probe rod caused by particle-probe impact events are passed onto the accelerometer installed on the probe rod outside the pipe at a position between the external pipe wall and the fixture mount. The second accelerometer is installed on the VMU mounting frame to capture non-impact related vibrations. It is worth noting that the proposed VMU installation is not restricted to the vertical set-up in Figure 1 but can also be installed at multiple possible locations along the overflow pipe including horizontal placement.

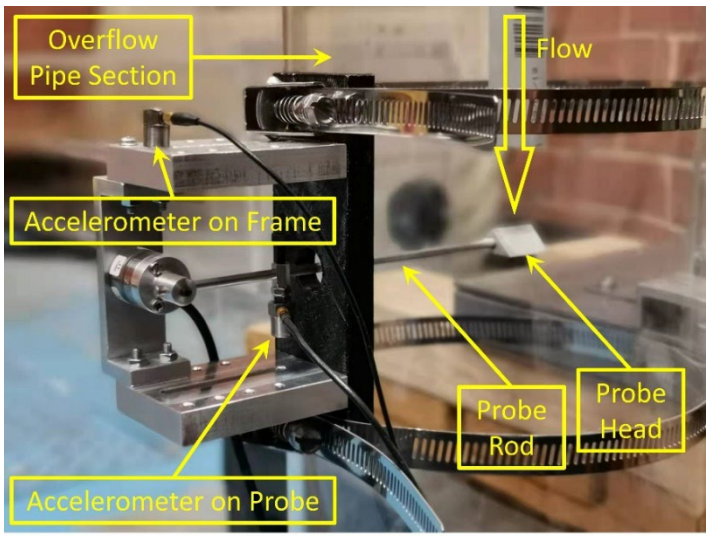

FIG 1 – Proposed VMU prototype.

Laboratory experiment set-up

In this paper, as a preliminary investigation, only the partible-probe impact events on the probe head under dry condition (without fluids) is considered, with the experiment set-up shown in Figure 2. The overall configuration is given in Figure 2a, where dry particles are placed in the computer-controlled particles disperser for release in free fall through the guide tube, with the VMU installed on a vertically placed transparent pipe section and positioned under the guide tube to receive impacts. As illustrated in Figure 2b, the release of dry particles is controlled by the opening between the motorised plug conical tip and the hopper bottom aperture. The opening is finely adjusted via computer by lifting the plug vertically with position feedback, which guarantees consistence in the resulting mass flow rate. A 6-axis force/torque transducer is used to measure the weight change of the entire hopper unit containing dry particles. The mass flow rate can then be readily acquired by calculating the rate of weight reduction.

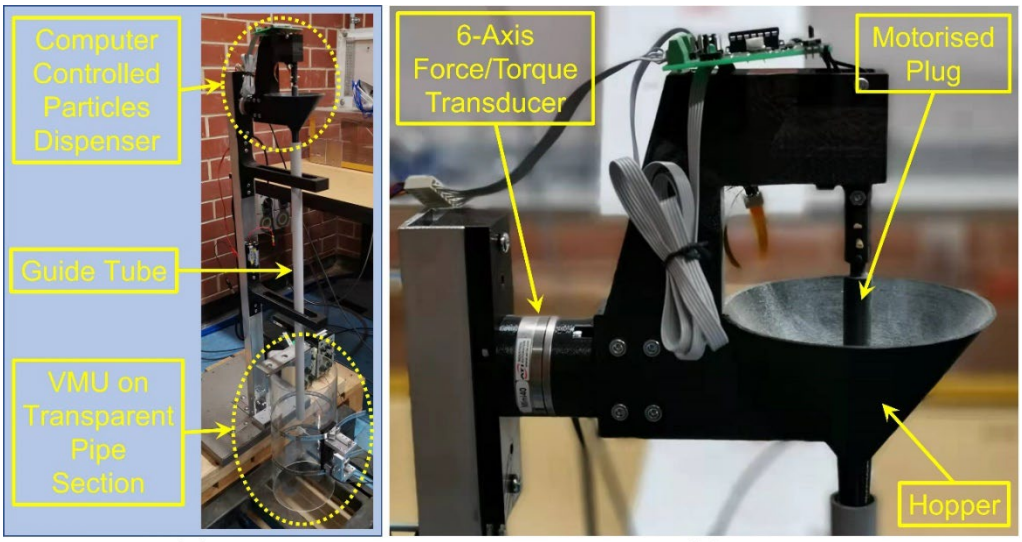

FIG 2 – Laboratory experiment set-up.

Experiment procedures

Particles used in experiments were dry sand sieved into four size classes in micrometres: 150–212, 212–300, 300–425, and 425–600. The mass flow rate was monitored at a rate of 1000 Hz, while particle-probe impact events were sampled at 3×10^5 Hz. The mass flow rates for each size class were varied from 0.5 g/s to 3.5 g/s with 0.2 g/s increment and was maintained constant for every

single test lasting over 12 s. Data were recorded from the start of releasing sand till 10 s in each test. Background noises, that is, conditions under no loading, were also recorded for reference.

To obtain clean data that only contains particle-probe impact events (excluding transient responses before and after impact events), data between 3 s and 7 s were analysed. Scattered data points of accelerometer output amplitudes against mass flow rates are fitted with second order polynomials to give a clean representation of trends. Data are analysed in both time domain and frequency domain.

Root-mean-square (RMS) is adopted to evaluate the time response of particle-probe impact events in terms of the resulted accelerometer output amplitudes. Given that in time domain vibrations of different frequencies are mixed and overlapped, further investigation is conducted in frequency domain via fast Fourier transform (FFT). To reveal non-background signals, background noises are first subtracted from measurements that contain particle-probe impact events. To identify vibrations exclusively associated with particle-probe impact events, FFT of the accelerometer on the probe and the accelerometer on the VMU frame are compared. According to the Hertz impact theory (Hertz, 1881) which establishes the relation between contact time and particle size during an elastic impact, there exists a signature frequency (SF) corresponding to any particle size during a particle-probe impact event, and there exists a generalised SF for different particle size classes as a whole. Therefore, accelerometer output amplitudes and their corresponding frequencies are key variables under investigation.

RESULTS AND DISCUSSION

As an illustration of how particle-probe impact events are determined, Figure 3 shows the responses of the two accelerometers installed on the VMU in a test using 150–212 μm size class at 0.1 g/s flow rate. Instead of using acceleration unit, the accelerometer output in the form of voltage (V) is used for ease of explanation. Under laboratory environment, it is expected that the accelerometer attached on the probe should pick up stronger vibrations than those captured by the accelerometer installed on the VMU frame. This can be confirmed in Figure 3a where significantly higher output amplitudes are present for the accelerometer on the probe. In an *in situ* case where the VMU is mounted on an overflow pipe of a hydrocyclone unit, structural vibrations can also pass onto the accelerometer on the VMU frame and may cause stronger vibrations than those from particle-probe impact events. However, the latter case does not affect signal analysis since frequency components related to structural vibrations can be readily identified in frequency domain. As can be seen from Figure 3b, frequency components associated with measurements from the accelerometer on the VMU frame are dominant at low frequency regime ($< 2.5 \times 10^4$ Hz), whereas most high-frequency components are from the accelerometer on the probe. The amplitude peaks at high-frequency regime are related to significant vibration modes of the probe, which are indirectly linked to particle-probe impact events, as will be shown in Figures 4 and 5.

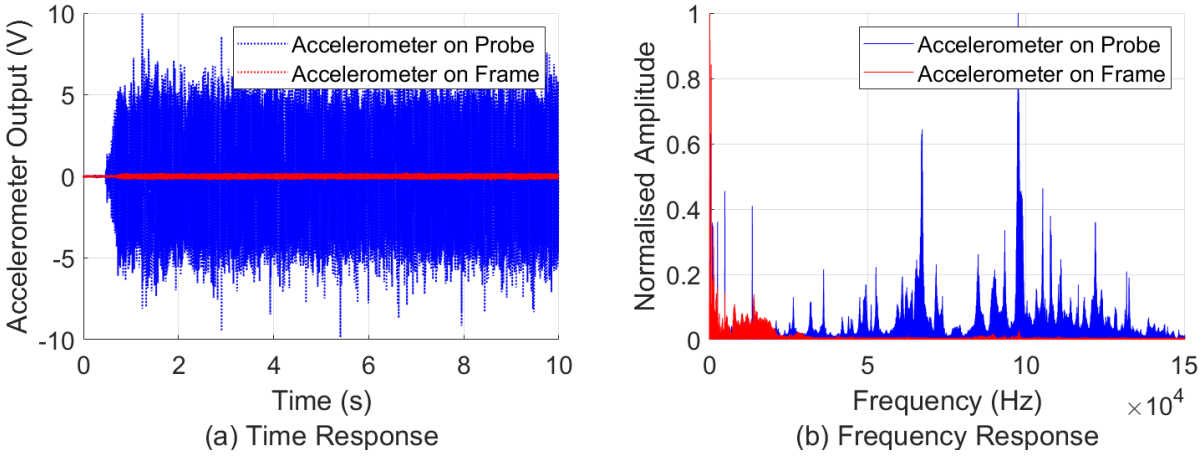

FIG 3 – Responses of accelerometers under particle-probe impact events with 150–212 μm size class at 0.1 g/s flow rate.

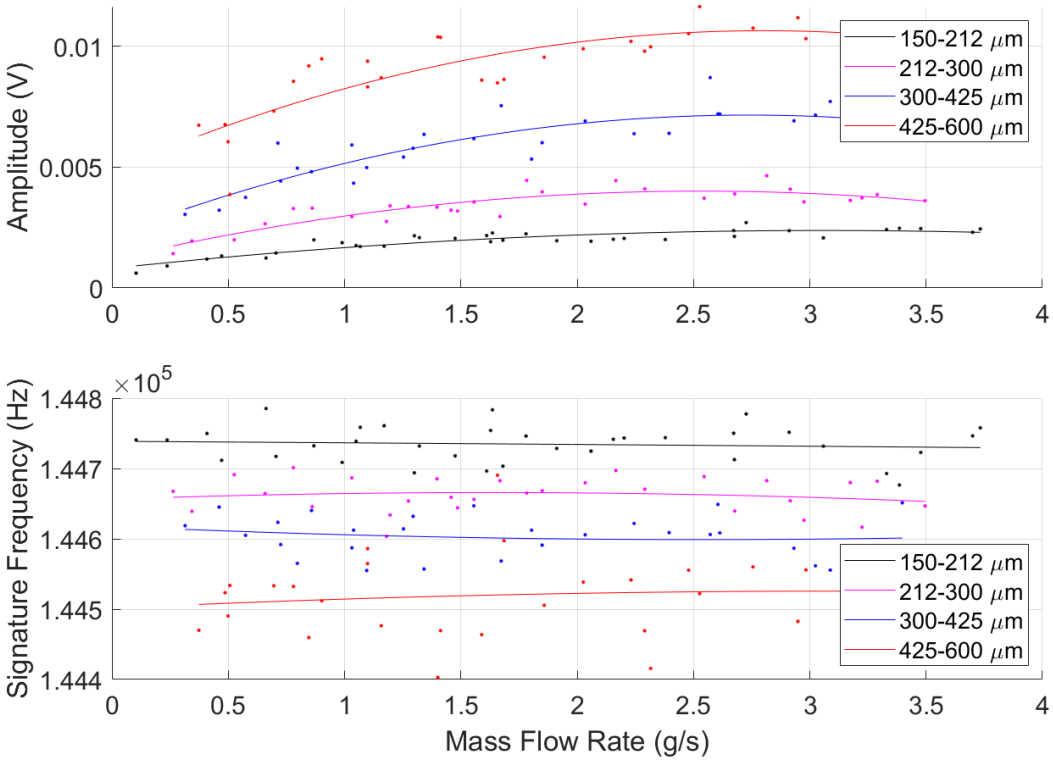

FIG 4 – VMU probe frequency response around 1.446×10^5 Hz.

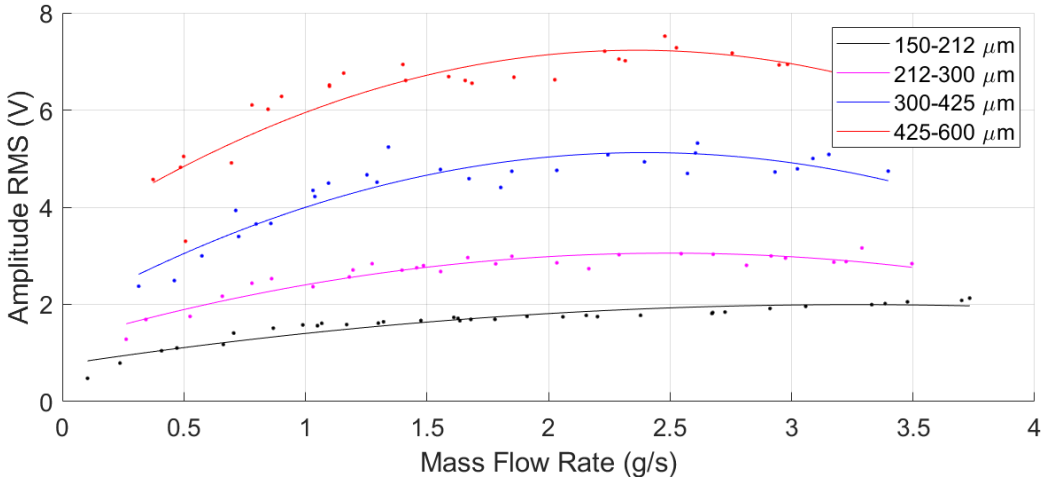

FIG 5 – Output amplitude RMS against mass flow rate for accelerometer on probe in time domain.

Due to the presence of low-frequency noises (as shown in Figure 3b), SF can be better captured at high-frequency regime ($> 2.5 \times 10^4$ Hz). Figure 4 illustrates the conditions evaluated at a frequency of 1.446×10^5 Hz, where vibrations due to particle-probe impacts are examined in accelerometer output amplitudes (V) and corresponding frequencies (Hz), and three main findings can be identified as follows.

Firstly, in the top subfigure, as the mass flow rate increases, the vibration amplitude gradually rises and then starts to decline after a particular mass flow rate. The specific mass flow rate after which the vibration amplitude starts to decline depends on the particle size class. These indicates a useful correlation between particle size classes and mass flow rates.

Secondly, the scattered data points associated with different particle size classes are nicely spaced and separated vertically in group in terms of accelerometer output amplitude, clearly distinguishing the different size classes from each other. It can be seen that particle-probe impact events of larger particles have higher vibration amplitudes than those of smaller particles. This reveals a correlation between vibration amplitudes and particle sizes.

Thirdly, and most importantly, despite the change in mass flow rate, the SF of each particle size class remains constant, and smaller size is associated with higher SF. This finding agrees with the Hertz impact theory (Hertz, 1881) mentioned in *Experiment procedures*. As contact time increases with particle size, the corresponding SF lowers, and vice versa. Therefore, the SF is an important measure to distinguish particles of different size classes given that it is independent of mass flow rates.

When accelerometer output amplitudes are evaluated in the form of RMS in time domain, results are given in Figure 5. Correlations similar to Figure 4 can be observed in terms of vibration amplitudes against mass flow rates. Again, larger particles correspond to higher vibration amplitudes and there exists a maximum value in amplitude for each size class along its fitted curve as the mass flow rate increases. This confirms the first finding from Figure 4.

CONCLUSIONS

Results show that accelerometer measurements are useful in estimating mass flow rates, which are nonlinearly correlated to the accelerometer output amplitude RMS values in time domain. Different particle size classes can be identified by evaluating the accelerometer output amplitude at a known mass flow rate, which can be either the absolute amplitude at a particular SF or the RMS value in time domain. The SF associated with a particular particle size class can be revealed and examined via FFT and is found to be independent of the mass flow rate. Particle samples of narrow size classes can be identified by their distinct SFs, where a larger size features a lower SF. The results imply that whenever the PCPP changes, it can be detected by the change in accelerometer output amplitude as well as a shift in SF. This demonstrates the effectiveness of using accelerometers to gauge changes in PCPP. On the basis of the current findings under dry condition, future work will investigate particle-probe impact events in slurry.

ABSTRACT

Traditionally, most Australian iron ore mining operations have been surface-based. Processing plants were designed to handle dry ores. In recent years mining operations in the Pilbara have progressively moved below the water table exposing wet, sticky ores which have caused lost efficiency in screening operations as particles tend to agglomerate and adhere, blinding screening media.

Miners and vibrating screen manufacturers have experimented with a shift from linear motion to elliptical motion screens. Elliptical motion conveys and lifts particles. Effective on flat deck (horizontal and inclined) or sloping decks it can be configured to provide a controlled transport rate, applying pressure in all directions to maximise screening efficiency. In practice, elliptical motion screens have proven to be effective in dislodging sticky particles from screening media, reducing blinding rates and improving screen efficiency.

Moisture and clay content change during the life of a mine. These changes are sometimes the effect of seasonal rainfall, in other cases due to increased groundwater and clay content as mining operations go deeper. To compensate for such changes and optimise screen efficiency, changing the 'shape' of elliptical screen motion is required. This has traditionally required shutting down processing plants and making mechanical screen adjustments. Plant downtime is costly and machine adjustment has been a 'trial and error' practice.

This paper will explore the results of a field trial that is currently underway in Brazil of a next generation elliptical motion screen design that allows operators to make changes to exciter rotational direction, speed and screen stroke angle, through electronic drive phase control. The machine's electronic drive system synchronisation is enhanced for stability with a unique mechanical timing system. Operating at up to 6 g, screen adjustments can be made on the fly without stopping production. Early trial results are showing up to 50 per cent improvement in screen efficiency compared with traditional elliptical motion machines under certain feed conditions.

INTRODUCTION

The earliest form of screening in mineral processing took place in the form of manual sizing. 'Breaker boys' would sit above the product stream and manually sort and size the large lumps as required by the process. Later, static screens were developed where the product was manually manipulated over apertured plate or bars with lateral spacing matching the sizing cut point as required by the process application. Typically, these were aggressively sloped from feed to discharge end to promote the material flow. With the introduction of electric motors to the mineral processing industry, some of the earliest forms of mechanised screening took place in the form of crank driven reciprocating shaker screens and simple spring mounted single shaft circular motion screens which are still used in some applications today (Figure 1). Where shaker screens had significant limitations in terms of capacity and adhesion (having little to no perpendicular acceleration component to the apertured deck), the circular motion mechanised screens facilitate both elevation of the product and transportation of the product from feed to discharge end.

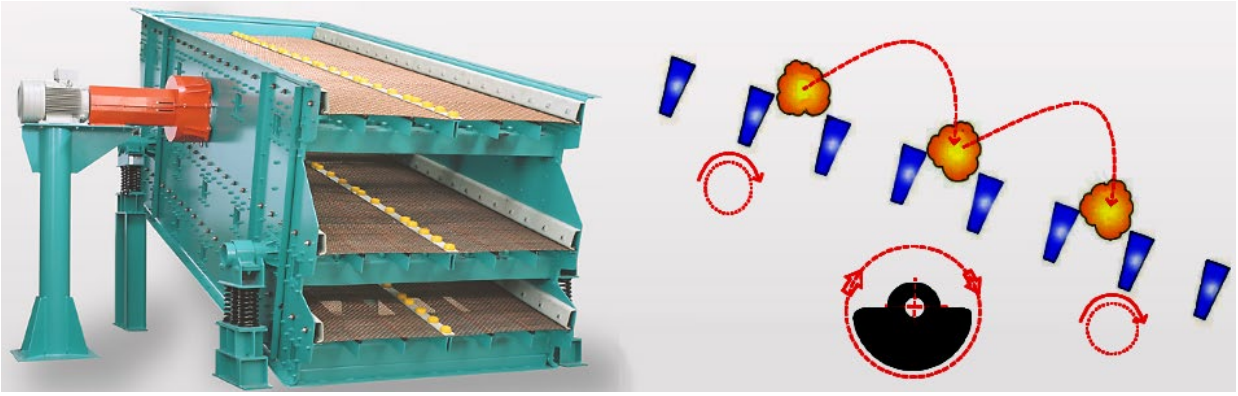

FIG 1 – Single shaft circular motion screen showing motion pattern and particle trajectory.

Circular motion screens are mounted on soft springs and are excited by a forcing function that generates a motion pattern which is essentially an orbital system between the screen body and the counterweight based on momentum principals. Due to the interaction between the particle trajectory of the bed of material and the screen panel apertures on circular motion screens, a very specific range of operating speed and acceleration are required to ensure that the product flow is not over energised resulting in a reduction in probability of separation and reduced overall efficiency, or under energised resulting in retarding the flow of product, increased bed depth, and a reduction in overall efficiency. A typical operating characteristic for circular motion screens would be 3.5 g acceleration at a speed close to 850 rev/min, and the theoretical feed material single particle trajectory from these operating characteristics can be seen in Figure 2. As demonstrated, the feed material particle trajectory with these operating characteristics results in impact with the apertured deck each cycle with the impact occurring somewhere between the maximum velocity of screen vertical motion, and the theoretical point of separation of particles from the apertured deck. It should be noted that particle interaction at the maximum vertical velocity point will result in no horizontal impact component being imparted on the particle, and that interaction at a velocity vector significantly greater than 45° from horizontal will result in under-energisation of the vertical velocity component. For this reason, the operating characteristics selected for circular motion screens need to be highly specific, and the decks need to be inclined to promote material flow. A pegged or adhered particle will however have force components applied in all directions.

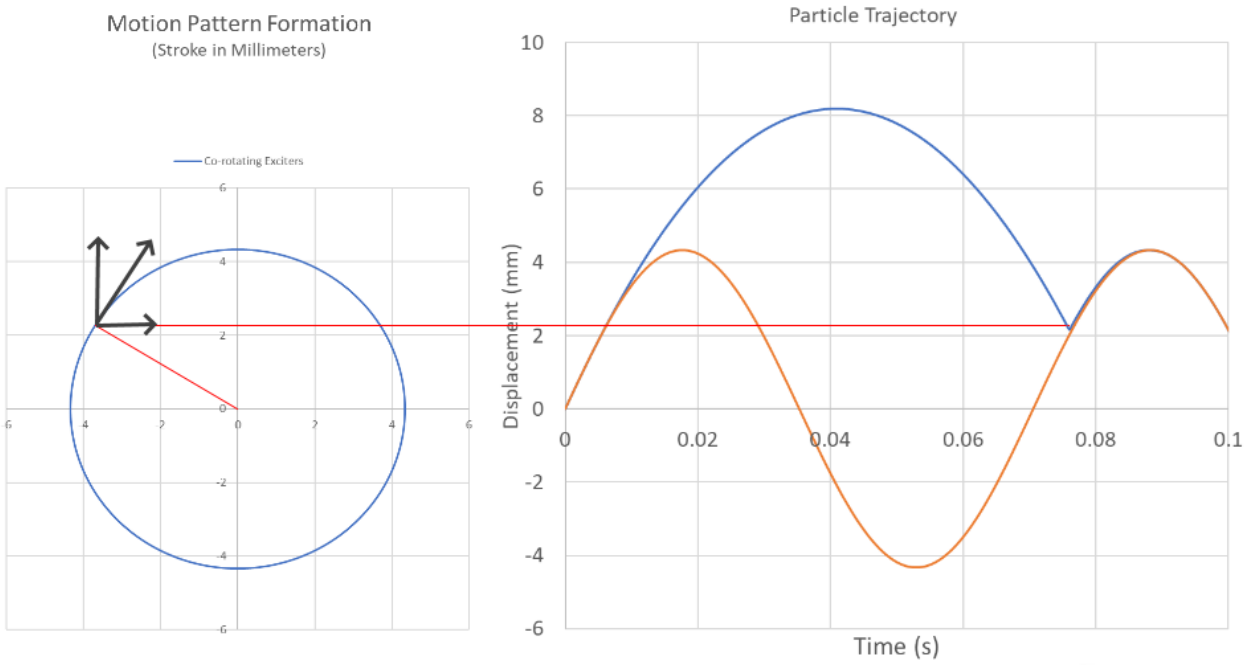

FIG 2 – Theoretical single particle vertical trajectory based on 8.7 mm stroke at 850 rev/min (3.5 g).

One of the benefits of the traditional circular motion screen is the acceleration component imparted on the particle in the plane of the apertured panel. This in plane motion is highly effective at dislodging near size and/or sticky particles when pegged in the apertures. Among the disadvantages are the specific operating characteristic requirements, and the difficulty in controlling flow velocity of larger particles down the deck of the screen. Using simple mathematical models of single particle trajectories to predict probabilities of separation based on operating characteristics of the screen alone, ignores particle on particle interactions and interparticle cohesion (Cleary, Wilson and Sinnot, 2018). A causal link between a simple particle trajectory calculation and material transport velocity and bed depths can be observed in practise. However, this has not necessarily translated to better particle size stratification or process efficiency.

Following from the development of the circular motion vibrating screen was the linear motion flat deck screen (Figure 3). The development of linear motion screening by utilising pairs of counter-rotating eccentric mass shafts addressed some of the issues associated with the requirement for highly specific operating characteristics. This meant that regardless of the speed and stroke length selected, there would always be a velocity component of the screen to lift the particle, and a component transporting the particle from feed to discharge end. Linear motion screens have the advantage of a horizontal velocity component to their stroke which conveniently allowed designers to achieve controlled transport velocities of feed material without needing to incline the screen decks. This facilitated lower overall build heights which allowed for more compact processing plants, and lower overall production power requirements due to the reduction in potential between the feed and discharge points of the screen. Whether appropriate for the application or not, a line of stroke at 45° was assumed as the industry standard as this provided equal vertical and horizontal velocity components.

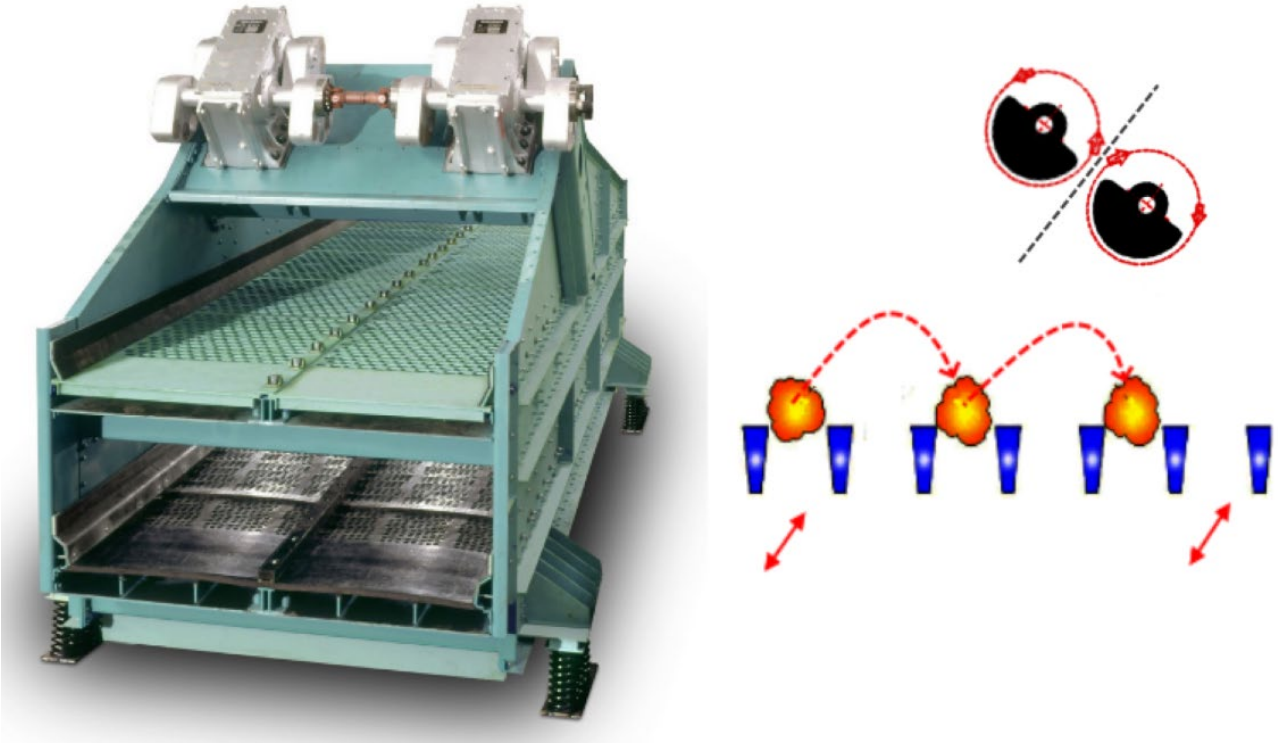

FIG 3 – Counter-rotating mass linear motion screen showing motion pattern and particle trajectory.

Despite having a completely different set of material interaction characteristics to circular motion screens, with the introduction of linear motion screens the nominal speed and maximum acceleration perpendicular to the screening panels of circular motion screens was maintained. For horizontal flat deck screens, this results in a peak acceleration of approximately 5 g along the line of stroke of 45° from horizontal. The theoretical feed material single particle trajectory can be seen in Figure 4.

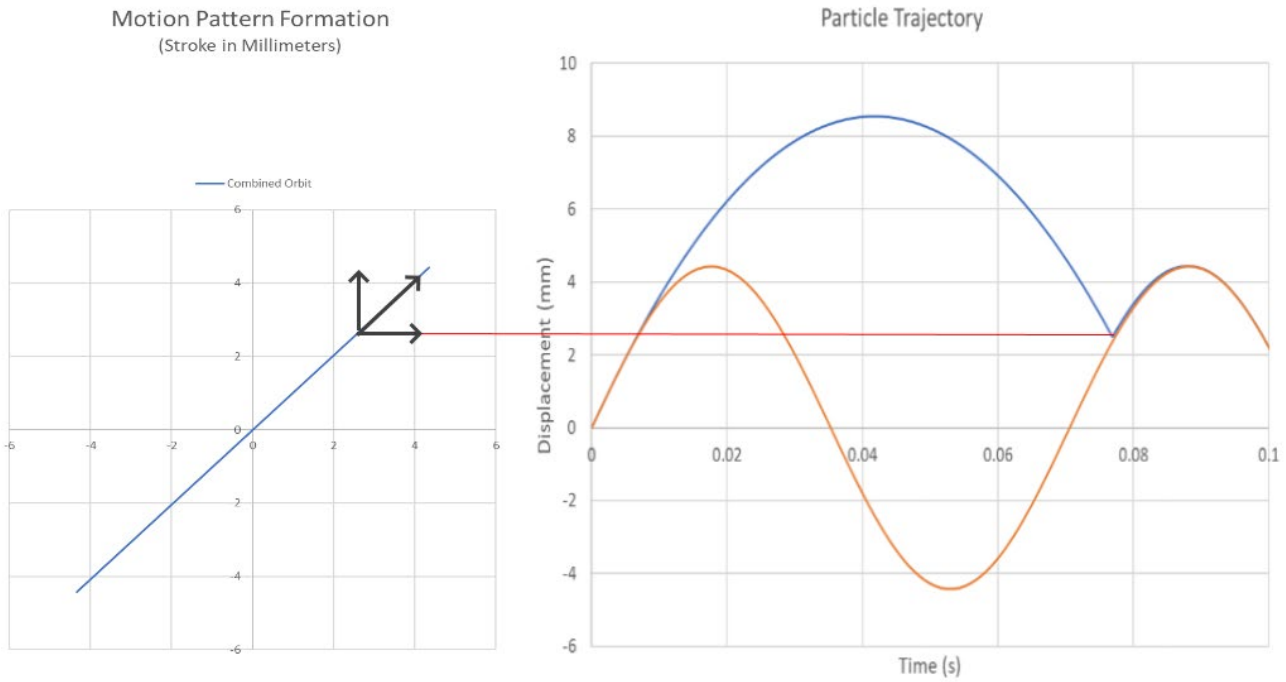

FIG 4 – Theoretical single particle vertical trajectory based on 12.4 mm stroke at 850 rev/min (5 g).

Alongside the benefits of the new linear motion screening concept was the limitation on structural capacity due to lower deck inclination and lower transport velocities of feed material. Previous studies undertaken on the phenomenon of particle separation using numerical methods (specifically DEM – Cleary *et al*, 2009; Shen and Tong, 2020) have identified several mechanisms for separation including:

- Energisation of the bed to create interstitial gaps.
- Percolation of finer particles through the bed of coarser material.
- Particle on particle interactions.
- Aperture penetration.

Little information is available in these studies on the segregation phenomenon due to the different levels of mobility of particles in the high velocity feed zone of aggressively sloped screen decks, whereby the higher transport velocity of the larger and less inhibited particles results in segregation, leading to larger particles transporting to the top of the material bed. This contribution to stratification is lost in the feed zone of horizontal flat deck screens. Flat deck screens are sometimes inclined up to 10° from horizontal to circumvent this problem, however in these cases the benefit of low potential between the feed and discharge points of the screen are lost. Pegging of feed material particles in the screening panel apertures of horizontal flat screens with high near size particle fractions in the particle size distribution is also common and strongly related to particle shape and adhesion characteristics. Pegged or adhered particles in linear motion screening only experience forces applied in one direction with fluctuating and completely opposing vectors.

In the last 30 years, the use of multi-slope ‘banana screens’ has become increasingly common for high-capacity screening for both wet and dry applications. Banana screens are constructed with an aggressively sloped feed end section which becomes progressively shallower in inclination toward the discharge end. Whilst some circular motion banana screens have been built, banana screens are predominantly driven by the same type of linear motion exciters as flat deck linear motion screens. Curved Banana screen decks introduce the benefit of high ore feed velocity at the feed end of the machine. The elevated transport velocity of the feed material up to 4 m/s results in a thinning of the bed depth, allowing for larger particle spacing of the larger lump fraction which facilitates liberation of more fines. The larger particles being unconstrained from high bed depth pressures are freer to mobilise down the deck at higher transport velocities than the fines fraction, assisting effective stratification at the discharge end. Relatively higher levels of shearing flow at the feed end

in comparison to horizontal flat deck screens coupled with progressive reduction in transport velocity due to particle interactions provides an effective means for larger particles to liberate agglomerated fines without relying solely on the machine's operating characteristics. Finally, pressure on the near size particles at the discharge end from the stratified bed with low transport velocity gives higher probabilities of separation.

Wet screening of slurries on banana screens is also effective despite interphase drag having a normalising effect on the particle size related and slurry velocity distributions (Cleary, Wilson and Sinnot, 2018). This effectiveness is due to the ready percolation of fines entrained in slurry through the dilute phase in the feed end bed depth. Despite the high proportion of the fines fraction in the feed material which passes through the apertures in the feed end of the screen, the lower transport velocity of the discharge end and greater number of cycles experienced by the feed material over the discharge stages is important for the screens to achieve the process efficiency target (refer to Figure 5).

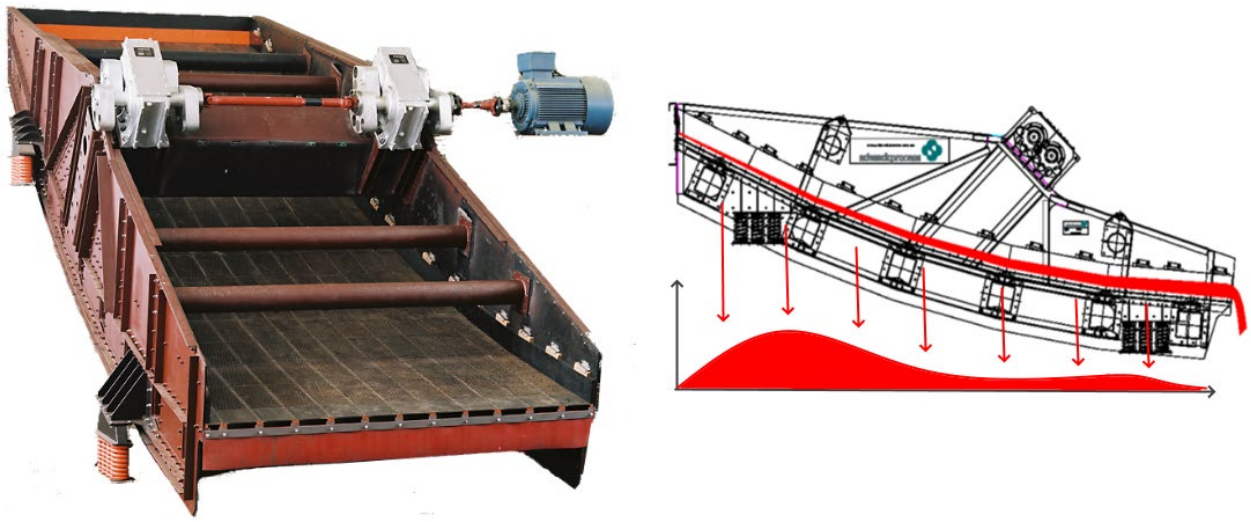

FIG 5 – Counter-rotating mass linear motion banana screen showing typical feed material distribution.

Elliptical motion screen concepts have been in existence since the 1970s but gained market traction over the past two decades as more ore producers have been attempting to mine product below water table or to screen product with natural moisture. The concept of elliptical motion screens is to develop a screen stroke with an orbit path that provides both the reliable transport velocity of a linear motion screen, but with the multi-directional force components of a circular motion screen. The aim is to provide sufficient energisation of the bed of material to maximise stratification by creation of interstitial gaps between larger particles, and to provide a multi-directional excitation to de-peg near size particle blockages of apertures and adherent material. Elliptical motion screens have been built in flat deck designs (both horizontal and inclined), and more recently in multi-slope banana style designs. Several techniques have been used for generating elliptical motion, including:

- Two counter-rotating single shaft exciters with differing eccentric mass positioned at distances from the screen centre of gravity inversely proportional to the eccentric masses.
- Utilising three single shaft exciters with the same or different eccentric masses, two exciters co-rotating and one counter-rotating.
- Mounting a series of single shaft or double shaft exciters on perpendicular axes and controlling their phase relationship to generate elliptical motion.

In dry coarse sizing, elliptical motion screens have consistently demonstrated the capacity for more efficient separation. Elliptical motion has already been applied to sticky or difficult to screen materials where the empirically derived formulas for screen sizing and efficiency are of questionable validity. This paper presents the findings of a field trial of a 2.5 m × 6.4 m Double Deck Banana Elliptical Motion Screen for natural moisture screening of coarse iron ore.

DESIGN DEVELOPMENT

The Schenck Process elliptical motion screen utilised in the trial was developed to fit the existing footprint of a South American iron ore producer and was designated the model name SED2564. The screen was designed to be driven by six Schenck Process VZ501 circular motion exciter cells closely spaced about the centre of gravity of the screen and mounted in three laterally opposed pairs connected with intermediate shafts spanning the screen. The screen was designed to be driven by three independent direct drive electric motors via universal shafts, with each motor being independently electronically synchronised. The product designation represents a double deck multi-slope elliptical machine with a 2.5 m wide and 6.4 m long apertured section, with this particular machine being designed for deck angles from 20° to 8° on the top deck.

The preliminary design stage commenced with the sizing of the screen using traditional proprietary calculation methods by modifying the moisture factor of the material. It should be noted for iron ore with significant fines fraction, feed material with surface moisture content exceeding 8 per cent of the product mass will typically suffer from adhesion of fines to the lump fraction. The adhesion of fines makes separation more difficult as the finer particles have a tendency to carry over to discharge from the machine with the coarser particles. Moreover, the particle size distribution (PSD) related transport velocity differential, which aides in stratification, in the feed end of multi-slope banana screens is present to a lesser extent. Historically, sizing and machine capacities have been determined by an empirically derived formula which treats the process parameters as being independent, for example:

$$C = B \times I \times D \times Sh \times So \times A \times Oa \times W \times Y \times M \times Z \times E$$

Where:

C	is tonnes/square metre
B	is base capacity
I	is inclination factor
D	is deck number
Sh	is % passing half the separation (cut) size
So	is % of oversize in feed
A	is the aperture shape factor
Oa	is the Open Area factor of the deck
W	is Bulk density of the feed material
Y	is Wet Screening. Water added as spray or in feed
M	is moisture content of the feed material – If screening is to be dry screening
Z	is Particle Shape factor
E	is Efficiency Factor

Shen and Tong (2020) identified that under varying material and operating characteristics, there was a noticeable degree of interdependencies between the process application variables. Since at the design stage of this project these interdependencies were unknown, an unmodified traditional application sizing approach was used.

The outputs of the application sizing calculations were required in order to determine worst case retained product loads for the upper and lower deck of the screen. These were dependent on maximum and minimum process efficiencies of the top deck based on both wet and dry season material conditions. The worst case retained deck loads were used for preliminary sizing of the deck components based on hand calculations of cross beam bending stress. Conservative permissible fatigue design stress acceptance criteria were applied according to the recommendations of BS7608–2014 Fatigue design and assessment of steel structures.

Following the basic sizing of the screen components, a bounding envelope for a side plate was defined and a mass estimate developed. Appropriate sizing of the exciters was then conducted to

ensure that 6 g of acceleration could be achieved within the bearing capacity limits. At this stage, the screen was modelled in Autodesk Inventor, and Finite Element Analysis (FEA) model produced. Given the primary objective of the screen to be adaptable to the process without shutting the machine down, one aim of the analysis was to achieve a separation between the operating speed and the closest modal frequencies of the screen body structure to permit operation of the screen between 850 rev/min and 950 rev/min. Since acceleration of the screen is a function of the square of the operating speed, with variable speed control in this operating frequency range the screen would be capable of delivering an ellipse with a major axis of between 4.8 g and 6.0 g acceleration without the requirement to change the eccentric mass of the exciter cells. The screen design was extensively analysed with the preliminary FEA focused on the mass and stiffness distribution to ensure the primary flexural natural frequency modes were significantly above the operating frequency so as not to adversely affect the operating characteristics. The FEA then focused on determining the suitability of the component selection under a number of exciter phasing positions and inertia load case combinations. Principal stress load case combinations were used for fatigue design purposes.

In tandem with the screen body structural design, the PLC control logic for phase adjustment between the exciter cells was developed. In order to test the control logic prior to the screen being built, a small-scale workshop test bed weighing 120 kg and driven by three Uras KEE-3-6WK vibrator motors was developed to prove the stroke predictions and test the stability of the control logic. Three operating configurations were tested as detailed in Figure 6.

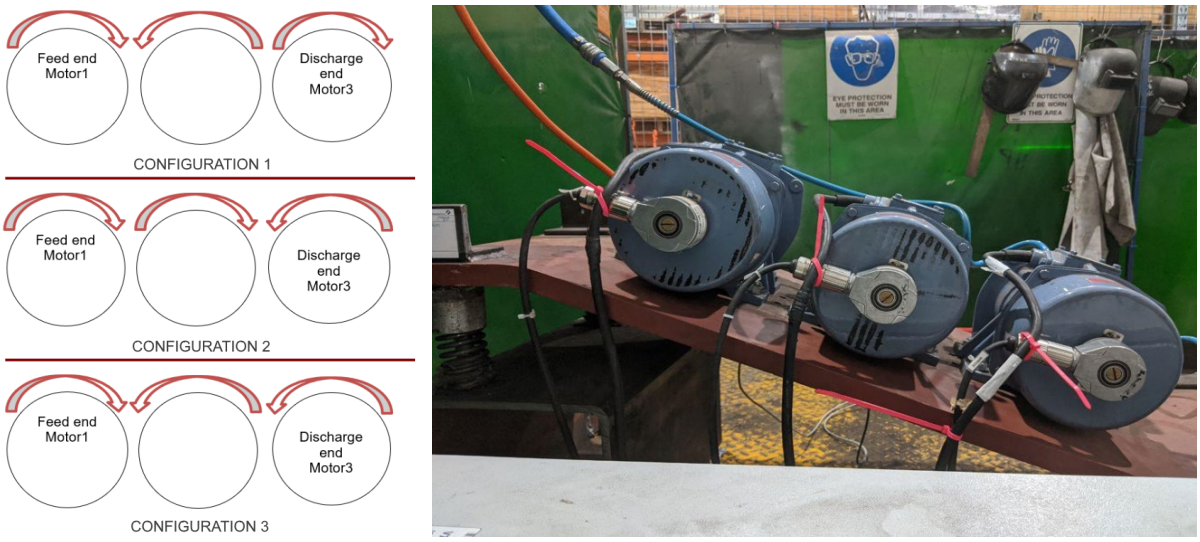

FIG 6 – Operating configurations tested on the scaled test bed.

For each design operating configuration, three intended weights setting (25 per cent, 75 per cent, and 100 per cent) at different phase angles and combinations of rotational directions were tested. For each direction of rotation the operating data of speed, torque, and position were recorded and plotted.

Consistent across all test results, design rotation Configuration 1 (both outer exciter pairs co-rotating) was shown to be the most stable. It performed better in terms of maximum and minimum possible phase angle adjustment, and synchronisation stability for different parameters of speed and eccentric weights. It was observed that a configuration with a 75 per cent eccentric mass setting and an initial 20° phase angle from horizontal, broke synchronisation stability at 70° phase angle from horizontal. It was further observed at the stability limits of the system that motors 1 and 3, whilst trying to achieve the command velocity, suffered significant signal disturbance in the actual velocity data. There was a torque spike which indicated that the control was suffering some degree of overshoot and a general divergence in the torque demand of motors 1 and 3 as seen in Figure 7. It was not established whether this was due to saturated control, control lag, or inertia torque effects. The same characteristic was not observed on motor 2. This indicated that the development of higher rotational inertia by use of flywheels and developing external synchronisation of co-rotating elements by mechanical means would be effective in eliminating system instability but would still permit complete angular control of the elliptical motion through changing the phasing relationship between

co-rotating and counter rotating elements by electronic means. To remove the inertia torque effects from the motor torque demand and make a more stable electronic synchronisation, mechanical connection of motor 3 and motor 1 with a timing belt system was proposed, developed, and tested on the small-scale test bed. A full-scale synchronisation system was developed for the SED2564 machine and was implemented for the duration of a six-month site trial. The synchronisation system development has a Patent Pending.

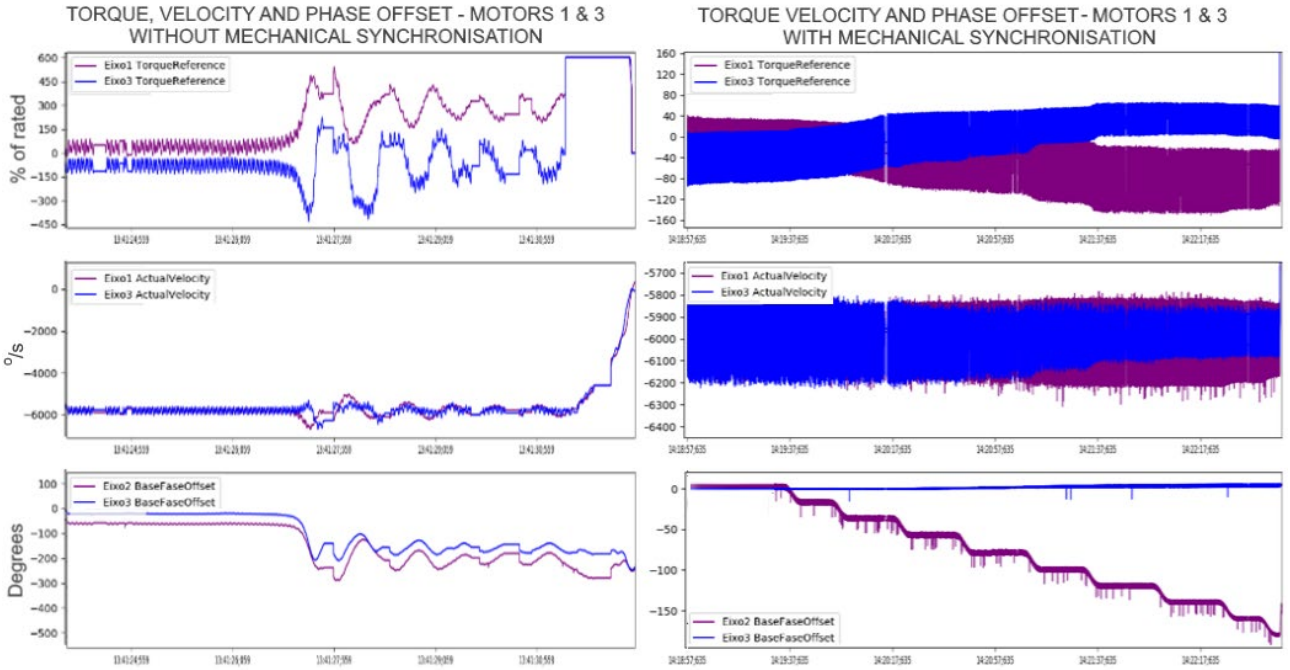

FIG 7 – Torque demand, instantaneous angular velocity, and phase relationship of elliptical test bed with and without mechanical synchronisation between co-rotating elements.

Data collected on the scaled elliptical test bed demonstrated that the system stability was determined by the two outer co-rotating motors due to inertia torque effects. The centre counter-rotating motor appeared not to be affected by inertia torque to the same extent. An actuation of phase angle relationship between the co-rotating and counter-rotating motors resulted in loss of synchronisation at a stroke angle of 70° from horizontal without the mechanical synchronisation system. The same configuration with mechanical synchronisation between co-rotating elements reduced the peak torque demand and permitted full control of the major axis of the ellipse through 180° by electronic synchronisation. Furthermore, a series of tests were run where a step input disturbance was introduced to the scaled test bed by dropping the weighted end of a 4 lb (~1.8 kg) mallet (with parabolic rubber buffer) a distance of 200 mm onto the end of the test bed adjacent to motor 1. In all cases without mechanical synchronisation the system lost synchronisation stability, but with mechanical synchronisation was capable of retaining synchronisation stability at all phasing angles. This indicated that the full-scale system with mechanical synchronisation would be more stable under transient dynamic events, which typically occur under on-feed and off-feed conditions.

The full-scale screen was built in the Schenck Process workshop in Taubate, Brazil, and tested under 6 g acceleration with a series of operating speeds between 850 rev/min and 950 rev/min. Strain gauge data was collected to verify the design, and some fine tuning to the intermediate shafts between exciters was conducted to improve modal separation from torsional resonance of the drive system. The screen was despatched for field trial in a wet season natural moisture iron ore screening application.

APPLICATION OVERVIEW

The scope of the machine development was to design a 2.5 × 6.4 m double deck multi-slope banana screen capable of screening a nominal 1200 t/h at less than 8 per cent surface moisture content (dry season) or 735 t/h of high moisture iron ore (up to 13 per cent surface moisture content – wet

season), but also capable of being adapted between the wet and dry season screening conditions. The material properties and operating requirements included:

- Bulk Density – 2.7 t/m^3.
- Specific Gravity – 4.7.
- Maximum Lump size – 120 mm.
- 76 per cent of the feed PSD <6 mm (approximately 1/3 the bottom deck cut point).
- 90 per cent operational availability.
- Operating acceleration requirement of between 5 g and 6 g.

The high fines content and seasonally high surface moisture content make the application a very challenging process to achieve with a vibrating screen. This is mainly due to adhesion of fines to the lump fraction, but also the cohesion between fines, and the adhesion of the fines to the screening panels. It was understood that this would further be challenged by a significant reduction in stratification caused by the normalising of particle size related transport velocity differences. It was hypothesised that some combination of operating speed between 850 and 950 rev/min, acceleration between 5 and 6 g, and some operating angle of the major axis of the ellipse between 20° to 70° from horizontal with operating direction either with material flow or counter material flow at the top of the ellipse, would provide a process efficiency and screen capacity advantage. The exciter configuration to achieve the adjustable elliptical operation can be seen in Figure 8.

FIG 8 – SED2564 electronic synchronisation testing in Tabaute workshop.

The trial of process performance was set at six months to ensure a good seasonal variation of surface moisture content dependent on performance and a target availability of 90 per cent set over the course of the trial. Process performance requirements were for a bottom deck discharge with less than 25 per cent sub 4 mm particles, and a bottom deck undersize with 0 per cent lump over 19 mm in particle size.

FIELD TRIAL RESULTS

The SED2564 6 g electronically synchronised elliptical motion screen was installed for field trials carried out in the period from 01 December 2020 to 31 May 2021. During the field trial, a significant variation in feed material characteristics was experienced based on differences in surface moisture content. Various operating characteristics of the screen were trialled with each feed material type. Figure 9 demonstrates the operating characteristics with low moisture content (approximately 8 per cent) from data collected between 25 November 2020 to 30 November 2020 in the initial commissioning stages of the project. At the time, the screen was operating at a nominal 500 t/h for commissioning purposes, with fines fraction high enough that no appreciable bed depth was forming on the discharge stage. Detail 'A' from Figure 9 demonstrates operation with a 6 g acceleration 60° major axis from horizontal with an ellipse aspect ratio of 3:1 with rotation direction of co-rotating exciters with the direction of material flow over top centre. Visual observations of the live operating characteristics clearly demonstrated over energisation of particles with high amplitude particle bouncing, and clearly visible interaction with the screen deck every second cycle. Whilst the general direction of transport was toward the discharge, there were an appreciable number of particles being projected backward during this operating characteristic. It was also evident that the fines carry over at the discharge end was relatively low, and well below the target of 25 per cent. Utilising the theoretical particle trajectory as a basis for comparison, the 0.5× subharmonic observed during operation was supported by the theoretical particle trajectory, and the low transport velocity and random particle directions were supported by the theoretical point of interaction with the deck panels having a vector almost vertical in orientation. The opportunity to trial the performance of the screen with these operating characteristics and a more heavily formed bed of material has not yet been negotiated with site personnel. Proposals for further testing have been developed.

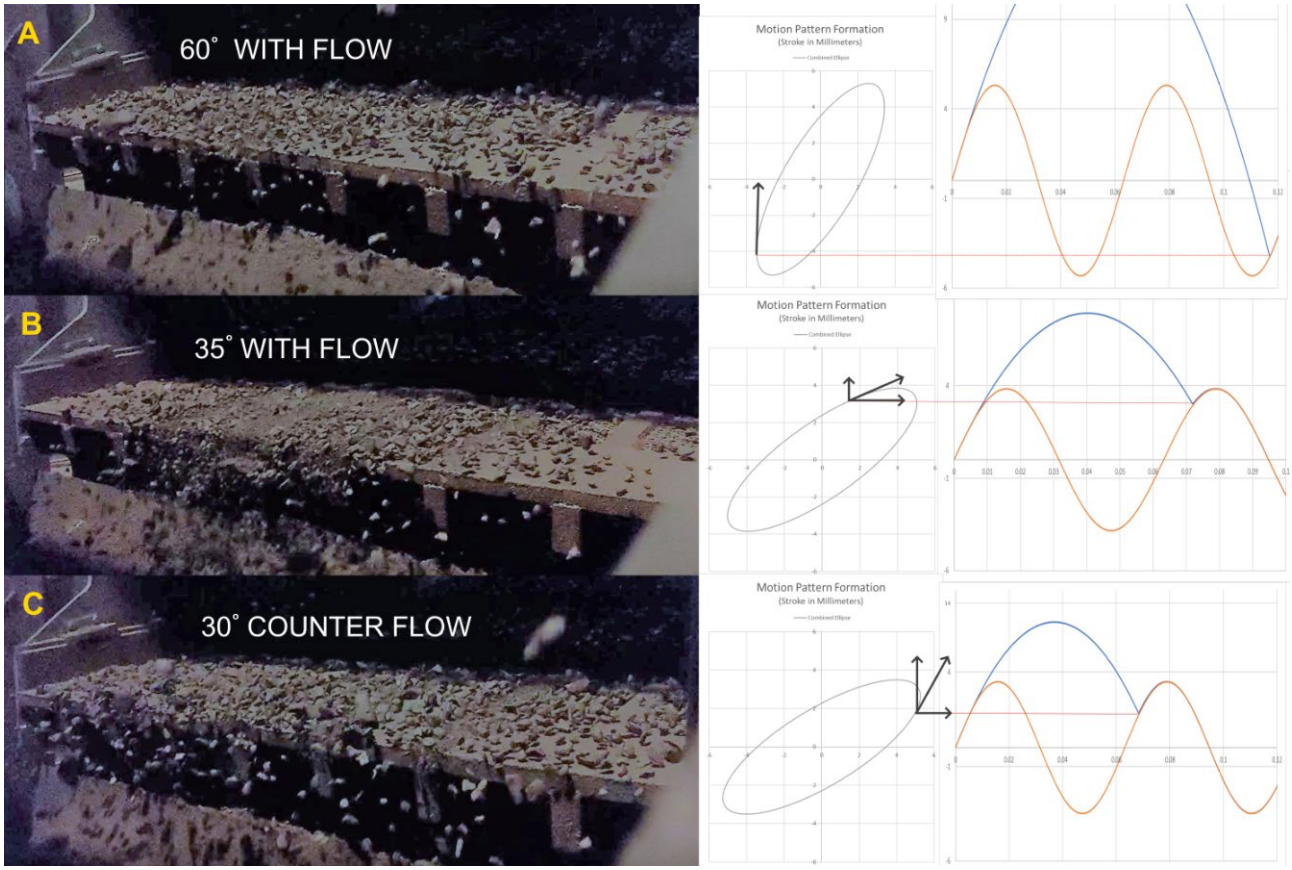

FIG 9 – Observed material conditions and associated theoretical material interaction with the screen deck.

Figure 9 Detail 'B' shows the operation with a 6 g 35° major axis from horizontal with an ellipse aspect ratio of 3:1 with rotation direction of co-rotating exciters with the direction of material flow over top centre. The material was visually under energised in the vertical direction resulting in mostly horizontal motion. The transport velocity was high, and fines carry over significantly higher than that

seen with operating major axis angle at 60°. The single particle theoretical trajectory also supported the under energisation seen in the actual material flow, and the excessive transport velocity and fines carry over was consistent with the theoretical vector of interaction with the screen deck panels being largely horizontal.

Figure 9 Detail ‘C’ was a trial run with the direction of co-rotating exciters counter flow over top centre with a major axis at 6 g 30° from horizontal. The aspect ratio of the ellipse was again 3:1 and visual observations were characterised by a good well controlled transport velocity, reasonable levels of particle energisation with a regular steady state impact period coinciding with the screen deck every cycle. Fines carry over was low and comparable to that seen with 60° major axis in the co-rotation direction. The main source of fines carry-over in this configuration was seen as material tracking along the blank join line between panels. This characteristic was not evident with the higher angle of major axis seen in Detail ‘A’.

Periodic fortnightly bucket samples of product PSD and moisture content failed to capture the true variance of PSD and moisture content observed in the performance of the screen. At times the fines fraction was seen to be a thick, muddy paste indicating surface moisture content at or above 12–13 per cent. Under these circumstances, operation with a low angle of the major axis and counterflow rotation even at 6 g acceleration allowed the bed at the discharge end to form large slabby cakes of agglomerated material. Under these material conditions operation with 60° major axis from horizontal with rotation direction with flow appeared to break up the slabby cakes and allow a significantly larger proportion of fines to pass the bottom deck apertures. Balls of agglomerated fines captured from the undersize fraction during this high moisture operating condition can be seen in Figure 10.

FIG 10 – Agglomerated fines obtained from the undersize of the screen whilst operating with high surface moisture content.

CONCLUSIONS

The development of the elliptical motion for the SED2564 machine demonstrated that phasing stability of the system was limited by the co-rotating exciters. When operating near stability limits, small perturbations to the system caused the scaled screen to lose synchronisation. The development of a mechanical synchronisation system linking the co-rotating exciter cells only, allowed complete phase stability throughout 360° of phasing actuation regardless of eccentric mass, acceleration, or introduced perturbations.

The loss of one of the main mechanisms of stratification with high moisture screening results in significantly restricted tonnage throughput. With surface moisture content between 8–10 per cent, the feed characteristics are such that elliptical motion with a traditional operating angle of 45° results

in poor efficiency performance. Two operating characteristics provided beneficial results on efficiency with these feed materials, operation with a 3:1 ellipse at 6 g acceleration and a major axis at 60° from horizontal and direction of rotation of co-rotating exciters with the direction of flow over top centre, and operation with a 3:1 ellipse at 6 g acceleration with a major axis 30° from horizontal and direction of rotation of co-rotating exciters against the direction of feed material flow over top centre. At feed surface moisture content above 10 per cent, the formation of slabby cakes of consolidated fines required the high vertical acceleration of 'with' flow rotation and 60° major axis from horizontal to break the material up enough to liberate fines that were capable of passing the bottom deck screen aperture.

ABSTRACT

In mineral processing of complex sulfide ores containing copper (Cu), lead (Pb), and zinc (Zn), flotation has been commonly used. Typical Pb mineral in the ores is galena (PbS), while some types of the ores contain anglesite ($PbSO_4$). This article reviews our recent studies on the effects of coexisting $PbSO_4$ on the flotation of complex sulfide ores, and a method to suppress the floatability of sphalerite (ZnS) in the presence of $PbSO_4$ was proposed.

Comparison of flotation experiments for different types of model samples showed that $PbSO_4$ makes the separation of Zn from Cu difficult; that is, for the model sample containing PbS without $PbSO_4$, Zn could be separated from Cu, while when the model sample containing $PbSO_4$, Zn was recovered together with Cu as froth. Solution analysis and thermodynamic calculation suggested that Pb^{2+} was released from $PbSO_4$ and reacted with ZnS to form PbS, acting as an adsorption site for the flotation collector, xanthate. This would be the main reason for high floatability of ZnS in the presence of $PbSO_4$.

As a method to suppress ZnS floatability for the ores containing $PbSO_4$, a pre-treatment of the ores to remove $PbSO_4$ prior to flotation was proposed. The results of model experiments using mixture of ZnS and $PbSO_4$ showed that ~97 per cent of $PbSO_4$ was dissolved within 30 minutes of pre-treatment using ethylenediaminetetraacetic acid (EDTA) as extractant, and thus ZnS floatability was markedly suppressed. Moreover, Pb^{2+} extracted from $PbSO_4$ during the pre-treatment could be recovered as zero-valent Pb by the cementation using zero-valent Fe as a reductant. The details of ZnS flotation in the presence of $PbSO_4$ and the effects of the pre-treatment are discussed based on the results of surface analysis like XPS.

INTRODUCTION

The demand for critical metals (eg, copper (Cu), lead (Pb), zinc (Zn) etc) is projected to be continuously increased in the future to achieve a carbon-neutral society (Nansai *et al,* 2014). In 2015, 193 governments adopted 17 sustainable development goals (SDGs) aiming to eradicate poverty, protect the planet and ensure peaceful and prosperous lives for everyone by 2030 (Hák *et al,* 2016; Tabelin *et al,* 2021). To keep up with the high demand for critical metals as following SDGs, mine developments should be in harmony with environment. Complex sulfide ores are one of the most important sources of critical metals because they are typically composed of several metal-sulfide minerals like chalcopyrite ($CuFeS_2$), galena (PbS), and sphalerite (ZnS). In mineral processing of complex sulfide ores, flotation has been commonly used to produce concentrates of each mineral for smelting. Typical Pb mineral in the ores is galena (PbS), while some types of the ores contain anglesite ($PbSO_4$) (Aikawa *et al,* 2021; Zeng *et al,* 2021). In a typical flotation method of complex sulfide ores, Cu-Pb-Zn sulfide minerals are processed via a two-stage flotation process whereby Cu- and Pb-sulfide minerals are recovered as froth in the first stage, followed by the recovery of Zn-sulfide minerals as froth in the second stage (Woodcock *et al,* 2007). This typical two-stage flotation process may be difficult to be applied to complex sulfide ores containing $PbSO_4$ because ZnS would

be activated and recovered in the froth together with Cu- and Pb-sulfide minerals in the first stage (Aikawa *et al,* 2021). In addition, $PbSO_4$ is typically distributed to flotation tailings because it has poor affinity with collector (eg xanthate) (Fuerstenau *et al,* 1987; Rashchi *et al,* 2005). When $PbSO_4$ is disposed of into the tailings dam, it would cause lead pollution to the surrounding environment (Schindler *et al,* 2021; Silwamba *et al,* 2022). Therefore, $PbSO_4$ would cause not only the difficulties in separation of ZnS from Cu- and Pb-sulfide minerals, but also lead pollution in the surrounding environment of tailings dam when $PbSO_4$ is contained in complex sulfide ores. In this article, our recent studies on the effects of coexisting $PbSO_4$ on the flotation of complex sulfide ores were reviewed, and a method for enhanced depression of ZnS by extracting $PbSO_4$ and recovery of extracted Pb^{2+} as zero-valent Pb by cementation using zero-valent Fe was proposed.

EFFECTS OF COEXISTING ANGLESITE ON THE FLOTATION OF COMPLEX SULFIDE ORES

Typical Pb mineral in complex sulfide ores is PbS, while some types of the ores contain $PbSO_4$. When $PbSO_4$ is contained, Pb^{2+} is readily released from $PbSO_4$ during flotation due to its higher solubility than that of PbS (K_{sp} of $PbSO_4$ and PbS are $10^{-7.79}$ and $10^{-26.77}$, respectively) (Ball and Nordstrom, 1991). When Pb^{2+} is released from $PbSO_4$ during flotation, lead activation of ZnS is known to occur as illustrated in the following equation (Aikawa *et al,* 2021; Laskowski *et al,* 1997; Trahar *et al,* 1997):

$$ZnS_{(s)} + Pb^{2+} = PbS_{(s)} + Zn^{2+} \quad (1)$$

Comparison of flotation experiments for different types of model samples showed that $PbSO_4$ makes the separation of Zn from Cu difficult; that is, for the model sample containing PbS without $PbSO_4$, Zn could be separated from Cu, while when the model sample containing $PbSO_4$, Zn was recovered together with Cu as froth (Figure 1). Solution analysis and thermodynamic calculation suggested that Pb^{2+} was released from $PbSO_4$ and reacted with ZnS to form PbS, acting as an adsorption site for the flotation collector, xanthate. This would be the main reason for high floatability of ZnS in the presence of $PbSO_4$. Moreover, $PbSO_4$ can cause lead pollution in the surrounding environment of tailings dam because it has poor affinity with collector (eg, xanthate) and would be distributed into tail in flotation (Fuerstenau *et al,* 1987; Rashchi *et al,* 2005). Therefore, a method to depress ZnS floatability and prevent lead pollution caused by the presence of $PbSO_4$, is necessary for mineral processing of complex sulfide ores containing $PbSO_4$.

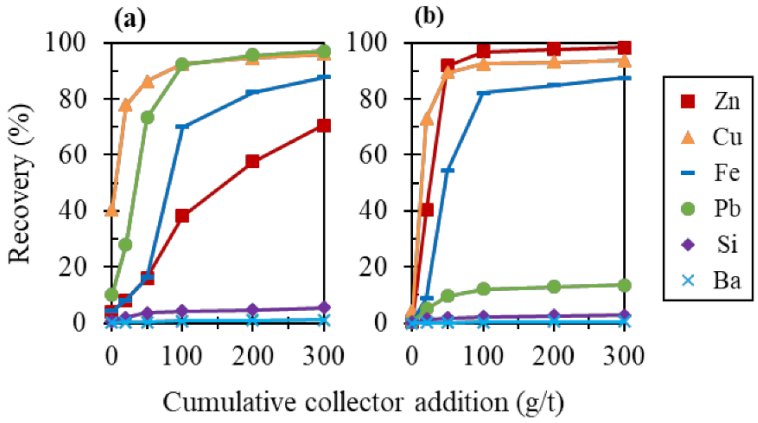

FIG 1 – Flotation results of (a) PbS-type model sample and (b) $PbSO_4$-type model sample with increasing potassium amyl xanthate (KAX) dosage (conditions: 20 µL/L methyl isobutyl carbinol (MIBC, frother), 20 kg/t of sodium sulfite (pyrite depressant), pH 6.5, 25°C, pulp density 5 per cent, air introduction rate 1 L/min, impeller speed 1000 rev/min) (Aikawa *et al,* 2021).

A proposed method for enhanced depression of sphalerite by extracting anglesite and recovery of extracted lead ion as zero-valent lead by cementation using zero-valent iron

For developing a sustainable process flow sheet covering both the improved flotation separation of complex sulfide ores as well as the detoxification of solid/solution wastes contaminated with Pb

species like $PbSO_4$, the authors have proposed a method for enhanced depression of ZnS by extracting $PbSO_4$ and recovery of extracted Pb^{2+} as zero-valent Pb by cementation using zero-valent Fe (Aikawa *et al,* 2022).

Two types of minerals were used: sphalerite (ZnS, Kamioka Mine, Japan) and lead sulfate ($PbSO_4$, 98 per cent purity, FUJIFILM Wako Pure Chemical Corporation, Japan). A mineral specimen of ZnS was characterised using X-ray fluorescence spectroscopy (XRF) and X-ray powder diffraction (XRD). Based on the XRF result, ZnS is composed of 55.7 per cent Zn, 6.2 per cent Fe, 0.2 per cent Pb, 21.3 per cent S, and 8.4 per cent Si. The XRD pattern of ZnS implied that ZnS is relatively pure based on the absence of peaks from common minerals like quartz (Aikawa *et al,* 2022).

Extraction of anglesite using EDTA

In flotation of complex sulfide ores containing $PbSO_4$, ZnS floatability increased due to lead activation of ZnS, resulting in the difficulties in separation of ZnS from Cu- and Pb-sulfide minerals. To address the above-mentioned problems caused by the presence of $PbSO_4$ (ie, un-wanted activation of ZnS and lead contamination), its extraction prior to flotation was investigated. Among the extractants, EDTA was chosen in this study because of its ability to extract metal ions from sulfates like $PbSO_4$, without dissolving metal sulfides (eg PbS and ZnS) (Aikawa *et al,* 2021; Bicak, 2019; Grano *et al,* 1988; Kant *et al,* 1994; Rumball and Richmond, 1996). Figure 2 shows effects of EDTA concentration and time on extraction of $PbSO_4$. Almost of all $PbSO_4$ was extracted When the stoichiometric ratio of EDTA/$[Pb]_{tot}$ was >1, ~97 per cent of $PbSO_4$ was extracted within 30 min with 500 mM of EDTA. These results indicate that EDTA pre-treatment can extract almost of all $PbSO_4$, thus preventing lead pollution in the surrounding environment of tailings dam by extracting environmentally hazardous minerals before flotation.

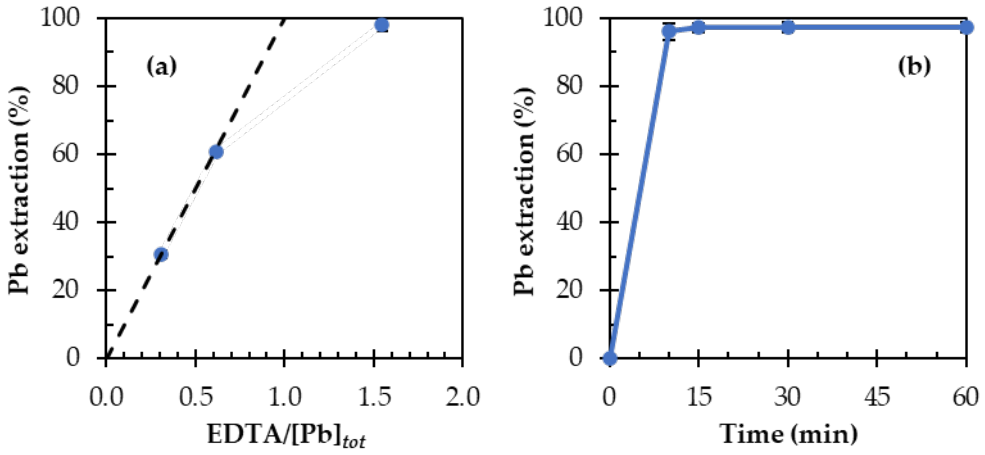

FIG 2 – (a) The extraction efficiency of $PbSO_4$ after 24 h with different concentrations of EDTA (100, 200, or 500 mM) and (b) effects of time on $PbSO_4$ extraction with 500 mM EDTA. Note that the dotted line in Figure 3a corresponds to the ratio of EDTA/$[Pb]_{tot}$ (conditions: $PbSO_4$ 1 g/10 mL of EDTA, shaking speed 120 rev/min, amplitude 40 mm, 25°C) (Aikawa *et al,* 2022).

Recovery of extracted Pb^{2+} as zero-valent Pb by cementation

After EDTA pre-treatment, recovery of Pb^{2+} from the leachate will not only add economic value but also protect the environment. Cementation is one of the effective methods to reductively recover metal ions as metals (Jeon *et al,* 2020). In this method, the metal ion (B^{b+}) receives electrons from a reductant, metals (A^0), via its dissolution and is deposited on the surface of A^0 as B^0 as illustrated in Equation 4 (Choi *et al,* 2021).

$$n\ A^0 + m\ B^{b+} \rightarrow n\ A^{a+} + m\ B^0\ (na = mb) \quad (4)$$

To recover the extracted Pb^{2+} as zero-valent Pb (Pb^0) from EDTA leachate, cementation experiments were carried out using zero-valent iron (ZVI, Fe^0) powder as a reductant. Figure 3 shows effects of ZVI amount and time on the recovery of extracted Pb^{2+} from the leachate after $PbSO_4$ extraction using 500 mM of EDTA for 30 min (solid/liquid ratio: $PbSO_4$ 1g/10 mL of EDTA). Almost of all extracted Pb^{2+} (~97 per cent) was recovered within 24h using 1 g/10 mL of ZVI. To confirm the

recovery of Pb^0 on ZVI, the residue of the cementation experiments using 1 g/10 mL ZVI for 24 h was analysed using SEM-EDS and the deposition of Pb on ZVI powder was observed (Figure 4), suggesting that extracted Pb^{2+} was reductively deposited via cementation reaction:

$$Pb(EDTA)^{2-} + 2e^- = Pb^0 + EDTA^{4-} \quad (5)$$

Figure 5 shows the XRD pattern of the residue of the cementation experiments. The peaks of Fe^0, Pb^0, PbO, and Fe_2O_3 were detected, indicating that Pb^{2+} was reductively deposited as Pb^0 on the surface of ZVI as illustrated in Equation 5. The presence of PbO and Fe_2O_3 is due most likely to the oxidation of Pb^0 and ZVI surface (Silwamba *et al,* 2020).

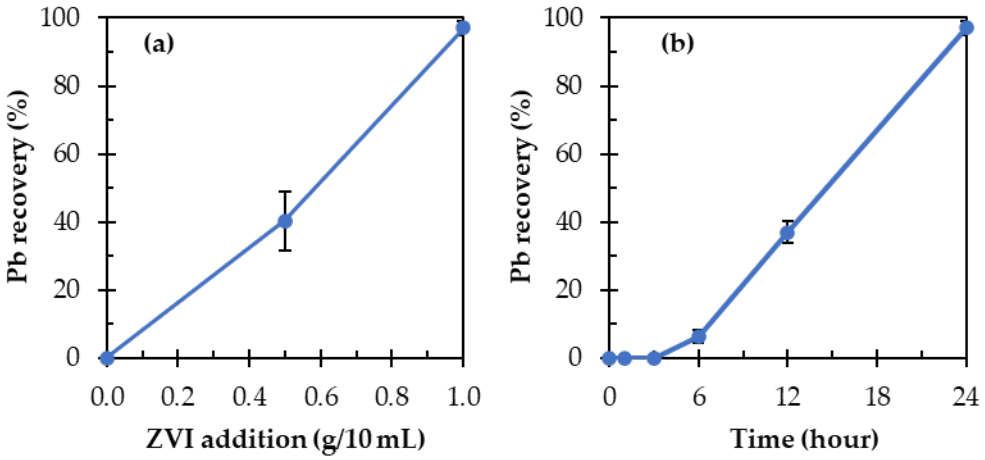

FIG 3 – (a) effects of ZVI amount on the recovery of extracted Pb after 24 h in the leachate after $PbSO_4$ extraction using 500 mM of EDTA for 30 min and (b) effects of time on the recovery of extracted Pb^{2+} using 1 g/10 mL ZVI in the leachate after EDTA pre-treatment using 500 mM EDTA for 30 min (conditions: shaking speed 120 rev/min, amplitude 40 mm, 25°C, purging with ultrapure nitrogen) (Aikawa *et al,* 2022).

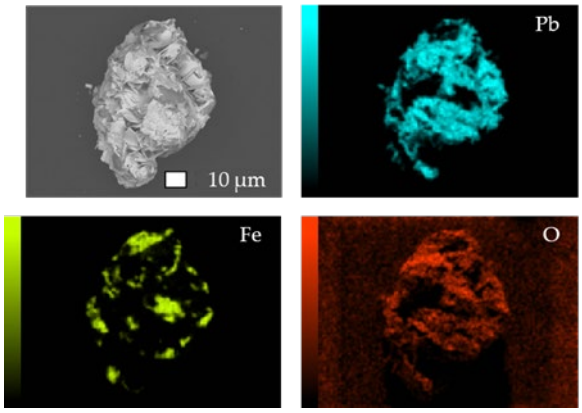

FIG 4 – SEM photomicrograph of the residue of the cementation experiment using 1 g/10 mL ZVI for 24 h with the corresponding elemental maps of Fe, Pb, and O (Aikawa *et al,* 2022).

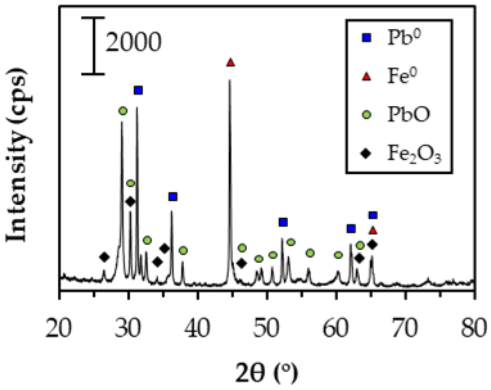

FIG 5 – The XRD pattern of the residue of the cementation experiment using 1 g/10 mL ZVI for 24 h (Aikawa *et al,* 2022).

Effects of EDTA pre-treatment on ZnS depression in flotation

As described above, almost of all $PbSO_4$ was extracted with EDTA. The effects of EDTA pre-treatment on ZnS depression in flotation was investigated. Flotation experiments of model samples containing ZnS and $PbSO_4$ with and without EDTA pre-treatment were conducted (Figure 6). Prior to flotation experiments, the mixture of 15 g ZnS and 5 g $PbSO_4$ was treated with 200 mL of 500 mM EDTA in 500 mL Erlenmeyer flasks for 30 min where the extraction efficiency of $PbSO_4$ was 99.8 per cent, and then flotation experiments were conducted with ~5 kg/t $ZnSO_4$ (100 ppm Zn^{2+}) and 1 kg/t Na_2SO_3 as depressants. Figure 6 shows the flotation results and the floatability of Zn was clearly depressed from ~82 per cent to ~30 per cent when EDTA pre-treatment was applied. Cementation experiments using the leachate of EDTA pre-treatment were also conducted to recover extracted Pb^{2+}, and 99.7 per cent of extracted Pb^{2+} was recovered as Pb^0 using 1 g/10 mL ZVI. To confirm depression of ZnS floatability after EDTA pre-treatment, pre-treated sample reacted with zinc sulfate for 3 min, ~5 mL of aliquot of the pulp was collected, and the filtrate and the residue were analysed by ICP-AES and XPS, respectively.

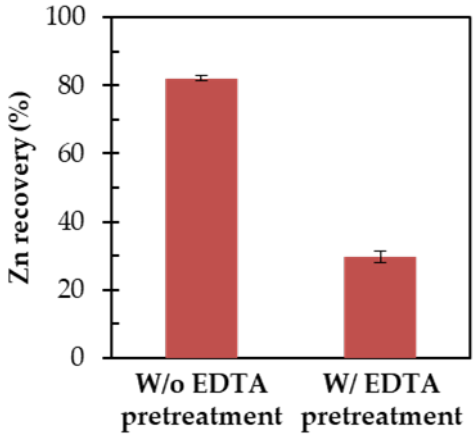

FIG 6 – Effects of $PbSO_4$ extraction on the floatability of ZnS in the presence of $PbSO_4$ (conditions: 20 µL/L MIBC (frother), 20 g/t KAX (collector), ~5 kg/t zinc sulfate (100 ppm Zn^{2+}, sphalerite depressant), 1 kg/t sodium sulfite (sphalerite depressant), pH 6.5, 25°C, pulp density 5 per cent, air introduction rate 1 L/min, impeller speed 1000 rev/min) (Aikawa *et al,* 2022).

The concentrations of Pb^{2+} in the filtrate with and without EDTA extraction showed 5.3 ppm Pb^{2+} without EDTA pre-treatment and 0.2 ppm Pb^{2+} with EDTA pre-treatment, indicating that Pb^{2+} concentration decreased by EDTA pre-treatment due to extraction of $PbSO_4$. The concentrations of Zn^{2+} in the filtrate with and without EDTA extraction showed 101 ppm Zn^{2+} without EDTA pre-treatment, 99.4 ppm Zn^{2+} with EDTA pre-treatment since 100 ppm of Zn^{2+} (zinc sulfate) was added as a depressant.

Based on thermodynamics calculation using Equation 6, the possibility of lead activation of ZnS (Equation 1) could be evaluated using the measured values of Pb^{2+} and Zn^{2+} (Aikawa *et al,* 2021; Basilio *et al,* 1996; El-Shall *et al,* 2000). In this study, the changes in free energy were calculated using the above measured value of Pb^{2+} and Zn^{2+}. Table 1 shows the calculated results of the changes in free energy based on the equilibrium constants of lead activation of ZnS (Equation 1). The change in free energy without EDTA pre-treatment was negative while that with EDTA pre-treatment was positive. When the change in free energy is positive, the backward reaction of lead activation (Equation 1) would occur spontaneously, indicating that lead activation would be limited by EDTA pre-treatment. These results support the flotation results that the depression of ZnS floatability was achieved by the pre-treatment which decreases Pb^{2+} concentration during flotation by extraction of $PbSO_4$.

$$\Delta G = -RT \ln K + \ln(\mathrm{Zn}^{2+}/\mathrm{Pb}^{2+}) \quad (6)$$

$$K = \frac{K_{sp}^{ZnS}}{K_{sp}^{PbS}} \quad (7)$$

TABLE 1

The calculation results of the change in free energy with and without EDTA pre-treatment (Aikawa *et al,* 2022).

K	ΔG (kJ/mol) Without EDTA pre-treatment	ΔG (kJ/mol) With EDTA pre-treatment
1000[a]	–6.9	1.8
704[b]	–6.1	2.7
1059[c]	–7.1	1.7
1127[d]	–7.2	1.5

[a] The equilibrium constant was referred from El-Shall *et al* (2000).

[b, c, d] The equilibrium constants were calculated using EQ 7 by the reported K_{sp} values of ZnS and PbS from Helgeson (1969), Latimer (1952), and Leckie and James (1974), respectively.

To confirm whether the lead activation of ZnS was limited by the extraction of $PbSO_4$ using EDTA, untreated ZnS as well as $ZnSO_4$-pretreated ZnS/$PbSO_4$ mixtures with and without EDTA pre-treatment were analysed by XPS (Figure 7). The $Pb4f_{7/2}$ core-level spectra of the samples are shown in Figure 7, and the corresponding curve fitting parameters are summarised in Table 2. Since the Zn3s peak is overlapping with the $Pb4f_{7/2}$ signals, the spectrum has been resolved by curve fitting to subtract the area due to the Zn3s peak (Basilio *et al,* 1996; Liu *et al,* 2020). As illustrated in Figure 7b and 7c, the deconvoluted XPS spectra of the residues with and without $PbSO_4$ extraction showed two types of Pb species: (1) Pb^{2+}–S of PbS (143.6 and 138.6 eV), and (2) Pb^{2+}–SO_4 of $PbSO_4$ (144.7 and 139.8 eV), while the deconvoluted XPS spectrum of untreated ZnS showed no Pb species (Figure 7a) (Aikawa *et al,* 2020; Hernan *et al,* 1995). The decrease in the intensity of Pb^{2+}–SO_4 is in a good agreement with the extraction efficiency of $PbSO_4$ using EDTA for ZnS/$PbSO_4$ mixture (~99.8 per cent). When EDTA pre-treatment was applied prior to flotation experiments, the peak intensity ratio of PbS/ZnS decreased from 2.3 to 0.2, indicating that EDTA pre-treatment is effective in limiting lead activation of ZnS. This is in line with the calculated results of the change in free energy based on thermodynamics (Table 1).

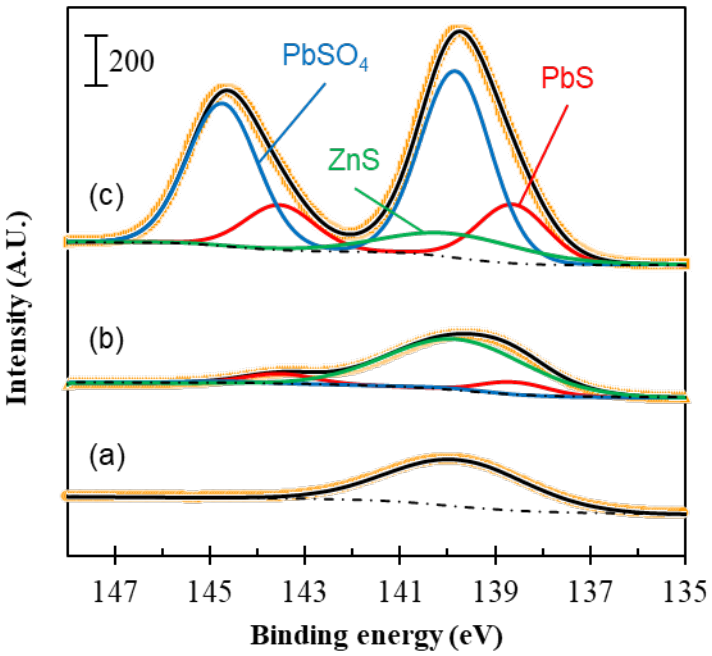

FIG 7 – XPS Pb4f$_{7/2}$ spectra of (a) raw ZnS, (b) ZnS/PbSO$_4$ mixture with EDTA pre-treatment, and (c) ZnS/PbSO$_4$ mixture without EDTA pre-treatment (Aikawa *et al,* 2022).

SUMMARY

Complex sulfide ores are important sources for critical metals like Cu, Pb, and Zn; however, when PbSO$_4$ is contained, its processing remains challenging due to the presence of easily soluble PbSO$_4$ that releases Pb^{2+} and activate ZnS, making the separation of Cu-Pb-Zn sulfide minerals difficult to accomplish. The results of this article have significant implications not only for understanding of how the presence of anglesite in the complex sulfide ores affects the floatability of ZnS but also for proposing a sustainable process flow sheet covering both the improved flotation separation of complex sulfide ores as well as the detoxification of solid/solution wastes contaminated with Pb species. Firstly, the presence of anglesite might have a detrimental impact on flotation separation of complex sulfide ores due to unwanted lead activation of ZnS that improved its floatability which could not be depressed with ZnSO$_4$ – the conventional depressant for ZnS. Secondly, EDTA pre-treatment could extract almost all PbSO$_4$ from ZnS/PbSO$_4$ mixture, and consequently, the floatability of ZnS decreased due to the limited amount of PbS-like compound formed on the ZnS surface by lead activation. Finally, cementation using ZVI could recover Pb^{2+} extracted from PbSO$_4$ during EDTA pre-treatment as Pb^0, which will not only add economic value but also protect the environment.

Based on the findings of this study, a sustainable process flow sheet for complex sulfide ores is proposed (Figure 8). In this proposed flow sheet, $PbSO_4$ is first extracted by EDTA pre-treatment before flotation. The residue obtained after EDTA pre-treatment is fed to a flotation stage where ZnS floatability is effectively depressed by the conventional depressant for ZnS due to the decrease in the ratio of Pb^{2+}/Zn^{2+} of the flotation pulp. Meanwhile, the leachate obtained from EDTA pre-treatment is rich in Pb^{2+} that can be recovered via cementation using ZVI as Pb^0. To keep up with the high demand for critical metals as following SDGs, mine developments should be in harmony with environment. This proposed flow sheet can achieve enhanced selective flotation of complex sulfide ores (depression of ZnS floatability) while preventing lead pollution in the surrounding environment of tailings dam (removal of toxic $PbSO_4$ before flotation) and maximising the recovery of critical elements by cementation (recovery of Pb^0 using ZVI).

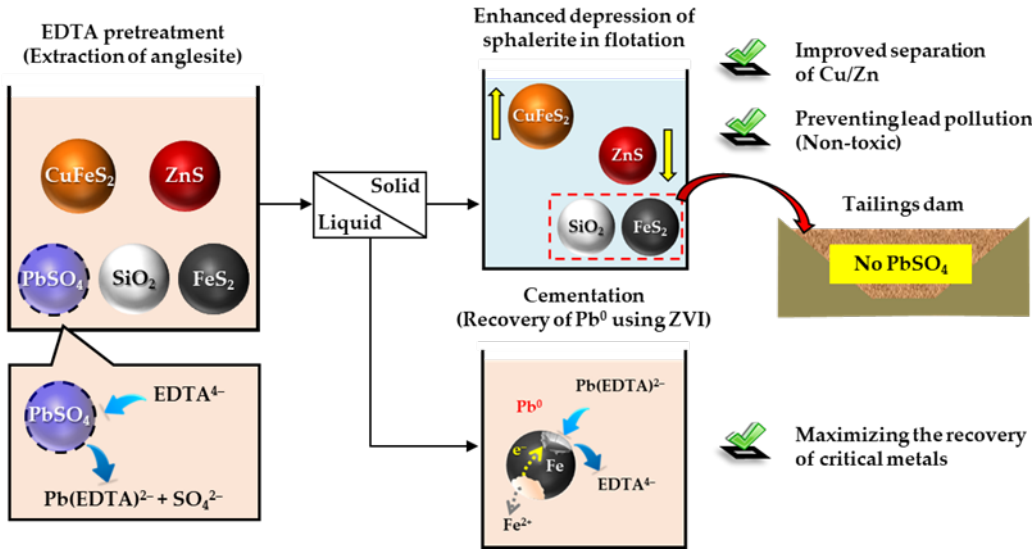

FIG 8 – Proposed enhanced depression of ZnS by extracting $PbSO_4$ using ethylene diamine tetra acetic acid (EDTA) and recovery of extracted Pb^{2+} as zero-valent Pb (Pb^0) by cementation using zero-valent Fe (ZVI) (Aikawa *et al,* 2022).

ABSTRACT

This research was done to reduce silica from mixed hematite concentrate of Barfkar Iron Ore Sample and increase Fe grade using reverse flotation method (Depressing Hematite and floating Silica). The used sample in the reverse flotation tests was a mixture containing two types of hematite concentrates (Spiral cleaner concentrate and Slon-VPHGMS cleaner concentrate) with the percentage of 16 per cent and 84 per cent, respectively. Fe grade of two samples was 59.31 per cent and 57.52 per cent and SiO_2 grade was 5.83 per cent and 6.71 per cent, respectively. After mixing, the Fe and SiO_2 grade of the mixed sample was measured at 58.10 per cent and 6.20 per cent. For flotation tests, effect of variable operational parameters including feed size distribution (d_{80} = 130 microns and d_{80} = 53 microns), pulp solidity (25 per cent and 30 per cent w/w), pH (9.70, 10.20 and 11), Sodium silicate as a dispersant (500, 1000 and 2000 g/ton), Starch as a depressant (500, 1000, 2000 and 3000 g/ton) and EDA as a collector (180, 300, 400 and 500 g/ton) were investigated. For evaluating the influence of Sodium silicate and Starch dosage, initial flotation tests were performed on the main sample (d_{80} = 130 microns). These two parameters had no significant effects on the yield, Fe, and SiO_2 grade of flotation concentrate based on test results. In the next step, screen analysis was carried out on the main sample for mineralogical studies. Accordingly, the suitable size distribution for releasing Fe and SiO_2 particles was smaller than 53 microns. Therefore, the sample was crushed until d_{80} = 53 microns. Then, supplementary tests were performed on the crushed sample for studying the pH range, pulp solidity, and EDA collector dosage. After doing silica removal flotation tests based on the designed pattern and comparison of the results, the conditions consisting of size distribution d_{80} = 53 microns, pulp solidity 25 per cent, pH 10.20, Sodium silicate 1000 g/ton, Starch 1000 g/ton, and EDA 500 g/ton was selected as optimum values. In the last test, Fe and SiO_2 grade was measured at 60.00 per cent and 3.93 per cent, respectively, and Fe recovery was obtained at 74.93 per cent.

INTRODUCTION

Impurities in iron ore are divided into useful and harmful parts. Useful impurities mainly contain lime or manganese compounds. The presence of these impurities improves the properties and increases the iron ore concentrate price (Forsmo *et al,* 2008). The most important harmful impurities in iron ore concentrate processing plants are silica, phosphorus, sulfur, and titanium. The existence of more than permissible amounts of them causes problems in downstream processes of iron and steel production. Other impurities are commonly found with iron ore that their grade is lower than the four mentioned cases, but if we do not use appropriate methods to remove them, they will result in many problems in downstream processes, especially steel production (Xie *et al,* 2021). These impurities mainly include copper, chromium, molybdenum, tin, and vanadium. For example, more silica in the concentrate (The permissible percentage is less than 5 per cent for the blast furnace method and less than 2 per cent for the direct reduction method) increases the amount of produced slag in the melting stage. Usually, for every kilogram of SiO_2 in iron ore that enters the furnace, about 3 to 4 kg of slag per ton of steel is produced. In the direct reduction method, due to the sensitivity of the process to the presence of silica impurities, the content of SiO_2 should be as low as possible in the pellets and consequently in the iron ore concentrate to avoid the production of excess slag and probable problems during the process (Lima, Valadao and Peres, 2013). On the other hand, illegal amounts of silica content in the produced concentrate also decline quality and lower product prices. Also, the presence of some impurities leads to the growth of undesirable gases in the environment.

These elements are generally chlorine, fluorine, arsenic, sodium oxide, potassium oxide, lead, and zinc. Therefore, it is necessary to remove these elements to the optimal level using appropriate and conventional methods (Sahoo *et al,* 2016).

One of the essential parameters for specifying the quality of produced iron ore concentrate is the ratio of CaO to SiO_2 so increasing this ratio decreases the consumption of melting materials and makes the conditions and costs of the melting process more favourable. Also, the ratio of Fe to SiO_2 is another effective parameter. Iron ore concentrate with Fe to SiO_2 ratio about seven is considered unsuitable, and with a ratio higher than 12, it is approximately proper concentrate (Filippov, Severov and Filippova, 2014).

Reverse flotation is one of the most important and widely used methods for eliminating silica from magnetite or hematite iron ore concentrates. Using suitable chemicals, at first iron is depressed in the sample. After adjusting other parameters such as pH, solidity, optimal size distribution of the sample, determining the surfactants, and the preparation time of each of them, a flotation test is performed. Chemical depressants of iron, such as Starch, Sodium silicate, and other chemicals, depress iron in the flotation feed sample and prevent its flotation (Houot, 1983). In the next step, after making the necessary adjustments, using a suitable collector such as EDA Flotigam, Armac C, or Armac D, conditions are provided for the flotation of silica particles with a proper liberation degree (Silva *et al,* 2021). Depending on the type of silica present in iron ore concentrate (Silica is usually present in form of ferrous silicate lattice or separate quartz particles in iron ore concentrate, which can be very difficult to omit from the concentrate in the first case and in contrast, simple in the second case) and also other particles or impurities, it may be necessary to use additional chemicals such as dispersants, activators or other surfactants (Aarab *et al,* 2021). For example, in samples containing a high percentage of clay mineral Particles, it is needed to disperse them utilising a dispersing agent such as Sodium silicate and then perform flotation of silica particles.

MATERIALS AND METHODS

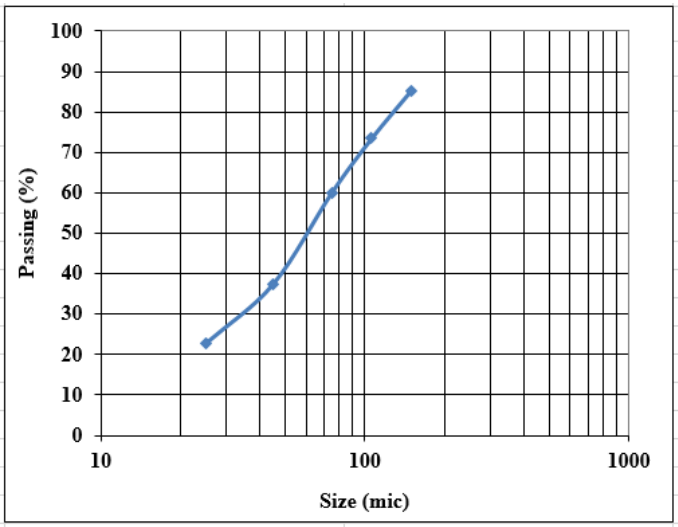
The sample used in this study was a mixture of concentrate produced from spiral gravity separation, and Slon electromagnetic separation (VPHGMS) that have performed on the samples of Kooh Barfkar mine located in Iran, Kerman province, Zarand. At first, a gravity separation test was carried out on the sample using a spiral as a rougher and cleaner stage. Then, the produced middle and tailing samples of the rougher and cleaner stages were mixed with a defined weight percentage, and then Slon electromagnetic separation was done on a mixed sample as a rougher and cleaner stage. Based on the results of total yield by gravity and electromagnetic tests, two types of concentrate samples were blended with a weight percentage of 16 per cent and 84 per cent, respectively. The Fe grade of the spiral and Slon concentrate were 59.31 per cent and 57.52 per cent, respectively. After mixing the samples, the Fe grade of the mixed concentrate was 58.10 per cent. Also, the SiO_2 grade of two samples was 5.83 per cent and 6.71 per cent, respectively, which was obtained after mixing 6.20 per cent and of course was 6.20 per cent after mixing both of them. For determining the size distribution of the sample, sieve analysis was performed by a wet method, and d_{80} = 130 microns were obtained. Table 1 shows the physical and chemical specifications of the flotation feed sample, including the size distribution diagram and also Fe, and SiO_2 grade of concentrate.

TABLE 1

Physical and chemical specifications of the flotation feed sample (size distribution, Fe and SiO_2 grade).

Chemical specifications	
Fe (%)	58.10
SiO_2 (%)	6.20
Al_2O_3 (%)	1.60
CaO (%)	0.22
MgO (%)	0.18
P_2O_5 (%)	0.17
K_2O (%)	0.12
Na_2O (%)	0.02
TiO_2 (%)	0.14
SO_3 (%)	0.04
LOI (%)	6.75

Size distribution diagram



For experiments, operational parameters containing feed size distribution (d_{80} = 130 microns, d_{80} = 53 microns), pulp solidity (25, 30, and 35 per cent w/w), pH (9.70, 10.20, and 11), Sodium silicate dosage as a dispersant of clay mineral particles (500, 1000 and 2000 g/ton), Starch dosage as an iron depressant (500, 1000, 2000 and 3000 g/ton) and collector dosage EDA (180, 300, 400 and 500 g/ton) were selected. Also, all experiments were operated using Denver mechanical flotation cell with 2 L cell volume. Constant Experimental parameters in this study were stirring speed of 1200 rev/min, preparation times of Sodium silicate, Starch and EDA collector 5, 5 and 2 minute, respectively, Combination ratio 9 to 1 of pH regulator including Na_2CO_3 and NaOH and finally seven steps of adding chemicals and frothing stages. The effects of Sodium silicate and Starch were investigated on the original sample with a size distribution of d_{80} = 130 microns. After obtaining the data of the initial tests, sieve analysis was performed to determine the liberation degree, type of mineralogy, and SiO_2 grade in each fraction of the sample. Also, microscopic mineralogical studies were determined on each fraction separately. Examine the effect of collector dosage and pH changes on the crushed sample (Crushing sample to investigate the effect of liberation degree of Fe and SiO_2 particles) were performed up to d_{80} = 53 microns. Results of tests were analysed, and the optimal level of each parameter was obtained. Then supplementary tests were experimented with appropriate amounts of each chemical.

RESULTS AND DISCUSSIONS

Initial flotation tests

Effect of Sodium silicate dosage

For investigating the effect of Sodium silicate dosage on the removing silica from concentrate, flotation test conditions consist of different dosages 500, 1000, 2000 g/ton in constant conditions such as d_{80} = 130 microns, solidity 30 per cent, Starch dosage 500 g/ton, collector EDA dosage 180 g/ton and pH about 9.70 were considered. The results (Figure 1) showed that yield decreased with increasing the Sodium silicate dosage, but significant changes were not obtained in the Fe and SiO_2 grade of concentrate. On the other hand, the insignificant effect of this chemical dosage on variation of Fe and SiO_2 grade indicates that the dispersing of clay mineral particles doesn't have an important role on the efficiency of the removal silica reverse flotation. In this part, the fractional reduction of Fe and SiO_2 grade was measured at about 0.30 per cent and 1 per cent, respectively.

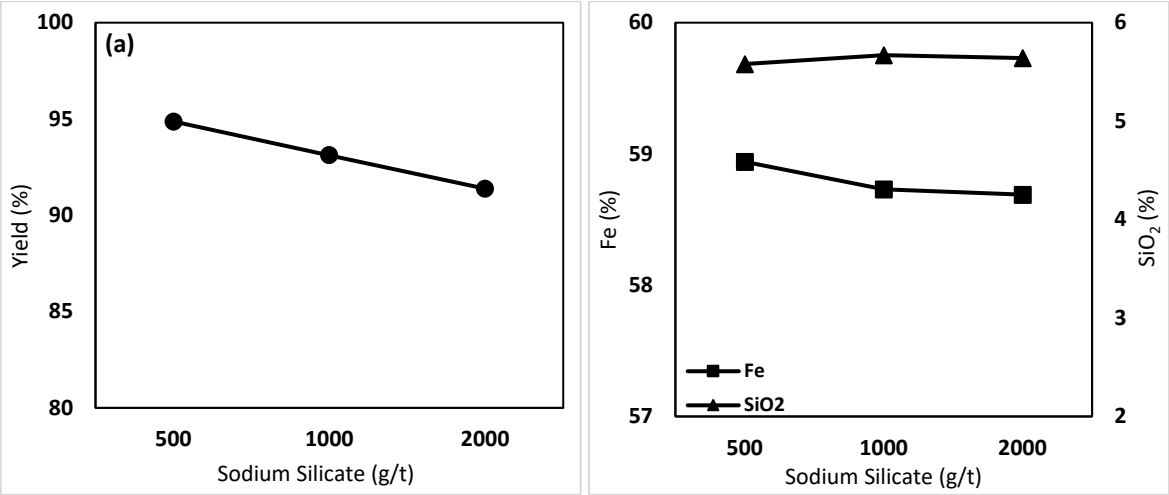


FIG 1 – Changes of (a) Yield, (b) Iron and silica grade versus Sodium silicate dosage (g/ton).

Effect of Starch dosage

In order to study the influence of Starch dosage on the omitting silica from concentrate, amounts of dosages 500, 1000, 2000, 3000 g/ton in constant conditions such as d_{80} = 130 microns, solidity 30 per cent, 500 g/ton of Sodium silicate, collector EDA dosage of 180 g/ton and pH about 9.70 were considered. The results are shown in Figure 2. By getting bigger of Starch dosage, the flotation concentrate yield decreases. The slope of yield decreasing is reduced, too. In fact, it can be predicted that if the experiments continue at values above 3000 g/ton of Starch, yield declining gradually disappears, and its amount will reach to a constant value. Furthermore, results revealed that changes in this parameter have an inconsiderable effect on the Fe and SiO_2 grade of concentrate in the flotation test. It had the same performance as the changes of Sodium silicate dosage.

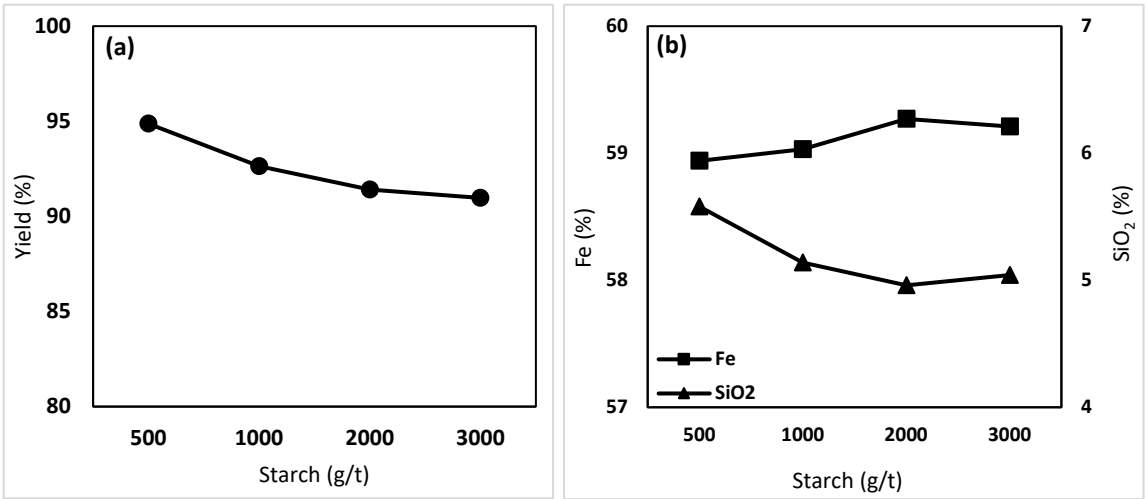

FIG 2 – Changes of (a) yield, (b) Fe and SiO_2 grade versus Starch dosage.

Flotation feed mineralogy

Based on the results of the initial tests and the lack of significant effect on the Sodium silicate and Starch dosage, which were done on the main sample (d_{80} = 130 microns), Sieve analysis was performed on the sample to determine the association and dispersion of silica in each fraction of sieving. Fractional chemical analysis of SiO_2 grade separately was done, too. Also, microscopic mineralogy was performed separately on polished sections and thin blades of each fraction. For fractions smaller than 75 microns, silica accumulation is less than larger fractions. On the other hand, in accordance with mineralogical observations, it was found that more than 80 per cent of the silica is ferrous silicate minerals that causes difficulty in removing silica by the flotation method. Also, less than 20 per cent of silica is quartz that had a suitable liberation degree in fractions smaller than 75 microns. In all fractions, the major tailings minerals in terms of abundance were quartz, calcite,

chlorite, biotite, and muscovite, and the main stocking of ferrous minerals were silica and chlorite. Accordingly, to create a suitable liberation degree especially for iron and silica particles and perform supplementary flotation tests, the sample was crushed up to d_{100} = 75 microns and d_{80} = 53 microns.

Supplementary flotation tests

Effect of pH

Supplementary flotation tests were performed to investigate the effect of pH on the flotation concentrate specifications for the crushed sample, with pH ranges of 9.70, 10.20, and 11 in constant conditions such as d_{80} = 53 microns, pulp solidity 30 per cent, Sodium silicate dosage 500 g/ton, Starch dosage 500 g/ton and collector EDA 180 g/ton. Results are shown in Figure 3. Based on the results, the concentrate yield increases by mounting the pH range. Also, the SiO_2 grade in concentrate decreased by about 1.66 per cent (removing approximately 28 per cent, relatively). Increasing the pH leads to more and better depression of iron particles in the flotation method, and also, it does not affect the flotation of silica with EDA. On the other hand, based on the graph of changes of Fe grade versus pH range, growing this parameter has caused a reduction of Fe grade in the concentrate. However, this reduction was not noticeable and only happened by 1 per cent, which indicates that the pH in the studied range (9.70 to 11) does not influence on the Fe grade of the flotation concentrate specifications.

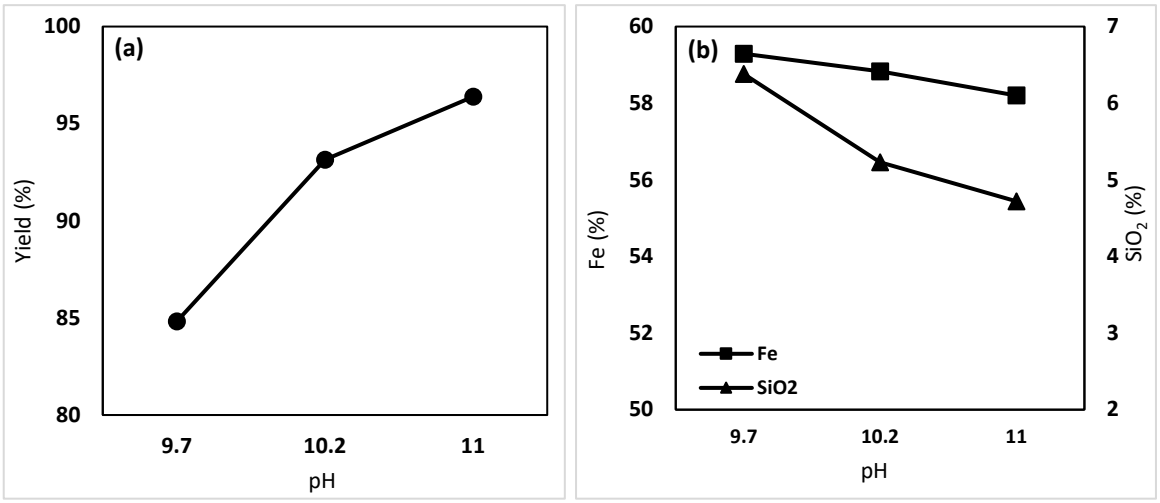

FIG 3 – Changes of (a) yield, (b) Fe and SiO_2 grade versus pH range.

Effect of pulp solidity

Supplementary flotation tests were performed to evaluate the pulp solidity on the properties of flotation concentrate. Therefore, three flotation tests were operated with pulp solidity 25 per cent, 30 per cent, and 35 per cent in constant conditions such as d_{80} = 53 microns, Sodium silicate dosage of 500 g/ton, the Starch dosage of 500 g/ton, pH range of 10.20, and collector EDA 500 g/ton. Results are shown in Figure 4. The results indicate that enhancing the pulp solidity increased the concentrate yield. Increasing this parameter resulted in lock and engage of inside the cell making difficult for particles to float and rise. Based on the diagrams, it is clear that the pulp solidity did not have a significant effect on the Fe and SiO_2 grade of the sample; because this factor does not cause any change in the main and fundamental properties of the sample, especially the surface physicochemical properties of the particles that play a significant role in the flotation process.

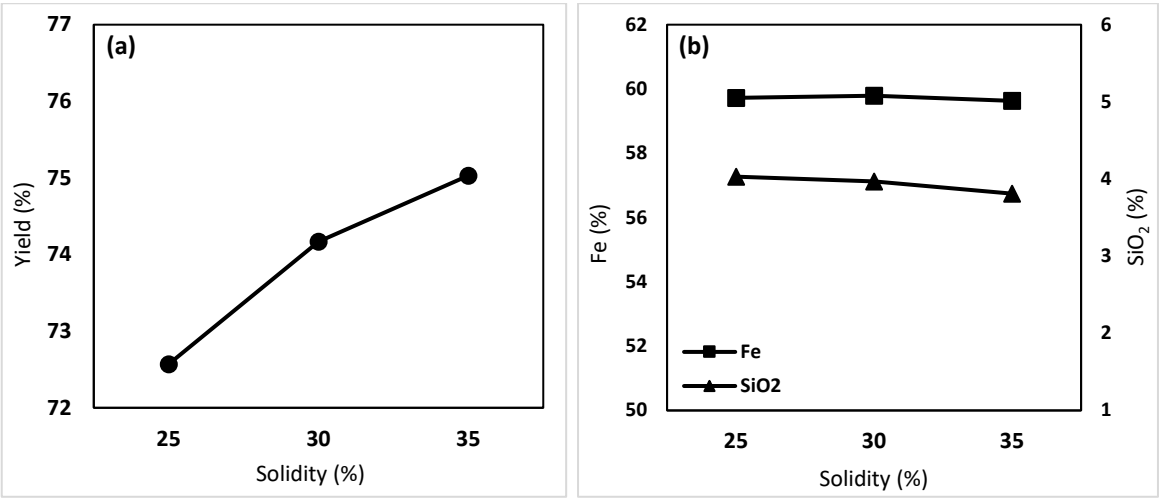

FIG 4 – Changes of (a) yield, (b) Fe and SiO_2 grade versus pH range.

Effect of EDA collector dosage

Supplementary flotation tests to investigate collector dosage (EDA) was performed at amounts of 180, 300, 400, and 500 g/ton and in constant conditions such as d_{80} = 53 microns, solidity 25 per cent, Sodium silicate dosage of 500 g/ton, Starch dosage of 500 g/ton and pH range 10.20. Test results are shown in Figure 5. Based on the results, increasing the collector dosage caused a decrease in concentrate yield. The increasing amount of this chemical causes it to be absorbed on silica particles higher locked with iron particles. This issue leads to transfer of a large part of low-grade silica particles to the tailing. On the other hand, changing the amount of EDA has not significantly affected the iron content of flotation concentrate. Based on this, the changes of Fe grade concentrate are only about 0.50 per cent. With the increasing dosage of this chemical, the SiO_2 grade in concentrate has decreased by about 16 per cent, relatively. Therefor EDA is one of the best chemicals for proper silica removal, and whatever the consumption of this chemical increases, absorption on the surface of silica particles and their flotation is better, which will result in a decline of this material grade related to flotation concentrate.

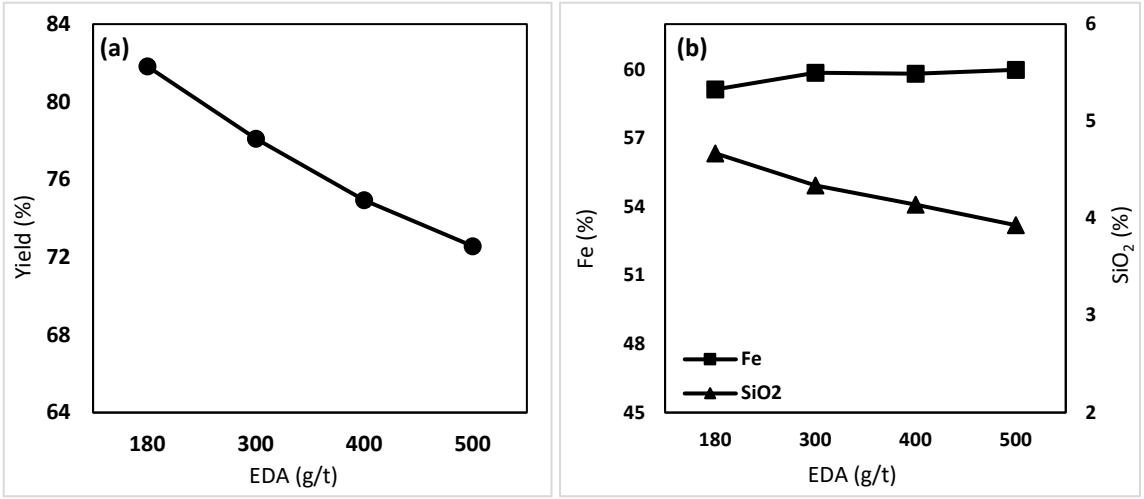

FIG 5 – Changes of (a) yield, (b) Fe and SiO_2 grade versus collector EDA dosage.

CONCLUSIONS

In this study, for producing hematite concentrate with appropriate grade and recovery from Kooh Barfkar sample and removing its impurities, especially silica, reverse flotation tests were designed and performed on a mixed concentrate of spiral gravity separation and Sloan electromagnetic test. Important Parameters, in this case, were feed size distribution, pulp solidity, pH, Sodium silicate (dispersant of clay mineral particles), Starch (depressant of iron particles especially hematite), and EDA collector (floating silica particles). Dependent variables were yield, Fe grade, and SiO_2 grade

of concentrate and effect of each independent parameter was investigated on them. Based on results, optimal test conditions were d_{80} = 53 microns, pH range about 10.20, Sodium silicate dosage 500 g/ton, Starch dosage 500 g/ton, and EDA collector dosage 500 g/ton. In this test, flotation concentrate yield was 72.57 per cent and Fe and SiO_2 grade was 60 and 3.93 per cent, respectively. Also, Fe recovery was 74.93 per cent. The most effective parameter was EDA collector dosage that caused significant changes on dependent variables such as yield, Fe, and SiO_2 grade of concentrate. Finally, due to the crystallisation of silica particles in the form of ferrous silicate crystals, using the flotation method, in order to reduce the silica content of this sample, was not suitable. On the other hand, the parameter with the most negligible effect was the pulp solidity that had an insignificant role on Fe and SiO_2 grade of concentrate. We can use Gravity methods such as Multi Gravity or spiral separation to achieve better results.

ACKNOWLEDGEMENTS

INTRODUCTION

There is a growing demand for copper driven by its applications in renewable energy and electric vehicles. Sulfide ores are an important source of copper. Flotation is a critical front-end process used to remove gangue minerals and concentrate the copper minerals. The electrochemical activity of sulfide minerals contributes to their overall activity in the flotation pulp. The mineral rest potential dictates how collectors interact with the mineral surface, and hence ultimately on the flotation response. Dissolved oxygen, (DO), pH, redox potential (Eh) and water composition and ionic strength are also significant in controlling flotation performance. The aim of this investigation was to determine the influence of the electrochemical environment both during milling and flotation on the flotation behaviour of bornite and chalcocite. For this investigation, the interactions of collector with bornite and chalcocite were studied using synthetic plant water (SPW1) and deionised water (DIW) at 5 different pH levels. Sodium isobutyl xanthate (SIBX) was used both in microflotation, collector adsorption and zeta potential tests.

MATERIALS AND METHODS

To investigate the surface chemistry of bornite and chalcocite individually and when mixed, experiments were conducted at pH 3, 5, 7, 9 and 11, under 2 different water qualities, Deionised water (DIW) and UCT Synthetic Plant Water (SPW1) (Wiese, Harris and Bradshaw, 2005).

Mineralogy

Bornite and chalcocite samples were analysed using XRD. The purity of the samples showed that the bornite (42 per cent) sample contained large portions of gangue minerals and chalcocite (62 per cent) had significant portions of marcasite (FeS_2) and pyrite (FeS_2) which are iron containing minerals, which makes differentiating between them when in a mixture complex.

Microflotation

The water type being used was adjusted to the required pH by adding HCl or NaOH. three g of the mineral was weighed in a beaker and the adjusted pH water added to create a slurry. The pH was adjusted to maintain the desired pH and dosed with SIBX collector at a dosage of 0.5 pseudo monolayer which is 493 g/ton for chalcocite and 386 g/ton for bornite. Microflotation was conducted using a standard procedure. Four concentrates were collected over 20 minutes.

Adsorption studies

Adsorption tests were carried out on the pure mineral samples and the concentration determined using UV/Vis spectroscopy (ƛ= 301 nm).

Zeta potential studies

Zeta potential tests were conducted using a Malvern ZetaSizer 4.

RESULTS AND DISCUSSION

Figure 1 shows that bornite recovery between pH 5 and 11 was generally the same, while pH 3 recorded the lowest recovery and recovery in SPW1 was lower compared to DIW. Chalcocite in

DIW had two distinct flotation recovery regions, one below 50 per cent recovery (pH 5 and 7) and recoveries above 50 per cent at pH 3, 9 and 11. Chalcocite in SPW1 showed a slight drop in recovery compared to DIW. The highest recovery was at pH 3 while pH 5 had the lowest recovery.

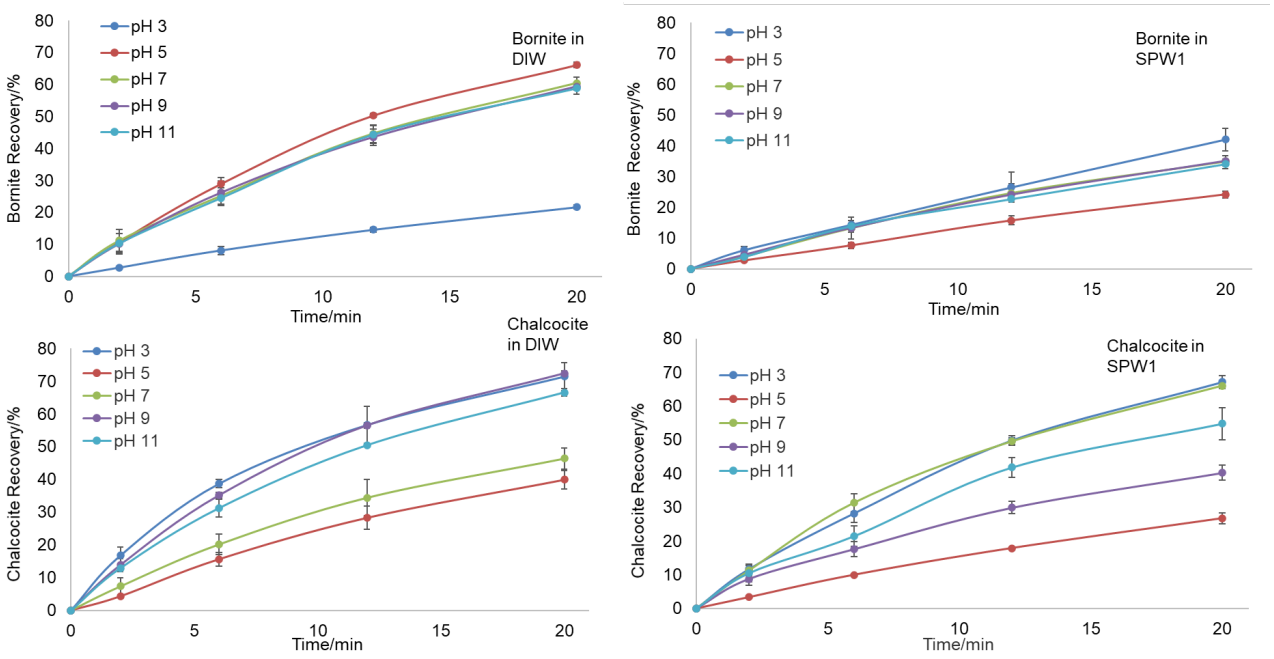

FIG 1 – Recovery versus time for bornite and chalcocite under DIW and SPW1 at pH 3, 5, 7, 9 and 11.

Figure 2 showed that there is distinctly better adsorption of SIBX onto the surface of chalcocite compared to bornite at all conditions. The key difference likely lies in the presence of iron in bornite and the lack thereof in chalcocite. There was also higher residual collector concentration when using 1 monolayer versus 0.5 monolayer collector dosage. For bornite the residual collector concentration decreased as the pH increased from 3 to 7 with the minimum residual concentration observed at pH 7 for all dosages and water types. From pH 7 to 11, the concentration steadily increased. Hence most of the collector was adsorbed at the mineral surface. There was higher residual collector concentrations in the DIW compared to SPW1 for the 1 monolayer dosage in bornite (except for pH 11). At 0.5 monolayer dosage, there was higher residual concentration in SPW1 at pH 3 to 7 whereas under alkali conditions there was higher residual concentration in DIW. Chalcocite generally showed a high adsorption rate, particularly using the 0.5 monolayer dosage where all pH values showed minimal residual collector concentration. The differences in collector adsorption are regulated by the pH, which dictates the specific collector mineral interactions, and the xanthate species formed under the given conditions. The collector mineral interactions are dictated by the pulp potential, which is heavily influenced by the pH of the system.

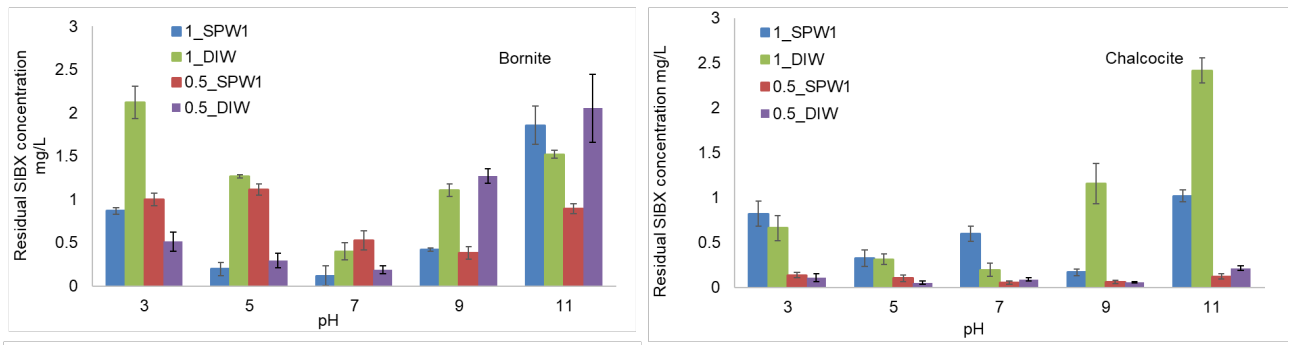

FIG 2 – Residual xanthate in solution after contacting bornite and chalcocite with 0.5 pseudo-monolayer and 1 pseudo-monolayer dosages of SIBX under DIW and SPW1 at pH 3, 5, 7, 9 and 11.

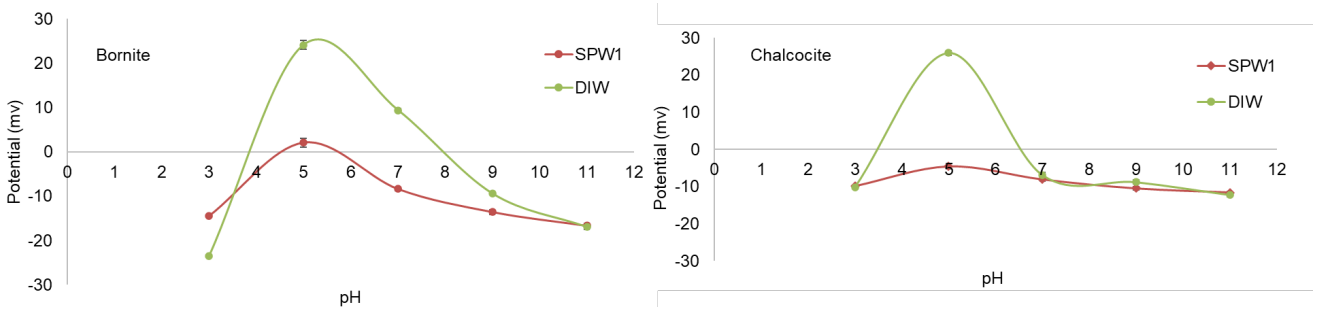

FIG 3 – Zeta Potential profiles for bornite and chalcocite under DIW and SPW1 at pH 3–11.

It is interesting to note that for DIW both bornite and chalcocite have quite similar zeta potential profiles. And that both bornite and \ exhibit 2 isoelectric points and higher potentials than in SPW1. Under SPW1, the profiles of both minerals are quite similar.

CONCLUSIONS

The purity of the minerals may have mitigated against the validity the results of this study although it could be argued that they may be more typical of real ore samples. In evaluating the flotation results in the context of collector adsorption and the zeta potential data it is possible to make reasonable deductions about the behaviour of these minerals in a flotation process.

INTRODUCTION

Mining operations in arid regions are compelled to reduce their consumption of fresh water. Closed water circuits are an attractive solution and, in addition to reducing freshwater consumption, have the added benefit of reducing reagent consumption as well as the environmental impact by eliminating effluent discharge. Accumulating ionic species have been shown to hinder collector adsorption which reduces the recovery of valuable minerals.

Numerous studies have investigated the effect of degrading water quality on collector adsorption however there is very limited understanding as to how this takes place from an electrochemical perspective. This study therefore aims to investigate how the presence of accumulating ionic species at varying concentrations affects the electrochemical adsorption of sodium ethyl xanthate onto galena. The synthetic plant water used in this study comprised of single salt solutions to isolate the effects of the ionic species of interest. The ionic strengths were varied between 0.0242 M, 0.0727 M, 0.1212 M and 0.2426 M which correspond to University of Cape Town (UCT) Centre for Minerals Research (CMR) synthetic plant waters of 1, 3, 5 and 10SPW, respectively. Mineral rest potentials indicated how changing water quality affected xanthate-mineral interactions. Microflotation observed the impact of changing water quality on mineral floatability.

MATERIALS AND METHODS

Synthetic plant water

In order to consider changes in water quality within flotation, the UCT CMR developed a synthetic plant water (SPW) recipe (Wiese, Harris and Bradshaw, 2005). The accumulation of ions in process water owing to on-site recycling impact the redox reactions taking place. These reactions can be considered through electrochemistry experiments. Single salt synthetic plant water solutions were generated to isolate the effects of specific ions. Sulfur chemistry is paramount to the flotation of sulfide minerals; thus, the ions of interest are SO_4^{2-} and $S_2O_3^{2-}$. The salt solutions were prepared in ultra-pure water with sodium as the counterion: $Na_2S_2O_3$ and Na_2SO_4. Table 1 shows the ionic composition of the waters.

TABLE 1

Composition of synthetic plant waters (adapted from Wiese, Harris and Bradshaw, 2005; Manono, Corin and Wiese, 2018; Ndamase, Tadie and Corin, 2020).

Water type	SO_4^{2-} (ppm)	$S_2O_3^{2-}$ (ppm)	Ionic strength (M)
1SPW	2325	2714	0.0242
3SPW	6984	8152	0.0727
5SPW	11 642	13 589	0.1212
10SPW	23 304	27 202	0.2426

Electrodes

A pure galena mineral electrode acted as the working electrode. The galena electrode was made and prepared for measurement as described by Tadie *et al* (2015). Ag/AgCl (3 M KCl) was used as

the reference electrode. Platinum was used to monitor the standard potential throughout. The electrodes are shown in Figure 1.

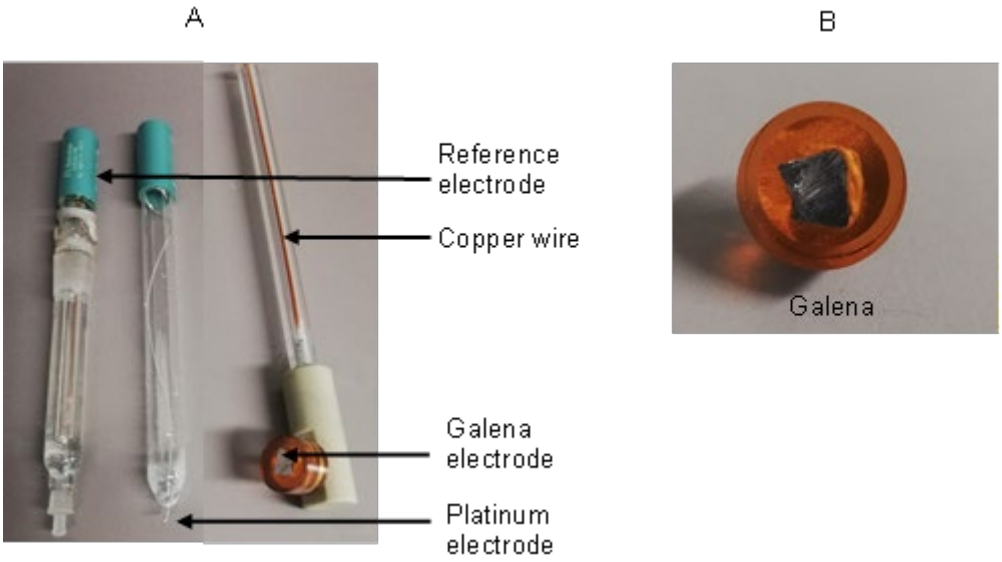

FIG 1 – (A) Electrodes used for electrochemistry measurements (B) Galena electrode (Ndamase, Tadie and Corin, 2020).

Collector

The collector, sodium ethyl xanthate (SEX), provided by AECI Mining Chemicals, was used at a concentration of 6.24×10^{-4} M in the electrochemistry studies. This concentration was chosen to be able to compare to other electrochemical studies (Chimonyo *et al,* 2017; Tadie *et al,* 2015). Microflotation tests were conducted at 50 g/t SEX, intended to be low enough for partial surface coverage in order to be able to see changes in flotation responses.

Rest potential

A 500 ml double walled glass electrochemical cell was used for rest potential measurements. The cell temperature was maintained at 25 ± 1°C using a water bath. The cell was filled with 450 ml of the SPW of interest, agitated with a magnetic stirrer, and the electrodes were suspended in the solution. A Gamry 600 potentiostat connected to a computer recorded the measured potentials using the Gamry Framework software. Initial rest potentials of the mineral was conducted for 600 seconds, after which collector (SEX at 6.24×10^{-4} M) was dosed and another 600 seconds was allowed for measurements. Tests were conducted in duplicate.

Microflotation

A 250 ml UCT microflotation cell (Bradshaw and O'Connor, 1996) was used to determine mineral floatability. Three grams of pure galena was mixed with 50 ml of the SPW of interest to form a slurry, the slurry was sonicated for 5 minutes to disperse fine particle agglomerates. The cell was filled to the desired volume with the SPW of interest. 50 g/ton SEX collector was dosed. The slurry was agitated with a peristaltic pump at 65 rev/min and a microsyringe controlled the air flow rate of 7 ml/min. Concentrates were collected after 2, 4, 6 and 8 minutes, allowing a total of 20 minutes. The concentrates and tailings filtered, dried and weighed to determine the mineral recovery. Microflotation tests were performed in duplicate.

RESULTS AND DISCUSSION

Figure 2 shows the rest potential profiles of galena with changing ionic strength. The equilibrium potential, 0.15 V, of xanthate oxidation at 6.24×10^{-4} M has been determined elsewhere (Tadie *et al,* 2015; Chimonyo *et al,* 2017). Note that the starting potential of each solution is different owing to the different concentrations of the SPW single salt used. Figure 2 indicates that galena surface is susceptible to changes in water chemistry. The measured potentials for both species and at all concentrations were below the equilibrium potential of xanthate oxidation, indicating that

only the metal xanthate would likely be formed. Further, the potentials with $S_2O_3^{2-}$ were all negative.

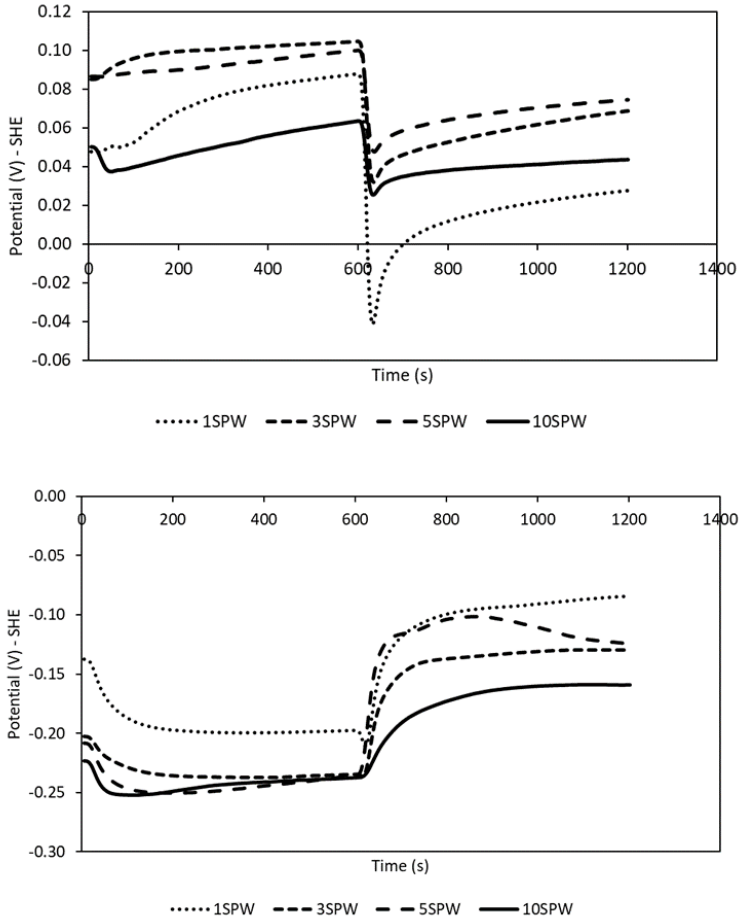

FIG 2 – PbS rest potential profile in Na_2SO_4 (left) and $Na_2S_2O_3$ (right) at varying ionic strengths.

The rest potential measurements provide further insight by predicting the extent of collector-mineral interaction. This can be observed by looking at the difference between the average rest potentials before and after collector addition. Consequently, the lower the difference the lower the extent of collector-mineral interaction. Figure 3 compares the first concentrate recovery to the extent of collector-mineral interaction predicted by electrochemistry. It should be noted that both Na_2SO_4 and $Na_2S_2O_3$ showed the formation of metal xanthate under all conditions. For Na_2SO_4 the change in potential showed an inverse trend to the recovery. While initial recoveries were very low with $Na_2S_2O_3$, this is complemented with negative changes in potential, indicating that the interaction between the mineral and the collector was not straightforward under these conditions and there may be a species generated at the mineral surface other than the metal xanthate.

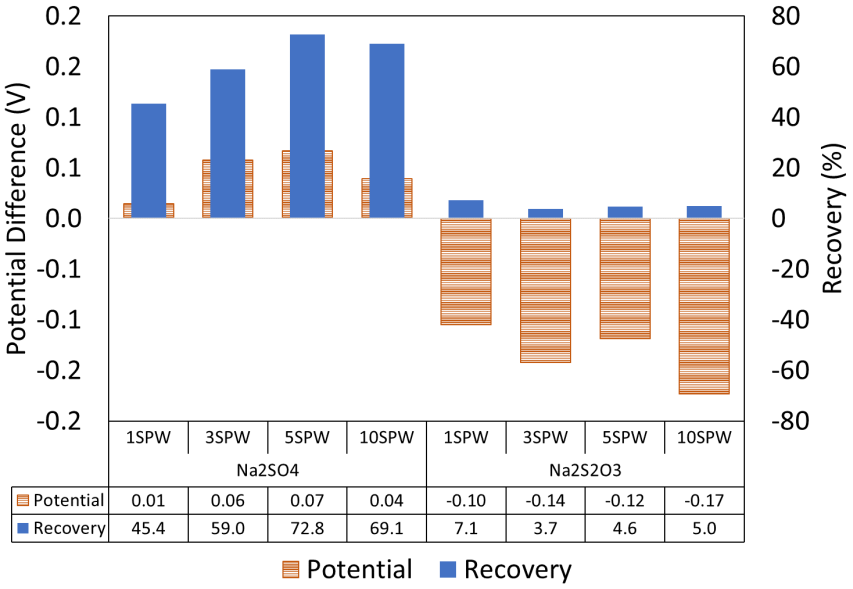

FIG 3 – 1st concentrate recovery versus average potential difference before and after collector addition.

CONCLUSIONS

This study investigated the effect of the presence of SO_4^{2-} and $S_2O_3^{2-}$ on the performance of galena flotation from an electrochemical perspective. Electrochemical techniques are able to show whether the mineral surface is impacted by changes in the water chemistry and can indicated possible flotation responses. In this case, the presence of ions such as SO_4^{2-} and $S_2O_3^{2-}$ has a significant impact on flotation performance with $S_2O_3^{2-}$ having a depressing effect on galena flotation, an indication that operations should be aware of ions such as this and where possible monitor their presence.

ABSTRACT

The Eriez HydroFloat® is a flotation device capable of recovering significantly coarser and less-liberated particles than is possible using a conventional mechanical flotation cell. Originally developed for industrial and bulk mineral beneficiation, the HydroFloat® is attracting increasing interest as a means of increasing the required grind size for metalliferous ore flotation. Doing so would reduce the costs of processing complex ores, either by decreasing the energy required to grind the flotation feed or by increasing the throughput achievable with a given comminution circuit. Processing coarser particles would also result in coarser waste streams, potentially improving the mechanical and hydraulic performance of the waste dams that they are sent to. Recent work at pilot – and industrial-scale has proven the potential of the HydroFloat® technology to achieve these gains in metalliferous applications. However, in order to realise the full potential of the HydroFloat® technology, it is necessary to understand not just its performance but also the drivers for that performance. Doing so will allow the design and operation of HydroFloat® devices to be optimised for different ores and applications. For this work, a HydroFloat® pilot rig was deployed to a copper-gold plant in Australia and was used to investigate the effect of stream and operating conditions for treating the tailings stream of one of the plant's rougher flotation cells. Under each set of operating conditions, samples were taken of the HydroFloat® feed, tailings and concentrate streams, and processed to yield the grade and recovery achieved by the device. At the same time, the bubble size and bed behaviour inside the device were measured. This paper presents preliminary relationships observed between the operating conditions and the performance of the HydroFloat® cell, and thus suggests a range of possible drivers for the measured coarse particle flotation performance.

INTRODUCTION

Flotation is a unit operation that separates valuable minerals from gangue by using particle surface properties. Flotation is a size dependant process. Gaudin *et al* (1931) presented the particle size effect on the flotation process that showed higher recoveries are typically achieved between 50 µm and 120 µm. With advances in flotation since this time, high recoveries are now achieved down to 5 µm particles. Coarse particle flotation recoveries, however, are still typically low in industrial plants for +120 µm particles. There would be many advantages to increasing coarse particle recovery, enabling increases in overall recoveries at a particular grind size or enable the grind size to be coarsened to enable increases in throughput or decreases in energy use in the preceding comminution process.

Eriez identified the opportunity of using a fluidised bed for flotation, potentially increasing coarse particle recovery. The HydroFloat® cell concept was patented in 2002 (Mankosa and Luttrell Gerald, 2002). The Eriez HydroFloat® is a flotation device capable of recovering significantly coarser and less-liberated particles than is possible using a conventional mechanical flotation cell. Originally developed for industrial and bulk mineral beneficiation, the HydroFloat® is attracting increasing interest as a means of increasing the required grind size for metalliferous ore flotation. By doing so,

it would reduce the unit processing cost of complex ores, either by reducing the required energy input to a grinding circuit or by increasing the overall throughput achievable with an existing comminution circuit. In addition to this, coarse processing of the ore would also result in coarser waste streams, potentially improving mechanical and hydraulic performance of the recycled water recovery from the tailings thickeners and tailing storage facilities (TSF).

The HydroFloat® cell can be divided into three regions, as depicted in Figure 1. First is a freeboard region which is located at the top of the cell where the feed pipe is located. The feed is fed through this pipe into the centre of the vessel. Particles in this region are exposed to hindered settling conditions due to the upward flowing fluidisation water. Particles can be attached by air bubbles in this region and directly report to concentrate. Flotation therefore starts in this region. The second region is called the fluidised bed region, where the density is much higher than the freeboard region, resulting in particles becoming more buoyant once they attach to a bubble. In this region, interaction between phases is maximised and it is envisaged that this facilitates attachment of particles to bubbles. Finally, there is a dewatering cone region where no flotation occurs. This section has a conical shape designed for dewatering of the tailing stream. Fluidisation water and air is added through a manifold located above the cone region. Because of the restrictive nature of the dewatering cone, the fluidisation water moves upwards, which in conjunction with the buoyancy of the bubbles, facilitates the upward movement of air particle aggregates which overflow into the concentrate launder.

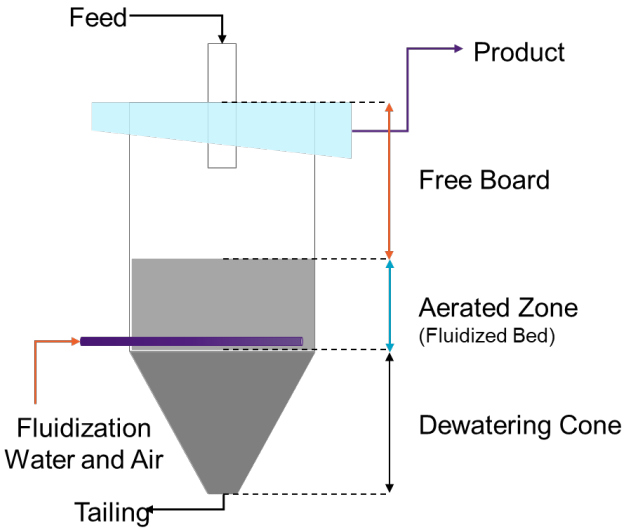

FIG 1 – Simplified schematic drawing of HydroFloat®.

The HydroFloat® has many features which make it more suitable for coarse particle flotation than a conventional mechanical cell. These include a low degree of turbulence because it does not require an impeller to keep particles in suspension. This will likely reduce the probability of bubble particle detachment. The fluidised bed promotes a high degree of interaction between the bubbles and particle, likely increasing the probability of particle bubble attachment. The upward flowing fluidisation water promotes the lifting of coarse heavier particles upwards into the concentrate launder. It also does not have a froth region, where coarse particle detachment is often observed to occur (Rahman *et al*, 2012).

The feed to the HydroFloat®, however, does need to be deslimed with the finer material removed before being fed to the device, This is because fines disrupt the formation of a stable fluidisation bed and also result in lower grades as they are unselectively entrained into the concentrate. Most industrial applications of the HydroFloat® to date have used a CrossFlow teeter bed for desliming. The CrossFlow is similar in design and operation to the HydroFloat® but without air addition.

Recent work published in the literature has proven the potential of the HydroFloat® cell to achieve the above-mentioned gains in metalliferous applications (Kohmuench *et al*, 2018; Seaman and Vollert, 2017; Vollert *et al*, 2019). However, in order to realise the full potential of the HydroFloat® technology, it is necessary to understand not just its performance but also the key drivers for that

performance. By doing so, it will allow the design and operation of the HydroFloat® cells to be optimised for different circuit options and orebodies. For this work, a pilot HydroFloat® plant has been designed, manufactured and deployed to a copper-gold plant in NSW, Australia. A site campaign has been performed using the JKMRC's pilot HydroFloat® rig to investigate the effect of operating conditions and determine the optimal operating conditions for treating the tailings stream of one of the plant's rougher flotation banks. Under each set of operating conditions, samples were taken of the HydroFloat® feed, concentrate and tailings streams and processed to yield the grade and recovery achieved by the device.

This paper presents the details of the testing program performed using the HydroFloat® rig and preliminary relationships and trends observed between performance and cell operating conditions. A range of possible drivers to explain the measured trends in flotation performance are proposed.

EQUIPMENT AND MATERIAL

JKMRC's pilot HydroFloat® rig

A modular, compact, pilot scale HydroFloat® rig has been designed and manufactured at the JKMRC. This rig is operated using a central automation and control system. The rig consists of a feed buffer tank, two process tanks, a CrossFlow (XF-101), a HydroFloat® cell (HF-150–152 mm diameter), slurry and dosage pumps, flow metres, sensors and actuated valves, configured as shown in the simplified process flow diagram given in Figure 2.

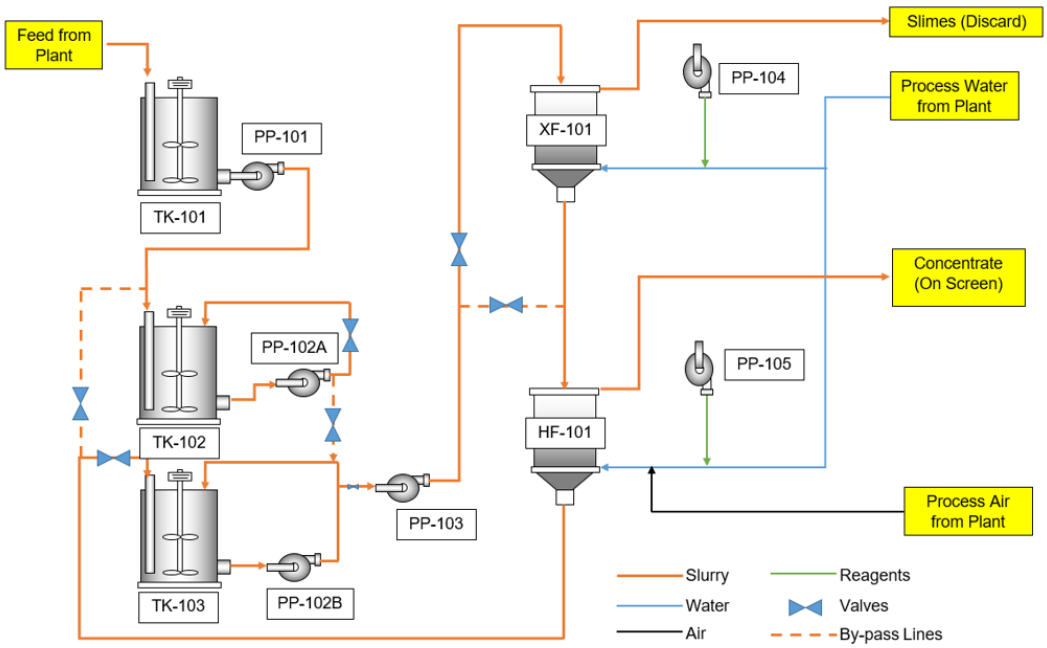

FIG 2 – Simplified process flow diagram of the JKMRC's pilot HydroFloat® rig.

TK-101 is the feed buffer tank, which is used to minimise the effect of process fluctuations on the experiments by collecting and storing the volume of sample required for the planned day of test work at the start of the day. The required sample required for each test is pumped from TK-101 to one of the process tanks (TK-102103). Pumps (PP-102A/B) are used to circulate the slurry to prevent segregation in the tanks. From the selected process tank, feed material for each test is pumped to XF-101 or directly to HF-101 by a Variable Speed Drive (VSD) controlled pump (PP-103). The CrossFlow is used for feed preparation desliming and collector conditioning prior to the slurry being pumped to the HydroFloat®. Processed tailings can be collected in the other process tank or be discarded. Note that with the rig design shown the Tailings can be reprocessed repeatedly. The aim of reprocessing the tails is to be able to test the operation of multiple units in series. In addition, when the feed is already deslimed, the CrossFlow can be bypassed with the feed directly routed to the HydroFloat® unit. Additionally, VSD controlled PP-103 can be used to set the throughput at different flow rates to investigate the throughput/residence time effect on the performance. In the study

outlined in this paper, the rig was operated in a configuration where the feed was sent first to XF-101, with the underflow sent to HF-101. The tailings were discarded.

In the test program performed for this study, collector (and promoter) were introduced through the XF-101 teeter water line (with water). The frother was added through the HF-101 teeter water and air manifold.

During the test program, fluidisation and dilution water flow, airflow and reagent flow rates were monitored continuously. In addition to these online measurements, pressure transmitters were used to determine the pressure within the fluidised bed at two heights. This information can be used to indirectly determine HF-101's bed height and bed porosity. For the CrossFlow, XF-101, a pressure transmitter was used to indirectly determine bed height only.

The JKMRC's Pilot HydroFloat® Rig has its own automation and control system which enables the operator to monitor and control the whole pilot rig by a computer (Figure 3). It also enables collection of measurements from each sensor as a report at the end of each test.

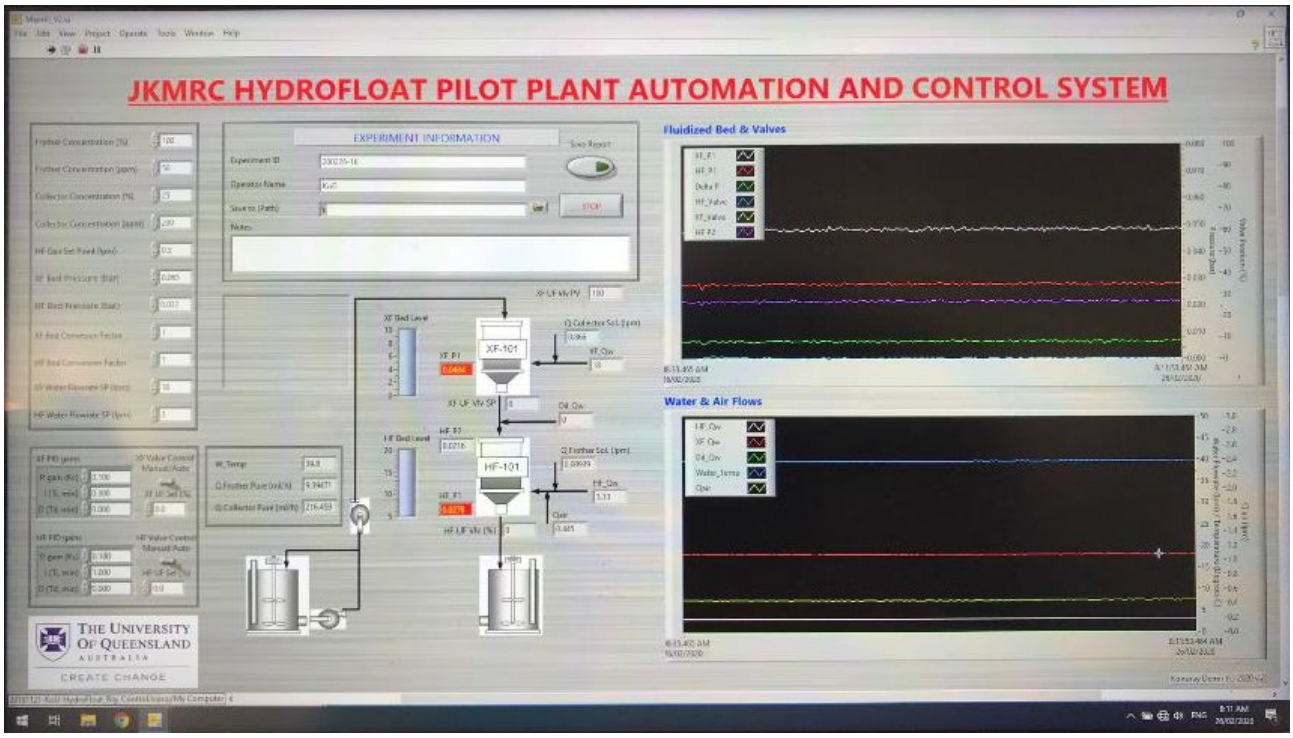

FIG 3 – JKMRC's Pilot HydroFloat® rig automation and control system.

Material tested

The sample used for the pilot testing in this study was sourced from one of the rougher tail streams of a copper-gold plant in NSW, Australia by using an auto-sampler pump. As outlined in the introduction, fines are not desirable in the feed material. Therefore, the CrossFlow incorporated in the rig was used to deslime the feed prior to HydroFloat® testing. Typical CrossFlow and HydroFloat® feed particle size distributions are given in Figure 4.

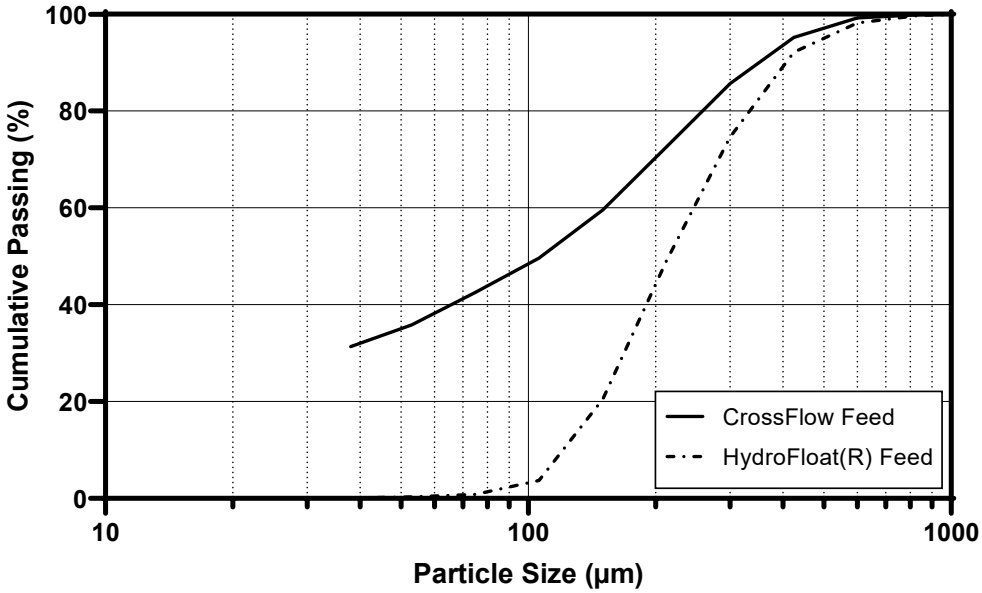

FIG 4 – CrossFlow and HydroFloat® feed particle size distributions.

The typical head assays measured in the streams feeding the CrossFlow and HydroFloat® are given in Table 1. It should be noted that the rougher tails test material was found to exhibit a consistent grade throughout the test campaign. Also, it should be noted, that the only feed material to the HydroFloat® was deslimed rougher tails and no other solid material was used to dilute the feed.

TABLE 1

Typical chemical assay measured in the feed streams.

	Al_2O_3	CaO	Cu	Fe_2O_3	K_2O	MgO	S	SiO_2
CrossFlow Feed	16.25	4.11	0.07	6.20	3.57	3.81	0.27	58.40
HydroFloat® Feed	16.30	3.33	0.13	5.10	3.41	3.08	0.19	60.50

METHODOLOGY

A series of statistically designed experimental programs were developed to investigate the effect of operational parameters and stream properties on HydroFloat® performance using the JKMRC's HydroFloat® pilot rig.

The operational variables varied during these tests included:

- fluidisation water flow rate (Q_w)
- air flow rate (Q_a)
- freeboard height (H_b).

In addition to these parameters, different feed particle size distributions have also been tested.

Each parameter was tested at three different levels within the factorial designs. Each test condition was also performed at a minimum of three throughput values. Changing the throughput was performed to enable an assessment of the effect of residence time and to potentially enable calculation of particle flotation rate at each test condition. The JKMRC's pilot HydroFloat® rig is a continuous, rather than a batch, system. It is not suitable for sampling at different time intervals to obtain a conventional mineral recovery by time curve. Thus, residence time was varied instead to enable this relationship to be determined.

Residence time is best varied in a fluidised bed system by changing the mass flow rate through the HydroFloat®. All other operational parameters and volumetric flow rates were kept constant.

For each test, HydroFloat® feed, concentrate and tailing streams were sampled and the time of collection recorded. Samples were then weighed wet and dry. This information was used to calculate the mass flow and solid concentrations for each stream. All dry samples were then divided into representative subsamples for analysis. One was used to determine the head assay. One was used for size analysis and the other kept in reserve. Sizing involved firstly wet sieving at 38 µm, then dry sieving from 850 µm down to 38 µm using a root 2 series of screens. Size fractions were also submitted for assay analysis.

Stream data was then mass balanced to make the data consistent and to enable calculation of balanced elemental grades and recoveries.

The following additional measurements were also performed during each test:

- fluidisation water flow rate
- air flow rate
- bed height
- differential pressure through the fluidised bed
- bubble size (*in situ*)
- pH, temperature
- reagent addition rates.

Replicate tests were performed throughout the test campaign, as part of the experimental design. Repeat testing was also performed prior to commencement of the work to ensure repeatability of the test procedure. These preliminary repeats comprised of four different tests. Two were aimed at investigating whether the reagent, which was typically collected fresh once a week on a Monday or Tuesday, would degrade and cause a change in performance. To do this investigation, one test was performed on Tuesday using freshly collected reagent and the other one was performed on the Friday just before discarding the reagent. The other two tests were performed on the same day but at different times (am/pm) to investigate whether surface oxidation that might occur as the sample was mixed within the feed buffer tank during the course of a day would result in a change in performance.

The recovery values measured in these four repeat tests are shown in Figure 5. For all of these tests throughput was maintained constant at about 40 to 45 kg/h (2.26 to 2.55 t/h/m^2). The operating conditions were Q_w = 6 lpm; Q_a = 1 lpm, H_b = 20 cm. The error bars shown on this graph represent the standard deviation (1σ) of the results of twelve tests performed within the main test program which were performed using the same operating conditions.

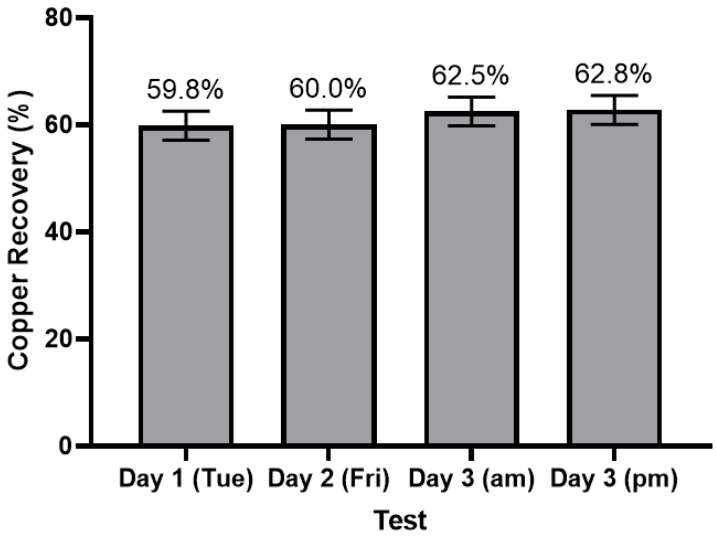

FIG 5 – Preliminary repeatability test results.

It is concluded from the preliminary testing that reagent degradation or surface oxidation during the day, did not result in an appreciable change in copper recovery. The results were within the error of the results produced during the test program.

RESULTS AND DISCUSSION

Effect of residence time

In flotation, residence time plays a critical role in unit operation performance. However, the extent to which this occurs in the fluidised bed flotation system is unknown. To change residence time in the continuously operating HydroFloat®, throughput was varied and the residence time was estimated at each condition by dividing the solids holdup estimated in the cell by the solids volumetric flow rate. Solids holdup at various conditions was estimated by dumping the cell contents at different operating conditions and developing a regression model between solids holdup and cell operation. The relative error for this solids holdup model is 5.9 per cent.

Figure 6 shows the copper recovery measured as a function of the estimated cell residence time at a range of different operating conditions. Increasing throughput (which would decrease particle residence time in the cell) resulted in a decrease in copper recovery. For higher retention times, recovery increases and asymptotes to a constant value as is typically observed in conventional flotation.

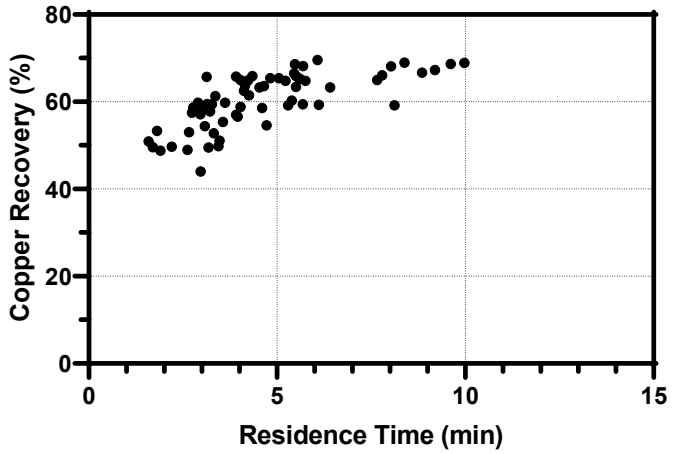

FIG 6 – Effect of residence time on HydroFloat® cell copper recovery.

An additional observation was that the extent to which residence time affects copper recovery is a function of the cell operating variables. When operating the cell under aggressive conditions which result in higher recoveries, there is very little difference between short and long residence time operation. In contrast, gentler operation where low recoveries and high-grades are typically achieved, larger variation in results with residence time are observed. This is demonstrated in Figure 7 (below) which shows the effect of residence time on copper recovery for three different fluidisation water flow rates. Higher water flow rates can be considered as more aggressive operation.

Effect of fluidisation water flow rate

An increase in fluidisation water was found to result in an increase in copper recovery (Figure 7). This increase in recovery was expected as it results from the increased flow of water upwards which increases the upward forces on the bubble-particle aggregates.

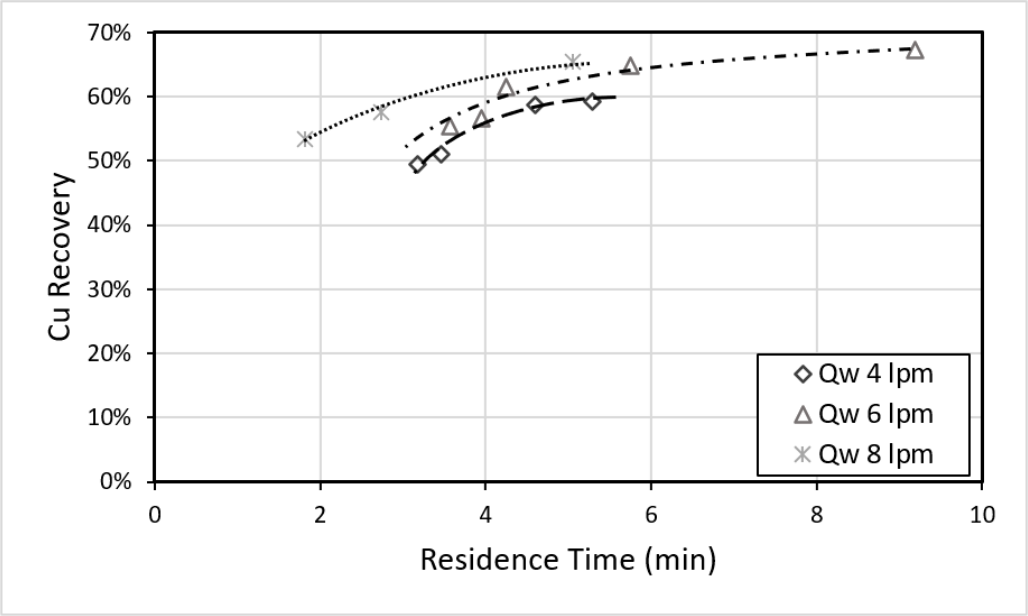

FIG 7 – Effect of residence time on HydroFloat® cell copper recovery at different fluidisation water flow rates.

Effect of air flow rate

Air is mixed into the fluidisation water and added via the fluidisation manifold. The air flow rate is an important operational parameter and it was also investigated during this test program. Tests were conducted during one day of testing at 0, 0.5, 1.0 and 1.5 L/min of air addition. Fluidisation bed height (H_b 20 cm) and fluidisation water flow rate (Q_w 6 lpm) were kept constant. Figure 8 shows the measured relationship between the air flow rate and the copper recovery. In this figure, vertical error bars represent the standard deviation of each point (calculated via repeat tests of the same condition); horizontal error bars represent the standard deviation of the air flowmeter readings for each flow rate.

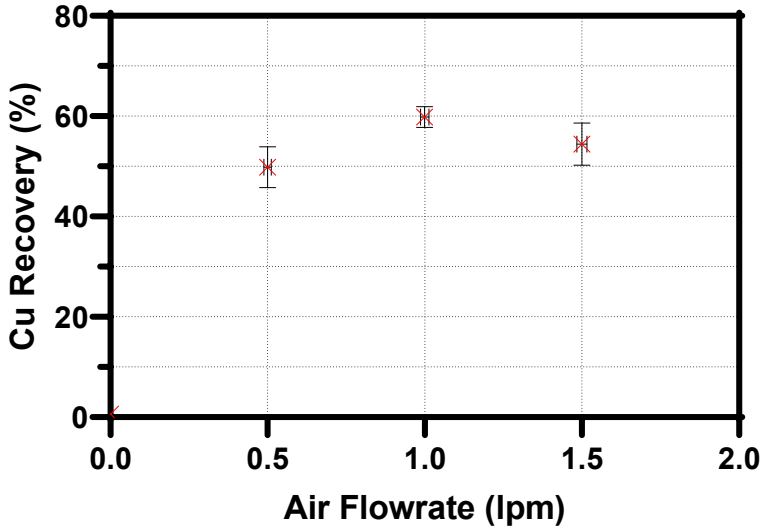

FIG 8 – Effect of air flow rate on HydroFloat® cell copper recovery.

The test performed at zero air rate was conducted to understand the hydraulic entrainment when no air is added to the cell. Air flow was cut, and only entrained material was collected as concentrate. The copper recovery is really low (0.6 per cent). It can therefore be concluded that entrainment recovery is minimal under the conditions tested.

At increasing values of air flow, copper recovery was found to increase and then decrease. It is found that there is an optimum air flow rate for the HydroFloat® with this point being in the order of 1 lpm (1/6 Q_a/Q_w ratio) under the conditions tested.

This shape of relationship is an indication that competing mechanisms exist in the system. Presumably, recovery increases in the low air region because an increase in air flow results in more bubbles and greater probabilities of recovery. Increasing air rate, however, must also be associated with another mechanism that decreases recovery and this mechanism becomes dominant in the high air flow rate region. High air flow rates may destabilise the fluidised bed or result in changes in bubble size that decrease recoveries. An analysis of bubble size and the bed properties is hoped to provide better insight into the actual mechanisms involved.

Previous researchers that have investigated the effect of air rate in conventional cells have also reported a peak in performance at intermediate air rates (Barbian *et al*, 2006; Hadler and Cilliers, 2009; Hadler *et al*, 2010). They showed that initial increases in airflow resulted in an increase in air recovery to concentrate, followed by a significant drop in air recovery at higher airflow rates. Hadler and Cilliers (2009) also showed that cell recovery was optimised when the airflow rate was at the point where peak air recovery was observed. They hypothesized that this trend was a consequence of changes in froth stability and mobility as air rate varied. However, the HydroFloat® cell does not have a thick froth layer but nevertheless also exhibits a peak with air. This suggests that the mechanism by which high air adversely affects recovery, at least in the case of the HydroFloat®, is not in the froth phase per se but is related to changes in the pulp or detachment at the pulp air interface. Could this mean that low recoveries in a conventional cell at high air rate are also a result of changes in the pulp phase or detachment at the pulp froth interface? Further studies are needed to clarify the reason for the observed phenomenon.

Effect of freeboard height

The third operating parameter tested in this work was freeboard height, which is the distance between the overflow lip and the top of the fluidised bed. The effect of freeboard height on recovery was investigated at two different fluidisation water flow rate conditions. The results are shown in Figure 9 which includes error bars that represent the standard deviation of each point (calculated using repeat tests of the same condition). A higher freeboard height equates to a lower fluidised bed height which is inherently harder to stabilise, and operation was observed to fluctuate more than at other conditions. This contributes to the higher standard deviation value for this point. The high SD value is also a consequence of the relatively small number of repeat tests performed at these conditions (N = 3).

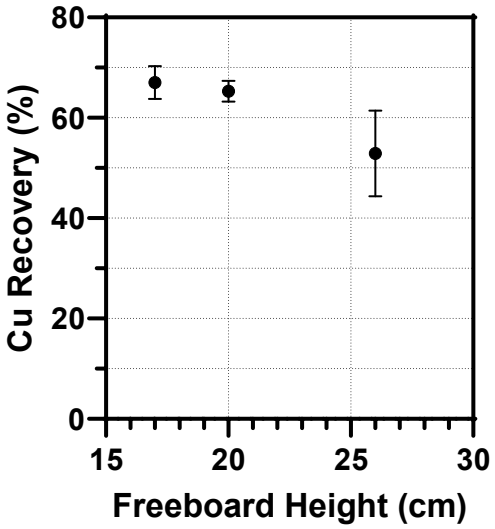

FIG 9 – Effect of Freeboard height on HydroFloat® cell copper recovery.

Decreasing the freeboard height results in higher recoveries. Presumably, this is because as the distance to reach the overflow lip for bubble-particle aggregates decreases, there is less chance for particle detachment. Smaller distances correlate with a greater probability of reaching the concentrate launder. As height increases, however, the magnitude of this effect diminishes. In addition to this, decreasing freeboard height, increases the fluidised bed height, and thus increases the residence time. It has been shown above that the residence time affects the recovery and presumably, it has an effect for this aspect as well.

Effect of the feed particle size distribution

In addition to the operating parameters, the feed particle size was varied to the HydroFloat® cell by manipulating operation of the upstream CrossFlow unit. The resulting three HydroFloat® feed particle size distributions are shown in Figure 10. Although the P80 values of the three feed size conditions are reasonably close, there are significant differences in the proportion of fines. The amount of material below 150 µm are 23.1 per cent for Fine, 17.2 per cent for Nominal, and 2.25 per cent for the Coarse case. Fine particles are considered to have a significant effect on HydroFloat® operation as they will alter the characteristics of the fluidised bed. Fines may also exhibit better liberation and therefore be easier to recover.

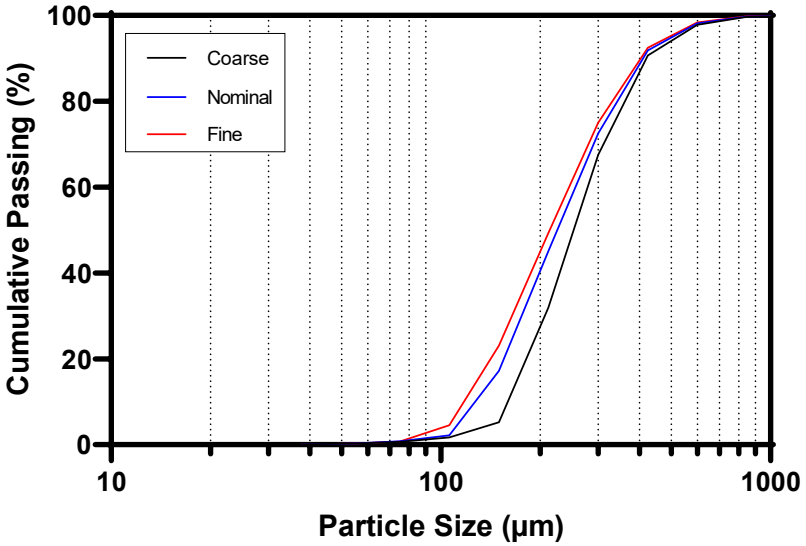

FIG 10 – Feed particle size distributions for three different feed conditions.

Feed particle size distribution was found to have a significant effect on HydroFloat® recovery (Figure 11). Copper recovery decreases as the feed particle size decreases. The magnitude of this effect varies depending on the operating parameters (ie how aggressively the cell is operated). The test conditions for the results shown on Figure 11 are listed in Table 2.

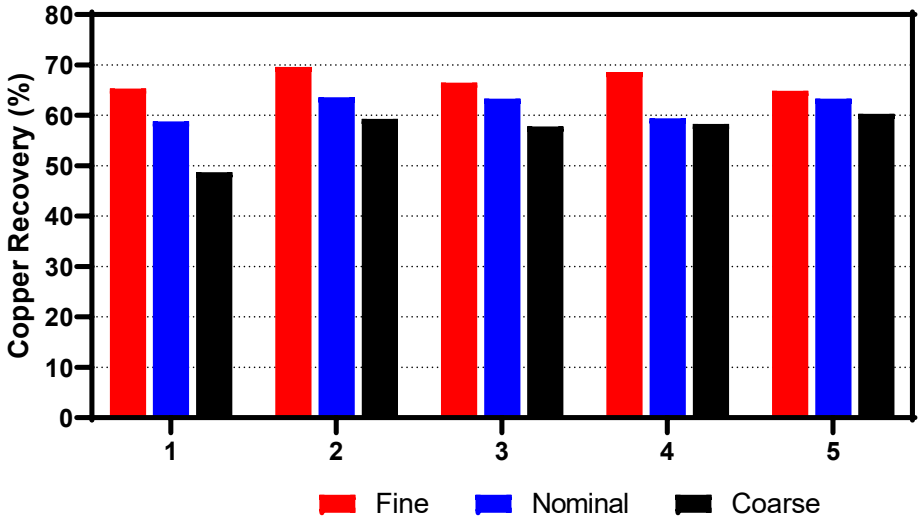

FIG 11 – Recovery values for different feed material under different test conditions.

TABLE 2

Operating conditions used in the different tests performed to investigate the effects of particle size distribution.

Test	Run Order	Q_w (lpm)	Q_a (lpm)	H_b (cm)
1	5	4.50	0.75	20.00
2	2	4.75	1.25	14.00
3	1	6.00	1.00	17.00
4	4	7.50	0.75	14.00
5	3	7.50	1.25	20.00

Gentle operation results in a much greater recovery difference between the feed sizes. In Figure 11, test condition 5 is an aggressive operation and it results in a minimal recovery change, with a change in feed size. On the other hand, test condition 1, which is a relatively gentle operating condition, results in large differences in the recoveries observed for the different feed PSDs values.

CONCLUSION

Within this study, the effect of operational parameters and particle size on HydroFloat® cell's performance was investigated. For this purpose, a comprehensive on-site test campaign was successfully carried out using a newly constructed JKMRC pilot HydroFloat® rig which was shown to be able to produce repeatable results. The results showed that recovery is affected by throughput, presumably because of its effect on particle residence time. Fluidisation water flow rate was found to have a positive correlation with copper recovery. There is an optimum recovery observed with the air flow rate setting within the range of operating conditions investigated. It is also observed that the freeboard height is inversely correlated with recovery. Particle size distribution has an effect on the cell performance, with a coarser particle size distribution exhibiting lower cell recoveries. However, this effect is minimised when operating under aggressive operating conditions such as higher fluidisation water and air flow rates. Aggressive operating conditions also resulted in less variation in HydroFloat® performance with retention time.

The experimental work in this study was performed using a series of statistical experimental designs, and the next stage of analysis will involve the use of statistical techniques to determine the extent to which the operating variables effect cell performance in comparison to each other. The analysis, which will be performed with respect to both overall recovery and size by size recovery, will also determine if there are any interactions occurring in the system.

Bubble size is a parameter which is expected to affect flotation performance because of its effects on the probabilities of particle attachment, detachment and the bubble/particle buoyancy. Future work will use the bubble sizes measured *in situ* during the test program to determine whether performance can be correlated to the bubble size produced in the cell. How operating conditions such as teeter bed water flow rate, air rate and bed height affect bubble size will also be investigated.

ABSTARCT

The recycling of process water comes with increased electrolyte concentrations that affect water quality, which may in turn affect the flotation performance of valuable minerals (Hirajima *et al*, 2016). Electrolytes such as Ca^{2+}, SO_4^{2-}, Mg^{2+} and $S_2O_3^{2-}$ have been surmised to have an impact on the action of flotation reagents such as collectors (Ikumapayi *et al*, 2012). Xanthate collectors are known to play a significant role in imparting hydrophobicity on mineral surfaces to enhance their flotation. The interaction between minerals and xanthates is well known to be electrochemical in nature. Such redox processes may be elucidated by electrochemical techniques. Since the mechanisms involving the interactions between electrolytes in process water with sulfide minerals and the subsequent adsorption kinetics of collectors are not well understood, this study therefore aims to provide fundamental knowledge to unpack the mechanisms involved when electrolytes interact with Platinum Group Minerals (PGMs) and how these interactions may affect xanthate adsorption.

The interaction of sodium iso-butyl xanthate (SIBX) in the presence of electrolytes at increasing ionic strength was investigated by rest potential measurements, to explain the impact of electrolytes on the adsorption of SIBX on PGMs in the flotation process. Rest potential measurements for $PdTe_2$ and PdS were conducted in an air saturated 0.05 M di-sodium tetraborate decahydrate solution, in the absence and presence of SIBX and electrolytes. It was found that the existence of sulfide and telluride on palladium affects the mechanisms in which electrolytes interact with Pd mineral surfaces. An increase in the ionic strength of $Na_2S_2O_3$, $CaCl_2$ and $MgCl_2$, increased the interaction between the salts and PdS, thus decreasing the extent to which SIBX interacted with PdS. An increase in ionic strength for $Na_2S_2O_3$ increased the interaction between $Na_2S_2O_3$ and $PdTe_2$ and therefore decreased the extent to which SIBX interacted with $PdTe_2$. Other salts investigated in this study increased the rate of oxidation of $PdTe_2$ with an increase in ionic strength thereby enhancing the interaction of SIBX and $PdTe_2$. This study has shown that mineral type, electrolyte type and concentration all have an impact on the mechanisms that result in the adsorption of SIBX on PGMs.

INTRODUCTION

The Bushveld Complex in South Africa is a well-known source of a substantial proportion of platinum and palladium in the world. PGMs associated with telluride minerals, moncheite ($PtTe_2$) and merenskyite ($PdTe_2$) contribute about 20–45 per cent of the PGMs present in the Platreef ore (Shackleton, Malysiak and O'Connor, 2007). Alternatively, the UG-2 and Merensky Reef are dominated by PGM sulfides (cooperate, braggite and vysotskite), which are considered as the most common minerals in a Pt-Pd-S system (Verryn and Merkle, 1994). This study will investigate the palladium minerals PdS and PdTe2.

PdS and $PdTe_2$ have been determined to possess tetragonal and hexagonal crystal structures, respectively (Berlincourt, Hummel and Skinner, 1981). Te has been reported to have a stronger σ-donation characteristic that renders it a greater trans influence than that of S, hence the bond lengths for Pd-S and Pd-Te have been found to be 2.268 Å and 2.492 Å, respectively (Singh *et al*, 1999). The strength of bonds within a crystal structure determines the reactivity of a mineral. The lower polarisability of Te than that of S is attributed by its larger ionic radius, consequently resulting in stronger intra-molecular bonds for PdS than PdTe (Westland, 1981).

The reactivity of PGM sulfides is almost similar to reactions of base metal sulfides, therefore it is valuable to understand the reactions of base metal sulfides. The oxidation of base metal sulfides (Equation 1), with regards to the flotation process has been extensively studied to determine the effects of oxidation products on flotation recoveries. However, there is very limited work in literature on the oxidation of PGMs (Elvy and Williams, 1996).

$$MS + xH_2O \rightarrow M(H_2O)_x^{2+} + S^- + e^- \quad (1)$$

The initial oxidation of PdS in alkaline conditions at pH 9, has been proposed by Westland (1981) as shown in Equation 2.

$$PdS + 4H_2O \leftrightarrow Pd + SO_4^{2-} + 8H^+ + 6e^- \quad (2)$$

Very limited work has been reported on the oxidation of PGMs with tellurides. Elvy and Williams (1996) proposed that the most stable species formed after the initial oxidation of PdTe is tellurite (Equation 3).

$$PdTe_2 + xO_2 \rightarrow PdTe_{1-x} + xTeO_2 \quad (3)$$

$PdTe_2$ is a novel transition-metal with an as-cleaved surface which possesses a surface termination comprised of an atomic layer of Te. Their surface stability is determined by the lone pair of electrons on the Te atoms. The Te termination has been determined to evolve into TeO_2 upon exposure to air, with the thickness of TeO_2 estimated to be 2.2±0.4 Å after 10 minutes exposure and was observed to remain in the subnanometric range of 8.8±0.5 Å after 1 year of exposure (D'Olimpio *et al*, 2019). The incongruent oxidation of $PdTe_2$ to palladium tellurite was initially established by Elvy and Williams (1996), who observed formation of the oxide layer covering the palladium enriched substrate. The order of reactivity of palladium minerals has been considered to be PdTe < PdTeBi < PdBi, where PdTe is the least reactive relative to other palladium minerals.

Research work on the flotation of PGMs in the past decades has mainly focused on the flotation of base metal sulfides due to their good association with PGMs. However, Penberthy, Oosthuyzen and Merkle (2000) disputed this assumption with the findings of their comprehensive study on recoveries of PGMs. It was found that though PGM grains are usually smaller than 10 µm in diameter, milling to 80 per cent <75 µm would successfully liberate about 50 per cent of the PGMs from the matrix. The PGMs associated with liberated base metal sulfides were established to be the fastest-floating species. It was also observed that the response of liberated PGMs to flotation was dependent upon the type of mineral and grain size. Therefore, the findings of this work make it of great importance to understand the flotation behaviour of PGMs.

Froth flotation is a water-intensive process, in which water represents about 80–85 per cent of the pulp phase. The most ideal media for the process is fresh water, however, due to the scarcity of fresh water, mining operations are required to reduce freshwater consumption by making use of alternative sources such as the use of relatively impure primary water supplies or recycled process water. Alternative sources of fresh water come with increased ionic strength of electrolytes such as magnesium, sulfate, thiosulfate, chlorides, calcium etc, which consequently affect the flotation performance of valuable minerals (Boujounoui *et al*, 2015; Manono, Corin and Wiese, 2016; Li *et al*, 2018; Sinche-Gonzalez and Fornasiero, 2021).

Previous studies have shown that ions found in process water may either have a beneficial or detrimental effect on flotation recoveries of sulfide minerals (Hodgson and Agar, 1989; Kirjavainen, Schreithofer and Heiskanen, 2002; Elizondo-Álvarez *et al*, 2017). At 0.0242 M of Ca^{2+} and Mg^{2+} ions, it has been reported that the presence of divalent ions can increase frothability and alternatively reduce solids recoveries (Manono, Corin and Wiese, 2016). Similarly, it has been reported that an increase in the ionic strength of process water may result in an increase in water recoveries due to increased frothability (Corin *et al*, 2011). Furthermore, low concentrations of Ca^{2+} ions at 186 mg/l and SO_4^{2-} ions at 153 mg/l have been found to have a detrimental effect on the flotation of galena (Ikumapayi *et al*, 2012). Sea water is known to have concentrations of Ca^{2+} and Mg^{2+} ions at approximately 0.01 M and 0.05 M, respectively (Mewes *et al*, 2014). These have been observed to depress the flotation of chalcopyrite due to the adsorption of Mg and Ca hydroxyl complexes on the mineral surfaces, therefore giving rise to less hydrophobic mineral surfaces (Hirajima *et al*, 2016; Li *et al*, 2018). Divalent ions such as Ca^{2+}, SO_4^{2-} and $S_2O_3^{2-}$ were found to be significantly surface-active ions on both pentlandite and pyrrhotite surfaces at normal process water pH (Hodgson and

Agar, 1989). Ca^{2+} ions have been postulated to adsorb on the sulfur sites of a pyrrhotite mineral surface, with the SO_4^{2-} adsorbing onto the Fe sites. The $S_2O_3^{2-}$ ions were presumed to coordinate to the mineral surface via an oxidised Fe site of $Ca(S_2)$ product. Ultimately, adsorbed $S_2O_3^{2-}$ ions were determined to reduce mineral hydrophobicity by reducing its selectivity.

The presence of ions in process water has been found to interfere with the adsorption of surfactants on mineral surfaces (Kirjavainen, Schreithofer and Heiskanen, 2002; Ikumapayi *et al*, 2012; Chang, Chen and Peng, 2018). Ions may enhance the adsorption of surfactants by increasing the active sites on the mineral surface or alternatively depress the adsorption of surfactants by competitive adsorption on a mineral's active sites.

Surfactants such as collectors are used in the flotation process to modify the surface wettability of mineral particles to enhance their hydrophobicity (Wills and Napier-Munn, 2006). The polar regions of collectors adsorb onto selective sites on the mineral surface with their non-polar hydrophobic hydrocarbons protruding into the bulk, thereby rendering the mineral surface hydrophobic. Sulfydryl collectors such as xanthates have been used in the effective flotation of base metal sulfide minerals (Usul and Tolun, 1974; Leppinen, 1990; Wang and Forssberg, 1991; Herrera-Urbina and Sotillo, 1999). The interactions between xanthates and base metal sulfide minerals are believed to occur through a mixed potential mechanism, where the anodic oxidation reaction involves transfer of charge from the xanthate collector onto the mineral surface and a simultaneous cathodic reaction involves the reduction of oxygen (Equation 4). The oxidation of xanthates has been established to occur in three different ways, the first mechanism involves the chemisorption of a xanthate collector on the mineral surface as shown in Equation 5. The second mechanism involves the chemisorption of a xanthate ion onto a mineral surface to form a metal xanthate. The latter equation may occur as a single step (Equation 6) or through separate surface oxidation and ion exchange processes (Equations 7 and 8). Additionally, the third mechanism involves the formation of dixanthogen (Equation 9).

Cathodic reaction, reduction of oxygen:

$$O_2 + 2H_2O + 4e^- \leftrightarrow 4OH^- \tag{4}$$

First mechanism, chemisorption of xanthate:

$$X^- \leftrightarrow X_{ads} + e^- \tag{5}$$

Second mechanism, formation of a metal xanthate – single step:

$$2X^- + MS + 4H_2O \rightarrow MX_2 + SO_4^{2-} + 8H^+ + 8e^- \tag{6}$$

Or through separate surface oxidation:

$$MS + 4H_2O \rightarrow MSO_4 + 8H^+ + 8e^- \tag{7}$$

And ion exchange:

$$MSO_4 + 2X^- \rightarrow MX_2 + SO_4^{2-} \tag{8}$$

Third mechanism, formation of dixanthogen:

$$2X^- \rightarrow X_2 + 2e^- \tag{9}$$

It has been reported in literature that the presence of Ca^{2+} and $S_2O_3^{2-}$ ions may enhance the flotability of copper sulfides in the presence of a potassium ethyl xanthate collector (Kirjavainen, Schreithofer and Heiskanen, 2002). Floatability was observed to increase steadily with an increase in ionic strength. Ca^{2+} ions were proposed to increase xanthate adsorption on copper sulfides whereas on the contrary $S_2O_3^{2-}$ ions were proposed to decrease xanthate adsorption. The effect of $S_2O_3^{2-}$ ions was aligned to the ability of the ions to reduce the effect of hydrophilic species formed on sulfide mineral surfaces than the actual activation effect caused by Ca^{2+}. The effect of Ca^{2+} and SO_4^{2-} ions on the flotation of galena was investigated by Ikumapayi *et al* (2012) and it was observed that the presence of the two divalent ions reduced xanthate adsorption. Furthermore, it was reported that in the presence of calcium ions, there was a decrease or disappearance of surface oxidised products probably due to the formation of soluble calcium complexes with sulfoxy species and surface carbonate. High concentrations of NaCl have been reported to inhibit xanthate adsorption on sphalerite particle surfaces due to competitive adsorption between the NaCl ions and xanthate ions

on the mineral surface. Additionally, Ca^{2+} and Mg^{2+} ions have been presumed to adsorb on mineral surfaces and thus play an important role in the bubble-particle interaction (Wang *et al*, 2015). This observation could be ascribed to the ion valence and ion type that play an important role in depressing the chemical adsorption of collectors on mineral surfaces. Moreover, the presence of ions may also change the structure and morphology of adsorbed xanthate collector layers primarily by screening the electrostatic repulsive forces between the polar groups which oppose aggregation (Chang, Chen and Peng, 2018).

Though the effects of ions on the flotation of base metal sulfides using bench-scale flotation techniques have been well documented, their mechanisms of interaction are not well understood. However, due to the good PGM textural association with base metal sulfides, previous studies have centred their work on the flotation of base metal sulfides. Furthermore, the assumption made on PGMs was challenged by the work of Penberthy, Oosthuyzen and Merkle (2000), who conducted an extensive study on the recoveries of PGMs from UG2 and found that approximately 50 per cent of PGMs were liberated during milling. The subject on the effect of ions found in process water and/or xanthate collectors on PGMs has been neglected. It is therefore essential to understand the interactions of ions in recycled process water with PGMs and their subsequent effects on the adsorption of xanthate collectors.

Therefore, this study makes use of electrochemical techniques to understand the mechanisms of interactions of single ions at increasing ionic strength on the adsorption of SIBX on $PdTe_2$ and PdS mineral surfaces.

METHODOLOGY

Material

PdS and $PdTe_2$ minerals used in this study were synthesized at the Anglo-American Research laboratories as described by Shackleton, Malysiak and O'Connor (2007). The mineral compositions are shown in Table 1.

TABLE 1

Palladium telluride and sulfide composition.

Mineral	Stoichiometric composition selected	Product purity
Merenskyite ($PdTe_2$)	$Pd_{1.00}Te_{2.00}$ (20g Pd, 40g Te)	60g @ 68.7% purity
Vysotskite (PdS)	$Pd_{6.00}S_{6.00}$ (30.74g Pd, 9.26g S)	40g @ 97.4% purity

Due to the small size and scarcity of PGMs, the minerals were synthetically prepared to reflect on the behaviour of naturally occurring minerals (Vermaak, Pistorius and Venter, 2005; Shackleton, Malysiak and O'Connor, 2007).

The xanthate collector, SIBX, was supplied by Senmin (Pty) Ltd as yellow pellets. The chemical salts used in this study sodium thiosulfate ($Na_2S_2O_3$), sodium chloride (NaCl), calcium chloride ($CaCl_2$), magnesium chloride ($MgCl_2$) and magnesium sulfate ($MgSO_4$), were supplied by Merck. The sodium tetraborate decahydrate ($Na_2B_4O_7.10H_2O$) was supplied by Sigma-Aldrich Co. 0.05 M $Na_2B_4O_7.10H_2O$ buffer solution was prepared with ultra-distilled water to maintain a pH of 9.2.

SIBX was prepared prior to each run with ultra-distilled water to a dilution of 1 per cent, which was dosed at a volume that would bring the final concentration of SIBX to 6.24×10^{-4} M in the electrochemical cell.

The salts were prepared in order of increasing ionic strengths to represent different water qualities such as 1 synthetic plant water (1 SPW), 3 SPW, 5SPW and 10SPW which are equivalent to 0.0242 M, 0.0727 M, 0.1212 M and 0.2426 M, respectively (Wiese *et al*, 2005; Corin *et al*, 2011; Manono, Corin and Wiese, 2016).

All solutions used in the experimental work were prepared with analytical grade salts, diluted with ultra-distilled water and prepared prior to experiments.

Electrochemical measurements

Rest potential measurements were performed using a Gamry Instruments Reference 600™ Potentiostat. All reactions were performed in a double-wall glass reactor with a two-electrode system, Ag/AgCl reference electrode and a mounted working electrode. All potentials were measured against the standard Ag/AgCl reference electrode, which was filled with a 3 M KCl electrolyte, with a potential of +0.207 V against the standard hydrogen electrode (SHE). The mineral was embedded in a non-conductive epoxy resin, with a portion of the mineral exposed.

All rest potentials measurements were conducted at 25°C (±1°C). Prior to each test, the surface of each palladium mineral was freshly prepared by wet polishing using 1 µm, 0.3 µm and 0.05 µm alumina powder suspensions. The electrode was subsequently rinsed with ultra-distilled water and dabbed lightly with paper towel after which it was quickly transferred to the electrochemical cell for measurements (Tadie *et al*, 2015).

The measurements were performed in the absence and presence of salts and SIBX. The measurements were executed by dosing each salt solution at a specific ionic strength at 300 seconds (blue bars in Figures 1 and 2) after which SIBX was dosed at 600 seconds (orange bars in Figures 1 and 2). The total time for all the runs was 1200 seconds.

RESULTS AND DISCUSSION

Equilibrium potential of SIBX

Table 2 shows the equilibrium potential for the xanthate/dixanthogen couple for SIBX at 6.24×10^{-4} M which was measured to be 80 mV.

TABLE 2

Equilibrium potentials for xanthate/dixanthogen couple (SIBX).

Conc. of SIBX (M)	E/(mV versus SHE)		E^0/(mV versus SHE)	
	Buswell (1998)	Experimentally Measured	Buswell (1998)	Calculated
1×10^{-3}	49	**68**	-127	**-109**
6.24×10^{-4}	-	**80**	-128	**-110**
1×10^{-4}	108	**126**	-128	**-110**

The Nernst equation is considered as an important equation in electrochemistry that relates the reduction potential of an electrochemical reaction to the standard electrode potential, temperature and activities of chemical species undergoing reduction and oxidation reactions.

For unit activity X_2, the Nernst equation predicts that:

$$E = E^0 - {}^{RT}/_{2F.In[X^-]^2} \quad (10)$$

Where E represents cell potential, E^0 represents standard cell potential, R represents universal gas constant, T represents temperature in Kelvin, F represents Faraday constant and X represents xanthate.

The Nernst equation (Equation 1) predicts a 59 mV increase in equilibrium potential for every order of magnitude decrease in xanthate concentration (Buswell, 1998). A 58 mV change was obtained both in this work and by Buswell (1998). The results obtained in this work agree with the prediction from the Nernst's equation. E^0 values for each concentration of SIBX as shown in Table 1, were calculated using the Nernst's equation. The work of Allison *et al* (1972) determined that all systems in which dixanthogen is formed, have their rest potentials above the equilibrium potential of the

dixanthogen/xanthate couple, whereas systems with rest potentials below the equilibrium potential will most likely form metal xanthate as the principal product.

In this work, rest potential differences (Ndamase, Corin and Tadie, 2020) for salts and SIBX have been defined as the difference in rest potential between the potential obtained immediately upon adding the salt and SIBX and the potential obtained prior to adding SIBX and after adding SIBX, respectively. Figures 1 and 2 show rest potential differences for PdS and $PdTe_2$, respectively in the absence and presence of single salts and SIBX. The changes in potential are indicative of reactions occurring at the mineral surfaces. The difference in rest potentials can be used to interpret the extent of interactions between PGM mineral surfaces with salts and xanthate collectors.

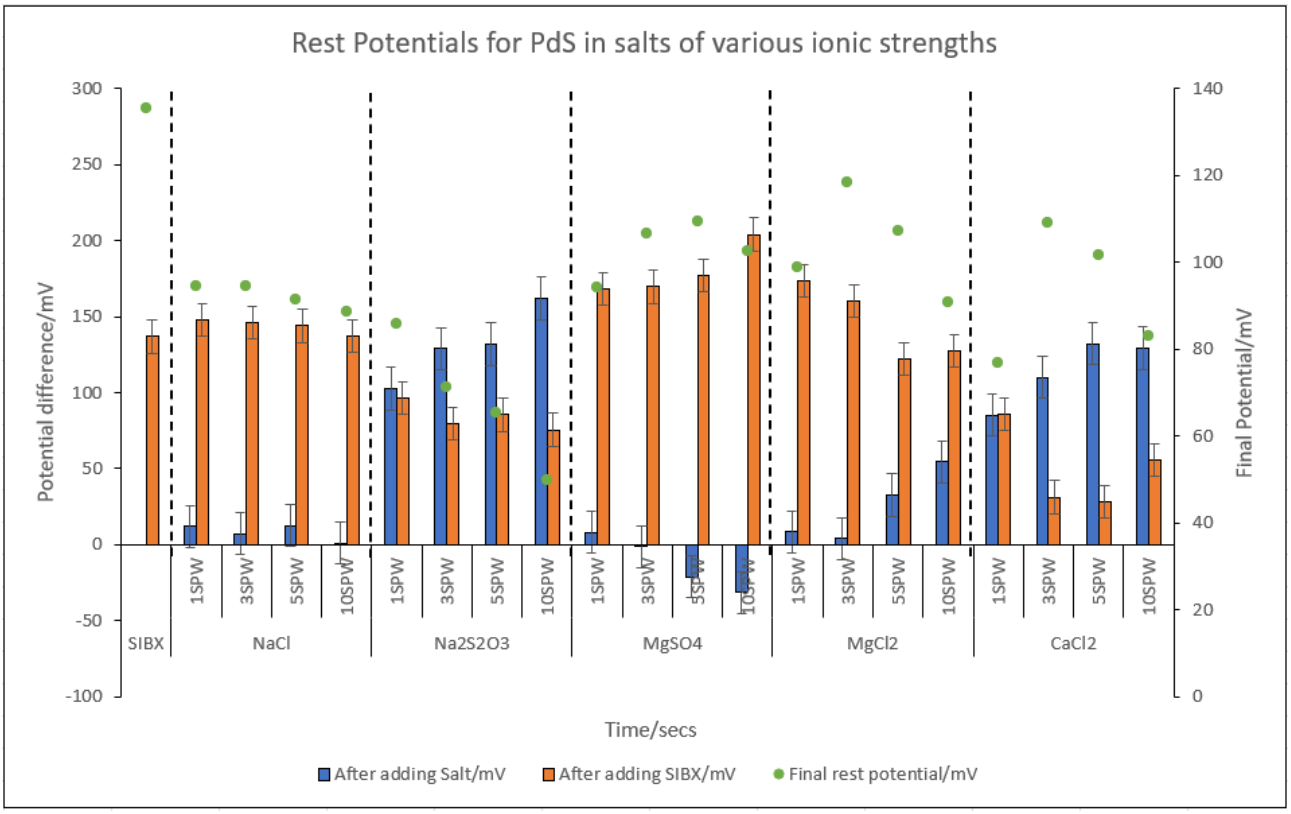

FIG 1 – Final rest potentials and rest potential differences for PdS in the presence and absence of SIBX and single salts at various ionic strengths at pH 9.2 and 25°C.

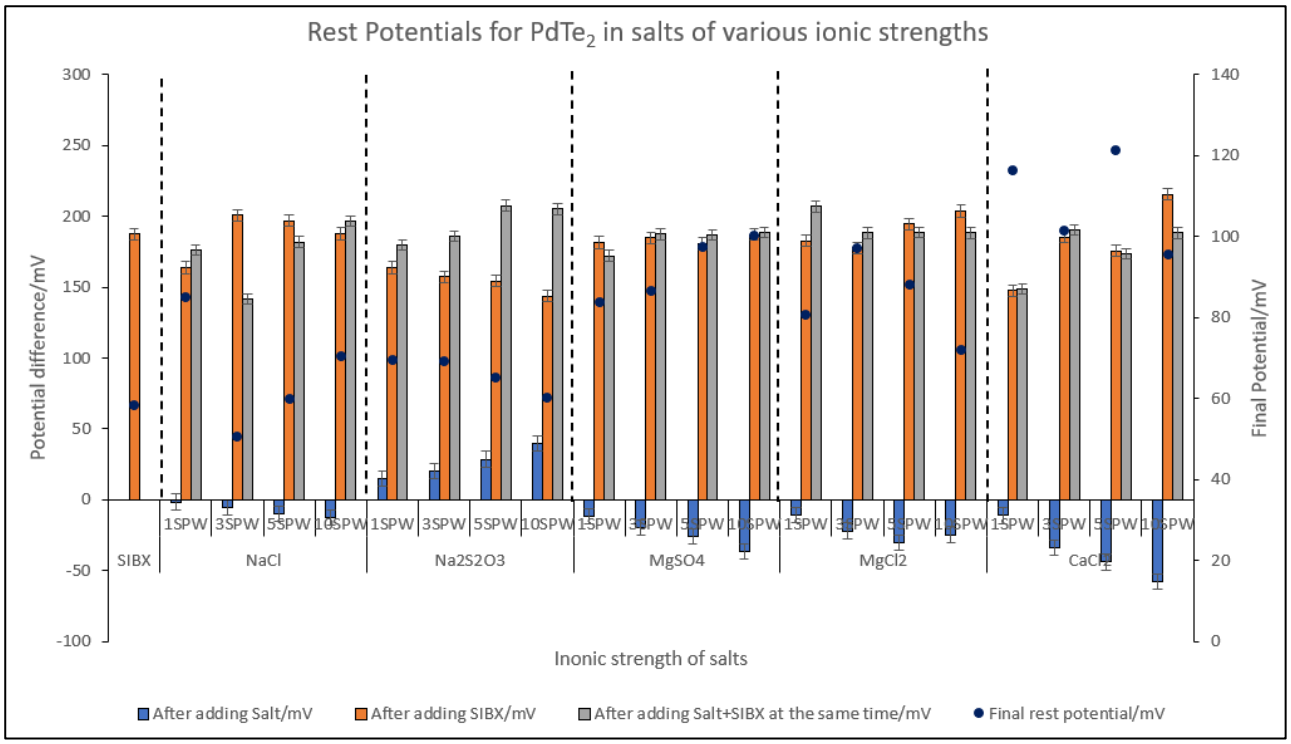

FIG 2 – Final and differences in rest potentials for $PdTe_2$ in the presence and absence of SIBX and single salts at various ionic strengths at a pH of 9.2 and 25°C.

Figures 1 and 2 show differences in rest potentials and final rest potentials for PdS and $PdTe_2$. For conditions where the final rest potentials were higher than the equilibrium potential of the xanthate-dixanthogen couple of SIBX (80 mV), the oxidation of SIBX most likely favoured the formation of dixanthogen (Equation 9). Alternatively, lower final rest potentials than the equilibrium potential of the xanthate-dixanthogen couple of SIBX imply that it is likely that the oxidation of SIBX favours the chemisorption reaction (Equation 5) or the formation of a metal-xanthate species (Equations 6 or 7 and 8). It is shown in Figure 1 that the final rest potential in the absence of salts is higher than the potential for dixanthogen formation. The oxidation of SIBX in this case favours the formation of dixanthogen. On the other hand, it is shown in Figure 2 that in the absence of salts the final rest potential is lower than the potential for dixanthogen, denoting that the formation of dixanthogen is not favoured. Therefore, the oxidation of SIBX favours either the chemisorption reaction or formation of a metal xanthate species. An electrochemical investigation of similar PGMs by Tadie *et al* (2015) shows that the opposite is true in the case of sodium ethyl xanthate. A comparison between this work and observations reported by Tadie *et al* (2015) shows that despite similar minerals, concentration of xanthate collectors and test conditions, collector type plays a significant role in defining the mechanism by which the collector oxidises at a mineral surface.

Effect of $S_2O_3^{2-}$ ions

$Na_2S_2O_3$ was observed to interact more with both PdS and $PdTe_2$ minerals than other salts investigated in this study. An increase in interaction with both PdS and $PdTe_2$ was observed with an increase in ionic strength. This implies an increase in the rate of reduction of both minerals as the ionic strength of $Na_2S_2O_3$ increases. Subsequently, the interaction between SIBX and both minerals decreased, thereby indicating a lower rate of reduction of both mineral surfaces with an increase in ionic strength of $Na_2S_2O_3$. The final rest potential of PdS in the presence of $Na_2S_2O_3$ at 1 SPW is higher than the potential for dixanthogen formation. This implies that dixanthogen may be formed on the mineral surface under these conditions. However, higher ionic strengths of 3 SPW, 5 SPW and 10 SPW $Na_2S_2O_3$ in the presence of PdS resulted in final rest potentials that were lower than the potential for dixanthogen formation. This indicates that the dixanthogen species should not form under these conditions. Similarly, it was observed that final rest potentials for $PdTe_2$ in the presence of $Na_2S_2O_3$ at all ionic strengths investigated were lower than the equilibrium potential for dixanthogen formation. Since the formation of dixanthogen did not contribute to the rest potential

differences under these conditions, two alternative reactions possibly occurred on the mineral surfaces. A chemisorption reaction (Equation 5), which is thermodynamically favoured in the interaction between xanthates and sulfide minerals and therefore occur at lower potentials than the formation of the corresponding dixanthogen (Buckley and Woods, 1997). The lower rest potentials may also indicate the formation of the less hydrophobic metal xanthates species. Metal xanthate species may be formed through a single step reaction (Equation 6) or through a surface oxidation and ion exchange mechanism (Equations 7 and 8). This study proposes that a chemisorption reaction (Equation 5) most likely occurred or the formation of metal xanthate (Equations 6 or 7 and 8) in the case of $PdTe_2$ at all ionic strengths of $Na_2S_2O_3$ investigated. It is possible that a Te-xanthate formed in addition to Pd – xanthate (Tadie *et al*, 2015). The increase in interaction of $Na_2S_2O_3$ which subsequently decreases the interaction of SIBX is proposed to reduce the hydrophobic nature of PdS and $PdTe_2$ in a real flotation system. It is possible that in this study, the thiosulfate ion might have interacted readily with Pd to form a Pd – thiosulfate complex on the mineral surface (Eliseev and Kirbitova, 1984; Petrus *et al*, 2012). An investigation by Petrus *et al* (2012) presumed the formation of a copper thiosulfate complex in the presence of thiosulfate on both chalcopyrite and tennantite mineral surfaces. The copper thiosulfate complex formed was proposed to inhibit the adsorption of diethyl dithiophosphate collector, thereby depressing the flotation of both minerals. The findings of this study also agree with the observation made by Kirjavainen, Schreithofer and Heiskanen (2002), where a reduction in xanthate adsorption and adsorption rate was observed in the presence of $S_2O_3^{2-}$ ions on nickel and copper sulfide ores.

Effect of Ca^{2+} ions

Figures 1 and 2 show the different mechanisms in which $CaCl_2$ interacts with the two minerals. With regards to PdS, an increase in ionic strength of $CaCl_2$ increases the extent to which PdS interacts with $CaCl_2$. This observation implies that the rate of reduction of the PdS mineral surface is increased in the presence of $CaCl_2$ at increased ionic strengths. Subsequently, this decreases the rate of reduction of PdS in the presence of SIBX. Possibly, the presence of the $CaCl_2$ creates steric hindrance, thus preventing SIBX from interacting directly with the metal sites on the mineral surface. Higher concentrations of calcium ions have been reported to have a detrimental effect on the flotation recovery of chalcopyrite due to the adsorption of calcium hydroxyl precipitates on the mineral surface thereby giving rise to a less hydrophobic surface (Hirajima *et al*, 2016; Li *et al*, 2018). Previous work have ascribed a decrease in xanthate adsorption in the presence of Ca^{2+} ions to the chemisorption of calcium ions on the active sites in the case of galena. This observation was presumed to prevent the ion-exchange between xanthate-sulfate, xanthate-carbonate and xanthate-hydroxyl, therefore causing a decrease in hydrophobicity of galena and consequently decreasing its flotation recovery (Ikumapayi *et al*, 2012; Elizondo-Álvarez *et al*, 2017).

Alternatively, this study has shown that an increase in ionic strength of $CaCl_2$ increases the rate of oxidation of $PdTe_2$ and subsequently increases the extent of interaction between $PdTe_2$ and SIBX. Increasing the interaction of SIBX and $PdTe_2$ indicates an increase in the rate of reduction of $PdTe_2$ in the presence of SIBX. Furthermore, it has been shown that in the case of PdS, higher rest potentials were obtained relative to the potential required to form the dithiolate, at higher ionic strengths of 3 SPW, 5 SPW and 10 SPW $CaCl_2$. This work proposes that under these conditions, the reaction responsible for the changes in potential observed after adding SIBX, was most likely the formation of dixanthogen (Equation 9). The initial reaction could be the chemisorption of SIBX as in (Equation 5). The chemisorption reaction is most likely followed by a second reaction (Equation 9), which is the oxidation of the adsorbed xanthate species to dixanthogen. In the presence of $CaCl_2$ at 1 SPW, a lower final rest potential than the potential for dixanthogen formation was obtained with SIBX. As proposed above, the chemisorption reaction may have occurred (Equation 5) or alternatively the formation of a metal xanthate through Equations 6 or 7 and 8. Additionally, it is observed that the rate of dixanthogen formation decreased from 3 SPW to 10 SPW.

With regards to $PdTe_2$, for all conditions, the presence of $CaCl_2$ resulted in higher final rest potentials relative to the potential for dixanthogen formation. This denotes that under these conditions the changes in potential were due to the oxidation of the xanthate collector through the chemisorption reaction (Equation 5) and formation of dixanthogen (Equation 9).

Overall, the effect of concentration of Ca^{2+} ions plays a significant role in the interactions of xanthate collectors with mineral surfaces. Previous work has shown that at 3× and 6× less calcium compared to this study, calcium ions enhance the adsorption of xanthate on both nickel and copper sulfides (Kirjavainen, Schreithofer and Heiskanen, 2002). These findings were attributed to the decrease in adsorption of oxidation products formed on the sulfide minerals by calcium ions. At very low calcium concentrations of 9×10^{-3} mol/L (22× less than 1SPW), it was found that calcium ions have 7 times higher affinity for chalcopyrite than for galena, thus depressing the flotation of chalcopyrite and promoting the flotation of galena (Liu and Zhang, 2000).

Effect of SO_4^{2-} ions

It is shown in Figures 1 and 2 that $MgSO_4$ interacts in the same mechanism with both PdS and $PdTe_2$. This study has shown that an increase in ionic strength of $MgSO_4$, increases the rate at which PdS and $PdTe_2$ minerals are oxidised. Oxidising environments render sulfide minerals sulfur rich creating non-polar surfaces thereby enhancing hydrophobicity, hence improving the adsorption of xanthate collectors (Buckley and Woods, 1984; Hamilton and Woods, 1984). This work proposes that $PdTe_2$ goes through the same mechanism as PdS in the case of $MgSO_4$. The increase in the rate of oxidation of both palladium minerals in the presence of $MgSO_4$ increases the extent of interaction of SIBX and the minerals, implying an increase in the rate of reduction of PdS and $PdTe_2$ in the presence of SIBX. The changes in potential in the presence of SIBX for both minerals, favour the formation of dixanthogen as indicated by the higher final rest potentials than the potential for dixanthogen formation. This work therefore proposes the possibility of the thermodynamically favoured chemisorption reaction (Equation 5) and the subsequent formation of dixanthogen as shown in Equation 9 for both PdS and $PdTe_2$. It has been shown that an increase in ionic strength of $MgSO_4$ results in an increase in the greater driving force for the formation of dixanthogen on both palladium minerals (Khan and Kelebek, 2004).

The interaction of $MgSO_4$ on the active sites of oxidised palladium minerals may be influenced by the electrostatic charge on the mineral surface. Both of which are governed by the concentration and intrinsic binding affinities of the SO_4^{2-} ions (Wu *et al*, 2002; Lefevre and Fedoroff, 2006). Considering the high interactions of SIBX with both PdS and $PdTe_2$, in the presence of $MgSO_4$, it is likely that the conditions used in this study could result in improved flotation recoveries. This assumption is due to the cleaning effect of sulfate ions on mineral surfaces. Previous studies have proposed that the presence of sulfate ions result in the formation of heavy metal sulfite salts which are slightly soluble (Boujounoui *et al*, 2015). This could be the case in this study as palladium is considered a heavy metal. Contrary to the findings of this study, a recent publication by Sinche-Gonzalez and Fornasiero (2021) suggested that the presence of sulfate ions led to the oxidation of the mineral surface which resulted in hydrophilic mineral particles and thus lower recoveries. These two contradictory findings may be related to the rate of oxidation of the mineral surfaces in the presence of SO_4^{2-} ions which will subsequently affect the rate of reduction of mineral surfaces in the presence of xanthate ions. The mechanisms which are likely controlled by the concentration of sulfate ions in a particular system and the crystal structure of the mineral under investigation. Metal ions can interact differently with sulfate ions, thus resulting in the formation of different surface species thereby impacting the flotation recoveries obtained therein (Bulut and Yenial, 2016).

Effect of Mg^{2+} ions

Figures 1 and 2 show that $MgCl_2$ interacts with PdS and $PdTe_2$ through different mechanisms. This work has shown that an increase in ionic strength for $MgCl_2$ increases the extent of interactions between the $MgCl_2$ and the PdS mineral surface. Consequently, this interaction decreases the extent of interaction between SIBX and PdS. This denotes the increase in the rate of reduction on PdS as the ionic strength of $MgCl_2$ increases, thereby reducing the rate of reduction of PdS. Figure 1 shows a decrease in the rate of dixanthogen formation with an increase in ionic strength of $MgCl_2$ (from 3 SPW to 10 SPW). In the case of PdS, this study proposes a decrease in flotation recoveries with an increase in the ionic strength of Mg^{2+} ions in a real flotation system. Previous studies have reported a decrease in flotation recoveries with an increase in ionic strength of $MgCl_2$ owing to the formation of $Mg(OH)_2$ precipitates at the mineral surface (Hirajima *et al*, 2016; Li *et al*, 2017). In this study, the presence of $MgCl_2$ at all ionic strengths investigated, resulted in higher final rest potentials relative to the potential for dixanthogen formation. This implies that the oxidation of SIBX favoured

the formation of the dixanthogen species. This work proposes the oxidation of SIBX to occur in series through a chemisorption reaction (Equations 5), following the formation of dixanthogen (Equation 9). Alternatively, with regards to $PdTe_2$, the presence of $MgCl_2$ with increasing ionic strength, increases the rate of oxidation of $PdTe_2$. This effect consequently increased the interaction between SIBX and $PdTe_2$, denoting an increase in the rate of reduction of $PdTe_2$ with an increase in ionic strength. The oxidation of SIBX favoured the formation of dixanthogen through a chemisorption reaction (Equation 5) and the formation of a dithiolate (Equation 9) at lower ionic strengths (1 SPW, 3 SPW and 5 SPW). This is possible evidence of two reactions occurring in series. Chemisorption (Equation 5) or formation of a metal-xanthate (Equations 6 or 7 and 8) are presumed to be the favoured reactions at the highest ionic strength. In the case of $MgCl_2$ at 1 SPW. It is interesting to note that the final rest potential is almost the same as the equilibrium potential of SIBX.

Effect of Na^+ ions

Both Figures 1 and 2 show that the interaction of Na^+ ions with PdS and $PdTe_2$ is insignificant. However, NaCl has been observed to interact with both minerals in different mechanisms. Figure 1 shows that the rate of reduction of PdS in the presence of NaCl is insignificant such that it does not interfere with the interaction of SIBX with PdS. It is observed that the oxidation of SIBX for all ionic strengths of NaCl favours the chemisorption reaction (Equation 5) which possibly occurs in series with the formation of dixanthogen (Equation 9). However, a slight decrease in the rate of formation of dixanthogen is observed with an increase in ionic strength.

With regards to $PdTe_2$, Figure 2 shows that an increase in the ionic strength of NaCl slightly increases the rate of oxidation of $PdTe_2$. This observation resulted in an insignificant effect on the extent to which SIBX interacted with $PdTe_2$. It is interesting to note that the final rest potentials obtained in the presence of NaCl at 1 SPW were higher than the potential for dixanthogen formation. It is proposed that for NaCl at 1 SPW, the mechanisms favoured were the formation of dixanthogen possibly through a chemisorption reaction (Equation 5), followed by the formation of a dithiolate (Equation 9). On the other hand, lower final rest potentials were obtained in NaCl at 3 SPW, 5 SPW and 10 SPW, which are proposed to favour the chemisorption reaction (Equation 5) or formation of metal-xanthate (Equations 6 or 7 and 8). Overall, this study has shown that the effect of Na^+ ions in both PdS and $PdTe_2$ systems is insignificant. In agreement with the findings of this study, previous studies have reported that Na^+ ions slightly affect flotation recoveries owing to their insignificant effect on surface charge, adsorption behaviour and contact angle (Moudgil and Ince, 1991; Bakalarz, Duchnowska and Luszczkiewicz, 2017).

Previous work has also observed that the presence of NaCl enhances the adsorption of anionic surfactants, owing to the compensation of a negative mineral surface charge by Na^+ ions and thus reducing electrostatic repulsion between the mineral surface and xanthate ions (Nevskaia, Guerrero-Ruiz and Lopez-Gonzalez, 1998; Potapova *et al*, 2010; Hirajima *et al*, 2016). It Is proposed in this study that the presence of Na^+ ions slightly increased the positive charge on the positively charged palladium metal ions, therefore slightly increasing the electrostatic forces between the mineral surface and negatively charged xanthate ions, thus the high interactions of SIBX with the palladium minerals and high rates of reduction of the palladium minerals in the presence of SIBX.

This study postulates that due to the small size of the Na^+ ion, it could enter the layer spacing of a mineral surface and increase the dipole-dipole forces between the mineral surface and the collector ions, thereby improving the interaction between the collector and the mineral surface and hence high flotation recoveries. Overall, NaCl has been reported to have a ‘salt effect’ on anionic collectors which could possibly promote the flotation of valuable minerals (Chaojun *et al*, 2020).

CONCLUSION

- This study has shown that electrochemical techniques such as rest potential measurements can be used to predict mechanisms that occur in flotation systems. Rest potential measurements have proven to provide useful information on the interactions of ions and xanthates with PGMs and the rates of formation of xanthate species at specific conditions.

- This study shows the pivotal role played by S and Te bonded to the Pd metal ion. It is clear that different crystal structures of Pd that form as a result S and Te result in different mechanisms with ions present in process water.
- Thiosulfate ions interacted more or competed more with xanthate ions for active sites on Pd surfaces than other ions investigated, thus reducing the extent to which SIBX interacts with Pd mineral surfaces.
- In the case of PdS, as the ionic strength of $Na_2S_2O_3$, $CaCl_2$ and $MgCl_2$ increased, the interaction between the salts and PdS increased, thus subsequently decreasing the extent to which SIBX interacted with PdS. $MgSO_4$ enhanced the adsorption of SIBX on the PdS minerals surface whereas NaCl did not have a significant effect in the manner at which SIBX interacted with PdS.
- In the case of $PdTe_2$, as the ionic strength of $Na_2S_2O_3$ increased, the interaction between $Na_2S_2O_3$ and $PdTe_2$ increased thereby decreasing the extent to which SIBX interacted with the mineral surface. However, $MgSO_4$, $MgCl_2$, NaCl and $CaCl_2$ increased the rate of oxidation of $PdTe_2$ with an increase in ionic strength therefore permitting the SIBX to interact more with $PdTe_2$.
- Mineral type, ion type and concentration all have proven to have an impact on the mechanisms that result in the adsorption of SIBX on PdS and $PdTe_2$.
- It is essential to monitor concentrations of thiosulfate ions in flotation systems of sulfides and tellurides. Calcium ions showed a more detrimental effect on sulfides than tellurides, where they proved to enhance the adsorption of SIBX. Sulfate ions enhance the interaction of SIBX on both PdS and $PdTe_2$. Magnesium and calcium ions have been observed to interact with PdS and $PdTe_2$ by different mechanisms owing to the decrease and increase in rest potentials, respectively. Sodium ions have been observed to play an insignificant role on both Pd mineral surfaces.

ACKNOWLEDGEMENTS

The authors wish to express appreciation for funding received from South African Minerals to Metals Research Institute (SAMMRI) and the South African Department of Science and Innovation (DSI).
